mRNA for a number of serine/threonine protein kinases in the dentate gyrus;  $\alpha$ CaMKII, and PKC $\gamma$  showed transient increases, and increases in ERK2 and B-Raf were seen only at 24 hours. A finding that suggests a direct link to synaptic function was reported by Nayak et al. (1998): LTP in isolated CA1 dendrites is associated with a PKA- and transcription-dependent increase in the synthesis of AMPA receptors. Study of the identification and functional characterization of effector proteins that sustain maintenance of L-LTP, and the nature of their interaction with the putative synaptic tag, is likely to prove a challenging and fertile field for future research. Meanwhile, a systematic study of transcriptional changes related to LTP and their time courses has now become feasible through the use of DNA microarray screening (Lein et al., 2004; Lee et al., 2005; Wibrand et al., 2006).

#### Return Pathway: Signaling from Nucleus to Synapse and the Synaptic Tag Hypothesis

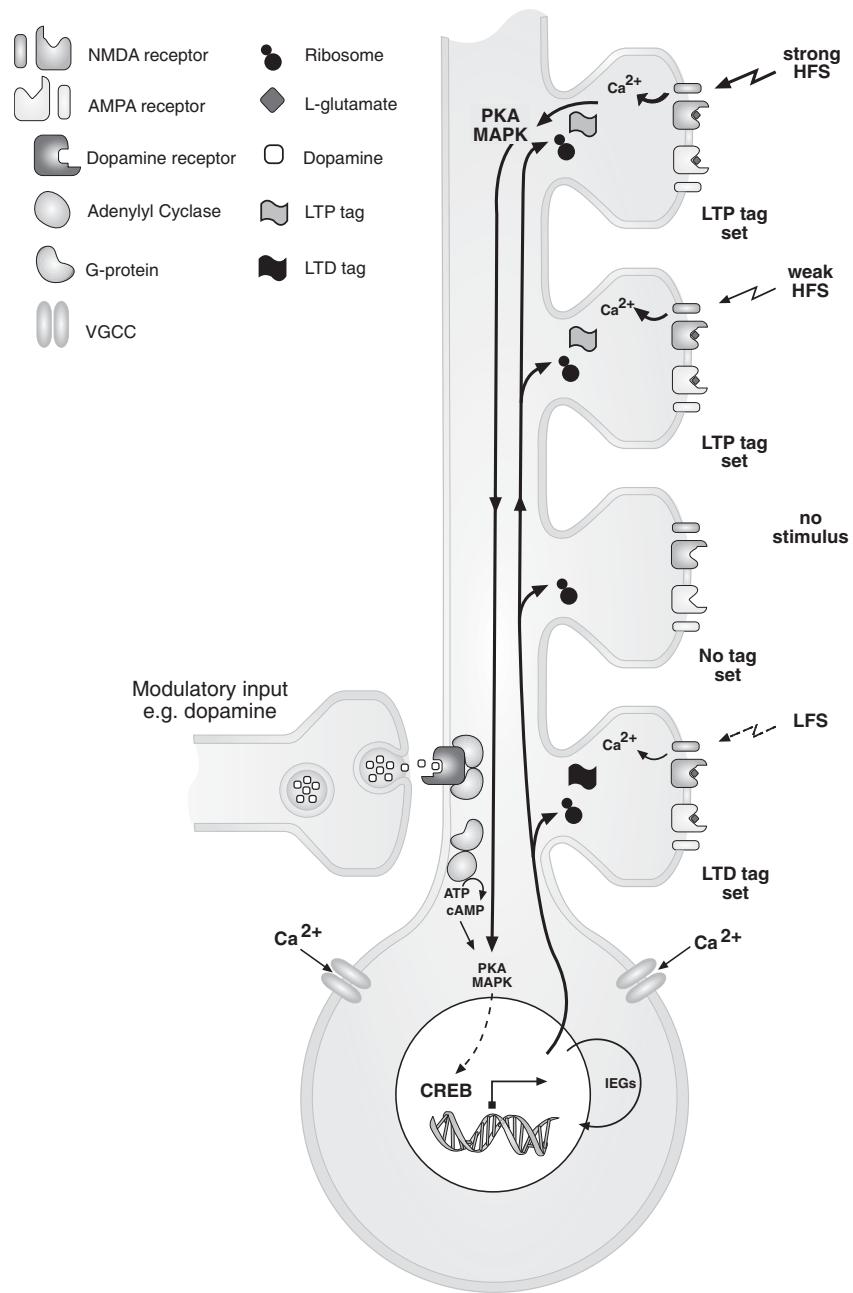

How are somatically generated transcripts and/or proteins delivered to the appropriate synapses? Frey and Morris (1997) considered a number of possibilities, of which conceptually the simplest was the idea that a potentiated synapse sets a marker or tag that is recognized by the mRNA or protein products that are transported into dendrites from the soma. This tag must have a lifetime at least long enough to engage with the newly generated mRNA or proteins. Transcriptional inhibitors given at the time of induction can take 2 hours or more to begin to affect LTP (Kelleher et al., 2004a; but see Barco et al., 2002 for a case where the transcriptional inhibitor actinomycin also acts rapidly). The relative delay in the action of transcriptional inhibitors presumably reflects the time taken for a signal to pass from synapse to nucleus for transcription first of IEGs and then of genes encoding effector proteins, followed by transport of mRNA and/or proteins into dendrites and their postulated capture by tagged spines. Frey and Morris speculated that the setting of the tag itself might be protein synthesis-independent. If this were the case, a tetanus to one pathway should still generate L-LTP even in the presence of a protein synthesis inhibitor if a second pathway was tetanized within a time window of 1 to 2 hours on either side of the tetanus to the first pathway. The tag would be set in the first pathway, notwithstanding the presence of the protein synthesis inhibitor, and would capture the plasticity-related proteins generated by the second pathway. These predictions were confirmed (Frey and Morris, 1997). (Note that the conversion of E-LTP to late L-LTP begins before the protein synthesis inhibitor has been washed out, which suggests that both the tag and the plasticity factor interacting with the tag are proteins rather than mRNA transcripts). Equally arresting was the demonstration that E-LTP, produced by a tetanus that by itself was too weak to produce L-LTP, could be converted to L-LTP by a preceding or subsequent strong tetanus given to a second pathway within a similar time window. Again, this result can be explained if the weak tetanus was below thresh-

old for triggering local or somatic protein synthesis but nevertheless was able to set a tag that could capture the new proteins synthesized as a result of the strong tetanus to the second pathway.

Late LTD is also associated with the setting of a tag (Kauderer and Kandel, 2000). Sajikumar and Frey (2004a) presented evidence that it is the tag, rather than the plasticity factors, that determines the direction of change; thus, LTD-inducing stimuli generate an LTD-specific tag and LTP-inducing stimuli an LTP-specific tag (but see below for evidence that PKM $\zeta$  is an LTP-specific plasticity factor). Although the tag normally has a lifetime of 1 to 2 hours, it can be canceled prematurely if depotentiation is induced by low-frequency stimulation delivered a few minutes after LTP induction (Sajikumar and Frey, 2004b). When tags are set on two pathways, they compete for the available supply of plasticity-related proteins, leading to a process of "competitive maintenance" in which potentiation at one pathway occurs at the expense of a reduction in potentiation at another (Fonseca et al., 2004).

Although the identity of the tag (or tags) is unknown, candidate tags must satisfy the following criteria (Barco et al., 2002; Kelleher et al., 2004a): (1) tags are generated by an activity-dependent, NMDAR-dependent, but protein synthesis-independent process; (2) they have a lifetime of 1 to 2 hours but are susceptible to cancellation by low-frequency trains within the first few minutes of being set; (3) at least two tags can be set, one induced by activity patterns that produce early or late LTP and the other by activity leading to early or late LTD; (4) tags are input-specific; (5) tags interact with proteins generated by de novo nuclear transcription (the process of "synaptic capture") to trigger the conversion of early to late LTP or early to late LTD. What clues to the identity of the tag do these criteria offer? The rapid, reversible, protein synthesis-independent setting of the tag points toward a protein kinase, possibly PKA (Barco et al., 2002), as candidate tags for LTP and protein phosphatases for LTD (Frey and Morris, 1998a; Kelleher et al., 2004a). The possibilities are much broader than this, however; any class of synaptic molecule whose phosphorylation state, configuration, or concentration is altered as a result of NMDAR-mediated events is in principle a candidate tag. Finally, it is worth emphasizing that a tag can be set without inducing L-LTP; so although the setting of a tag may or may not be a necessary precursor for induction of late LTP or late LTD, it is clearly not sufficient.

The Frey and Morris experiments revealed a complex pattern of temporal and spatial associativity in hippocampal synaptic plasticity, which they encapsulated by reference to the notion of "flashbulb" memory. A cell is continually bombarded with events of moderate significance to the organism; at inputs activated by these events, tags are set for an hour or two and then expire (whether tags decay over their lifetime or behave as molecular switches with on and off modes is unknown). When an event of major significance occurs, equivalent to a strong tetanus, late LTP is induced not only in

**Figure 10-13.** Signaling pathways involved in the genesis of late LTP. In this scheme, LTP induced by strong tetanic stimulation is represented by the distal synapse (top right). The large, rapid increase in  $\text{Ca}^{2+}$  stimulates local changes, leading to phosphorylation of receptors and other proteins (see Fig. 10-8); it also activates synapse-to-soma signaling cascades that may involve translocation of  $\text{Ca}^{2+}$ /calmodulin, PKA and MAPK. At the same time, a synaptic tag is set to identify the synapse as having been recently activated. Weaker stimulation, leading only to early LTP, does not trigger a synapse-to-soma signal but does set a tag. Unstimulated synapses are left in molecular peace, whereas synapses receiving prolonged low-frequency stimulation (LFS) set an LTD tag and may generate similar nuclear signals (not shown). Additional dendrite-to-nucleus and soma-to-nucleus signals may be contributed by modulatory inputs such as dopaminergic innervation and by  $\text{Ca}^{2+}$  entering the

soma through voltage-gated  $\text{Ca}^{2+}$  channels as a result of action potentials generated during activity. The targets of synapse-to-soma signaling are transcription factors, including CREB. Phosphorylation of CREB leads to the transcription of a number of genes that contain CRE (cAMP response elements) domains in their regulatory regions, among which are the early immediate genes such as *arc/arg3.1*, *homer*, *c-fos*, and *zif268*, some of which are themselves transcription factors. The return leg of the signaling system carries transcripts (e.g., mRNA for *arc/arg3.1* and  $\text{PKM}\zeta$ ) and unidentified proteins from the nucleus into dendrites. According to the tag hypothesis (see text), the soma-to-dendrite messengers are intercepted or captured by the tag, the nature of which has not been identified, and this triggers the changes that lead to late LTP (for an LTP tag) or late LTD (for an LTD tag).

that pathway, but via tagging and synaptic capture, with all other pathways carrying information about events of minor significance occurring an hour or two on either side of the significant event. We can speculate with Frey and Morris that through the tagging mechanism these secondary events acquire the same mnemonic potential as the major event and provide the contextual information that allows us to remember, for example, where we were and what we were doing on 9/11. A cartoon of some of the concepts we have been discussing in this section on late LTP is presented in Figure 10–13.

### The Duration of Late LTP Is Regulated by the NMDA Receptor

We have seen that the expression of L-LTP depends on *de novo* protein synthesis around the time of induction, give or take a few hours during which a prior or later setting of the synaptic tag can engage with newly synthesized proteins. Thereafter, LTP proceeds without benefit of further *de novo* protein synthesis. Surprisingly, among the various largely uncharacterized posttranslational molecules and mechanisms that sustain the expression of LTP is the protein indelibly associated with its induction, the NMDA receptor. The time course of LTP in the dentate gyrus of the freely moving rat is prolonged by many days if the NMDAR antagonist CPP is infused after the tetanus (Villarreal et al., 2001). Infusion can be delayed for 2 days after induction and still rescue the decay of protein synthesis-dependent LTP. This startling result demonstrates that long after induction NMDAR-dependent signaling continues to control the fate of the potentiated synapse perhaps via the block of NMDAR-dependent depotentiation. Here is another area ripe for further investigation.

### PKM $\zeta$ maintains LTP

In the search for molecules that mediate the long-term persistence of LTP an interesting candidate has emerged in PKM $\zeta$  (see Section 10.4.3). This member of the PKC family was identified as the only isoform that was activated 30 min after the induction of NMDAR-dependent LTP (Sacktor et al., 1993). PKM $\zeta$  is a constitutively active catalytic fragment of the atypical PKC $\zeta$ , which can be produced by proteolytic cleavage by proteases, such as calpain, or by synthesis from mRNA encoding just this fragment. Subsequent work showed that LTP involves the *de novo* synthesis of PKM $\zeta$  (Hernandez et al., 2003). Interestingly, PKM $\zeta$  appears to be both necessary and sufficient for L-LTP since PKM $\zeta$  mimics and occludes LTP and since inhibition of PKM $\zeta$  either by chelerythrine, which in low concentrations is selective for the  $\zeta$  isoform, or by transfection with a dominant negative inhibitor, PKM $\zeta$ -K281W, blocks LTP (Ling et al., 2002). The dominant negative inhibitor also blocked induction of E-LTP which led to the suggestion that PKM $\zeta$  enzymatically cleaved from PKC $\zeta$ , perhaps by the actions of calpain, may mediate the early protein synthesis-independent phase of LTP. However, a subsequent

study using a myristoylated form of a  $\zeta$ -pseudosubstrate inhibitory peptide (termed ZIP), that binds to PKM $\zeta$  and reconstitutes the autoinhibition in the absence of the PKC $\zeta$  autoregulatory domain, blocked induction of L-LTP but not E-LTP (Serrano et al., 2005). Indeed, there is evidence that PKM $\zeta$  is a plasticity factor that specifically targets synapses exhibiting a tag for LTP. In tagging experiments in which two independent pathways were given weak and strong tetani offset by 30 min, ZIP reversed L-LTP in both pathways. But when a strong tetanus to one pathway was given in conjunction with a weak LTD-inducing protocol to the other, ZIP reversed the maintenance of L-LTP but not of L-LTD; conversely, when a strong LTD inducing protocol to one pathway was paired with a weak tetanus to the other, the maintenance of L-LTP but again not of L-LTD was disrupted (Sajikumar et al., 2005). Note that this result is on the face of it inconsistent with the suggestion by Sajikumar and Frey (2004b) that newly transcribed plasticity factors are ‘process-independent’, with the direction of change being determined solely by local LTP- or LTD-specific tags.

The mechanism by which PKM $\zeta$ -dependent L-LTP is maintained appears to be an increase in AMPAR number, since potentiation of synaptic transmission induced by PKM $\zeta$  increased the amplitude, but not the frequency, of AMPAR-mediated mEPSCs and had no effect on their kinetics, or on mean single channel conductance,  $\gamma$ , the latter estimated using non-stationary fluctuation analysis (Ling et al., 2006). Interestingly, application of either chelerythrine or ZIP is able to reverse pre-established LTP (Ling et al., 2002) when applied 1 hour or later post-induction, though in another study chelerythrine given 30 min after induction did not block E-LTP (Bortolotto and Collingridge, 2000), suggesting that PKM is specifically involved in the maintenance of L-LTP. Perhaps most amazingly ZIP is able to reverse completely the potentiated response at perforant path synapses when injected 22 h following the establishment of LTP in the dentate gyrus of freely-moving rats, paving the way for an exploration of the role of LTP maintenance in memory (Pastalkova et al., 2006; see Section 10.10.4).

### 10.4.10 Structural Remodeling and Growth of Spines Can Be Stimulated by Induction of LTP

The idea that changes in synaptic efficacy could be embodied in changes in synaptic number or in remodeling of synaptic morphology predates the discovery of LTP by many decades and appears explicitly in the writings of Ramon y Cajal, William James, and Donald Hebb, among others. More spines, larger spines, and wider spine necks have all borne the burden of theories of memory, with the implicit assumption that appropriate changes occur also in the presynaptic partner. What is the status of these enduring theories today, and specifically do they provide a mechanism for the expression of LTP? The evidence is not straightforward, and disagreements among laboratories are as vigorous in this area as in many others (reviewed by Harris, 1999; Yuste and Bonhoeffer, 2001;

Nimchinsky et al., 2002; Kasai et al., 2003; Tashiro and Yuste, 2003; Lemphrect and Le Doux, 2004).

Spine numbers, even in adult animals, are not set in stone: Many experimental and indeed physiological situations are associated with dramatic changes in spine number. For example, spine densities in CA1 pyramidal neurons (but, interestingly, not in CA3 pyramidal cells or granule cells) vary by up to 30% during the estrus cycle in female rats (Woolley et al., 1990). Allowing adult rats a daily opportunity to explore a complex environment leads to an increase in spine density in CA1 pyramidal cells (Moser et al., 1994); and in organotypic cultures spines are rapidly retracted following bath application of botulinum toxin, which suppresses all transmitter release (McKinney et al., 1999). The physiologist engaged in cutting hippocampal slices no doubt prefers not to dwell too deeply on a report that CA1 neurons in slices from the adult rat contain 40% to 50% more synapses than similar cells in perfused and fixed tissue (Kirov et al., 1999). Comfort can perhaps be taken from the remarkable stability of spines in rat visual cortex when imaged over a period of many months (Grutzendler et al., 2002), although in mouse barrel cortex a more dynamic picture is seen, with only half of the imaged spines remaining stable over a period of a month (Trachtenberg et al., 2002).

#### **Ultrastructural Changes Associated with LTP**

The first investigation of tetanus-induced changes in spine morphology was published in 1975 (Van Harreveld and Fifkova, 1975). In this and subsequent studies, Fifkova and her colleagues reported an increase in spine area and the width of the spine neck in the outer part of the molecular layer of the dentate gyrus following tetanic stimulation of the perforant path. No changes were seen in spines in the unstimulated inner molecular layer. A problem with this work is that no recordings were made of evoked responses, so it is not possible to be sure that LTP was in fact induced. Further studies, notably by Desmond and Levy in the dentate gyrus, and by Lynch and his colleagues in area CA1, followed soon thereafter (Lee et al., 1980; Desmond and Levy, 1983; reviewed by Yuste and Bonhoeffer, 2001). Although Desmond and Levy found no consistent changes in spine density, they documented an increase in the length of the PSD following LTP induction (Desmond and Levy, 1986a) and an increase in cup-shaped spines (Desmond and Levy, 1986b). These observations supported the conclusion reached by Fifkova et al. (1997) that LTP is associated with changes in the morphology and ultrastructural organization of existing spines, rather than the generation of new spines. In area CA1, Lynch's group also saw no change in spine density but detected a substantial increase (35%) in the number of synapses—presumed inhibitory—on dendritic shafts (Lee et al., 1980). Technical advances in electron microscopy, including the introduction of the disector technique for unbiased stereological sampling and the use of serial sectioning to obtain authentic three-dimensional struc-

tural information, have strengthened the view that LTP is not associated with an overall change in spine density, either in the dentate gyrus 6 hours after tetanus *in vivo* (Popov et al., 2004; see Trommald et al., 1996 for a counter claim) or in area CA1 *in vitro* (2 hours after tetanus (Sorra and Harris, 1998). As we shall see below, this does not exclude the possibility that there are increases in the frequency of certain forms of spine at the expense of others.

In an influential series of studies, Geinisman documented an increase in the number of synapses with perforated and segmented PSDs in axospinous synapses in the dentate gyrus after daily episodes of tetanization for 4 days (Geinisman et al., 1991, 1993). Geinisman and colleagues proposed that these changes marked stages in the transformation of spines with single macular, or continuous, PSDs to potentiated spines with fully segmented PSDs, allowing two independent sites for synaptic transmission: a “spine splitting” model in which single boutons make multiple synapses on single dendrites. However, Harris et al. (2003) presented electron microscopic (EM) evidence that spine splitting is unlikely to occur in the adult hippocampus, as the gap between two spines is invariably filled with axons and dendrites. They concluded that the extra spine is more likely to represent new growth. However, even in potentiated tissue, instances where a single bouton makes contact with a pair of neighboring spines on the same dendrite comprise less than 3% of all synapses on hippocampal pyramidal cells and so are unlikely to provide a structural basis for more than a fraction of the potentiated response.

An ingenious method of labeling active synapses for EM was developed by Buchs and Muller (1996) based on the transient increase in the concentration of calcium that occurs in spines following tetanic stimulation. The method depends on precipitating calcium in smooth endoplasmic reticulum (SER) and rendering it electron-dense. Buchs and Muller noted an increase in the proportion of spines that contained perforated PSDs when synapses were labeled 30 minutes after the induction of LTP, compared to the proportion in labeled spines in naïve tissue or in spines examined 5 minutes after LTP induction. In a follow-up study using serial section EM, Toni et al. (1999) observed a delayed but persistent LTP-associated increase in the proportion of boutons making synapses on more than one spine (multiple synapse boutons); the proportion remained at its baseline value of around 6% for the first 30 minutes after tetanus, then rose to 15% at 45 to 120 minutes after tetanus (Fig. 10–14A). Moreover, in 66% of the latter cases, the two spines arose from the same dendrite, compared to 11% in tissue fixed 5 minutes after the tetanus. The method allows analysis only of the small proportion (15%) of spines that contain SER. Nevertheless, these striking observations suggest that LTP is expressed as an increase in the number of effective synapses, with input specificity conserved by the partitioning of tetanized boutons to allow for two release sites. This is similar to the spine-splitting model proposed by Geinisman; whether multiple spine synapses make up too small a proportion of the total to account fully for LTP, as

maintained by Harris et al. (2003), remains for future work to determine.

Serial section EM allows construction of three-dimensional images of synapses in control and potentiated tissue, which is often the only way to resolve the ambiguities that can arise with two-dimensional sampling. Sorra and Harris (1998) examined synapses in tissue from area CA1 prepared 2 hours after the induction of LTP in vitro. No change in the density or size of spines was found. However, in the absence of any marker for potentiated synapses, it remained possible that an enlargement of potentiated spines was balanced by a decrease in the size of unstimulated spines. This drawback was addressed in further experiments from the same laboratory that focused on a subpopulation of spines containing polyribosomes, the macromolecular complexes that contain the machinery for protein synthesis. Given the extensive evidence for local protein synthesis during LTP, could polyribosomes be used as a marker for potentiated synapses? Harris and her colleagues found that the proportion of spines containing polyribosomes was appreciably enhanced, from 12% to 39%, after LTP induction in area CA1 (Ostroff et al., 2002). Moreover, the surface area of the postsynaptic density in polyribosome-associated spines was greater in potentiated tissue than in control tissue, whereas for spines without polyribosomes the size of the PSD was unchanged (Fig. 10.14B). This result is consistent with a model in which potentiation is driven by synaptic enlargement. The situation is different in the dentate gyrus, however, where a decrease in polyribosome frequency occurs after LTP induction (Desmond and Levy, 1990).

Another three-dimensional EM study analyzed spines in the dentate gyrus 6 hours after the induction of LTP in vivo (Popov et al., 2004). Again, no overall change in spine density was seen, although in this case there was an increase in the proportion of synapses on thin spines and reductions in the number of stubby spines and spines on dendritic shafts (Fig. 10.14C). There was also a significant increase in the volume of thin and mushroom spines and an increase in the area of their PSDs. The picture that emerges from the EM studies considered thus far is that LTP is associated not with an overall increase in spine density but, rather, an increase in the size of certain subpopulations of spines.

#### Longitudinal Studies: Imaging Spines Before and After Induction of LTP

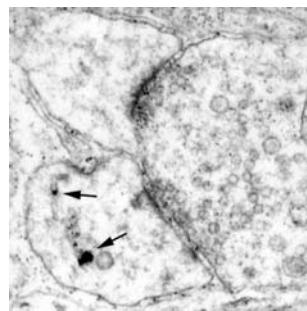

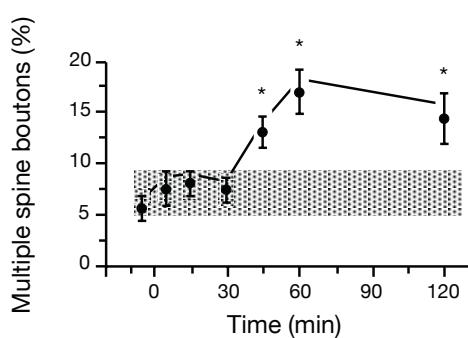

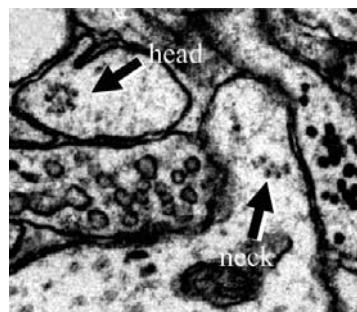

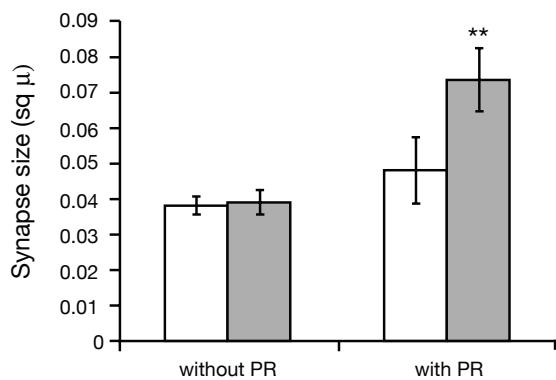

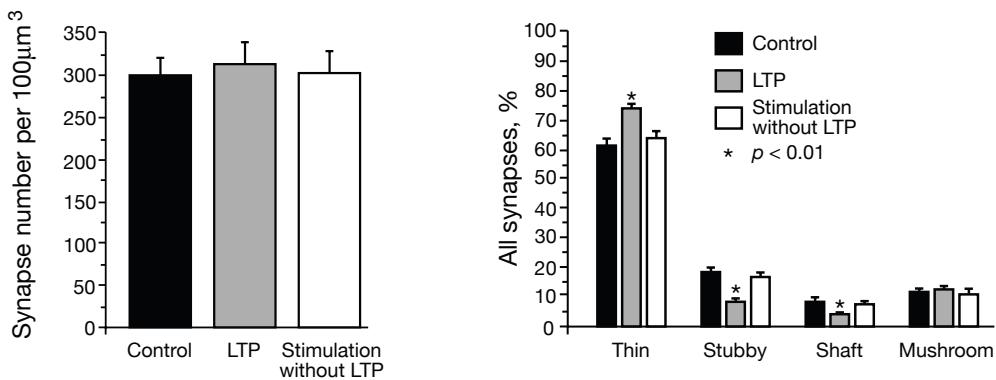

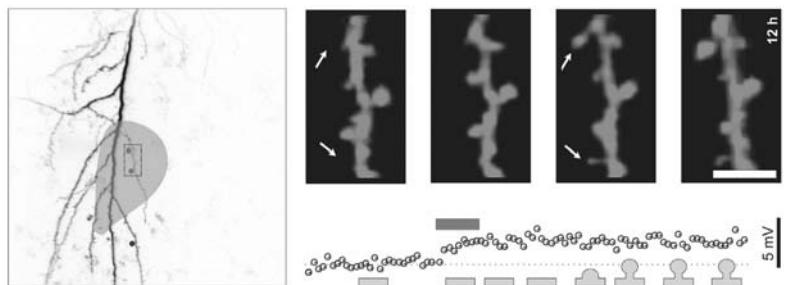

In addition to the problem of labeling potentiated synapses, an inherent limitation of electron microscopy is that it is not possible to image the same structure at multiple time points, so time-dependent changes have to be compared in different preparations. The advent of laser scanning confocal microscopy has improved the resolution of light microscopy to a level where synaptic structures (boutons and dendritic spines) can be visualized in living tissue, so the same spine, bouton, or length of dendrite can be measured before and at various times after

the induction of LTP (Hosokawa et al., 1995; Emptage et al., 2003; Matsuzaki et al., 2004), as discussed below.

Two other studies provide evidence that new spines can be formed after the induction of LTP in area CA1 in vitro. Maletic-Savatic et al. (1999) transfected CA1 pyramidal cells in organotypic culture with green fluorescent protein and used two-photon confocal microscopy to image synaptic structures. Within a few minutes of applying localized tetanic stimulation, they saw a rapid growth of filopodia-like structures emanating from the dendrite; filopodia were not seen in regions of the dendrite distant from the stimulating electrode and were not produced by low-frequency stimulation. Moreover, filopodial growth was blocked by AP5. A small proportion of induced filopodia developed bulbous heads within an hour of the tetanus, suggesting that the induced filopodia are precursors to new dendritic spines.

Engert and Bonhoeffer (1999) used two-photon microscopy to image dendrites and spines of dye-filled CA1 pyramidal cells in organotypic cultures and a local perfusion technique to restrict synaptic activity to a small volume (approximately 30  $\mu\text{m}$  in diameter). Within 20 to 40 minutes of the tetanus new spines began to form in the activated volume at an average frequency of 0.06 spines/ $\mu\text{m}$  of dendrite (relative to a basal spine density of 0.40 spines/ $\mu\text{m}$ ) (Fig. 10.14D). New spines were not formed elsewhere, and their appearance was blocked if the tetanus was given in the presence of AP5. The dramatic images obtained by Engert and Bonhoeffer are reminiscent of the tetanus-induced appearance of multiple synapse boutons on single dendrites described by Toni et al. (1999). Note, however, that the formation of new spines, in contrast to the near-immediate induction of LTP, was delayed by at least 20 minutes.

On the face of it, the studies described above make a strong case that new spines contribute to the expression of LTP in organotypic cultures and in acute slices. However, they are inconsistent with other confocal studies in area CA1 in which new spines were not observed, either after the induction of chemically induced LTP (Hosokawa et al., 1995) or after tetanus-induced LTP at visualized single spines (Emptage et al., 2003; Matsuzaki et al., 2004). Transformation of the spine from one displaying a continuous PSD to a perforated or segmented PSD would remain undetectable, as possibly would spine splitting; but the genesis of a new spine is well within the resolution of the technique. These discrepancies are unlikely to reflect differences in the time points chosen for study. Emptage et al. (2003) collected their data 30 to 60 minutes after tetanus, whereas Matsuzaki et al. (2004), using two-photon photolysis of caged glutamate, routinely extended their period of observation to 100 minutes after tetanus, spanning the period of 20 to 60 minutes during which the new spines charted by Engert and Bonhoeffer (1999) and by Toni et al. (1999) were being born. Once generated, the new spines survived for at least 2 hours in both sets of experiments and so should have been detected, if present in any number, by Sorra and Harris (1998), whose EM study in CA1 in vitro was car-

**A****B****C****D**

ried out 2 hours after tetanus (see below). The experiments of Matsuzaki et al. (2004) provided the first evidence of an increase in spine size in longitudinal studies LTP was induced by repetitive focal photolysis of caged glutamate in low  $Mg^{2+}$  to allow activation of both AMPA and NMDA receptors. Only small spines showed a persistent increase in size after the induction of LTP, and spine enlargement was accompanied by an increase in sensitivity to uncaged glutamate.

Despite two decades of work on structural changes associated with LTP, it is still not possible to reach a definitive conclusion on such basic questions as whether synaptogenesis plays a role in LTP or whether morphological changes in existing spines and boutons contribute to the enhanced response. In different preparations and at different times, there is evidence for one or other or both types of change. However, even where there is compelling evidence that such changes can occur, there is often no demonstrated causal link with LTP. Thus, when new spines have been observed, it has not been demonstrated that they contribute to the enhanced response (Engert and Bonhoeffer, 1999; Maletic-Savatic et al., 1999; Toni et al., 1999); moreover, the delayed time course of synaptogenesis rules out any contribution to the first 20–30 minutes of LTP. The experiments of Matzusaki et al. (2004) provide the strongest evidence that morphological changes are causally linked to LTP because the increase in spine size occurred immediately, was blocked by the same drugs that block the induction of LTP, and was associated with an increase in the response to uncaged glutamate. These experiments are also partly consistent with the LTP-associated increases in the volume of thin and mushroom spines observed by Popov et al. (2004) in their serial section EM analysis of LTP in the dentate gyrus. Matzusaki et al. (2004) speculated that large spines are

the repositories of previously stored information and are protected from further change. However, this prediction is not supported by the data of Popov et al. (2004), which shows an increase in the size of the largest subset of mushroom spines following the induction of LTP.

### Alterations in the Cytoskeleton Contribute to LTP and LTD

Dendritic spines are not static structures; rather, their shape is determined from moment to moment by the dynamics of their actin cytoskeleton, as dramatically demonstrated in cultured neurons transfected with actin-GFP (Fischer et al., 1998; Matus, 2005). There is a growing body of evidence that activity-dependent regulation of actin polymerization and the consequent changes in synaptic morphology contribute to the expression of synaptic plasticity. At low concentrations, latrunculin A, an inhibitor of actin polymerization, blocks late but not early LTP in area CA1 in vitro (Krucker et al., 2003); a similar result has been reported in the dentate gyrus of the freely moving rat (Fukazawa et al., 2003). In the latter study, induction of LTP resulted in an NMDAR-dependent increase in F-actin (the polymerized form of actin) that was restricted to synapses of the tetanized pathway. The increase in F-actin was of rapid onset (< 20 minutes) and could be detected in tissue from animals killed as long as 5 weeks after the induction of LTP. An EM analysis also revealed significantly increased F-actin in spines in potentiated tissue; the F-actin content was appreciably greater in large spines, consistent with a model in which actin drives enlargement of the spine. F-actin is polymerized from globular G-actin monomers. Okamoto et al. (2004) used a fluorescence resonance energy

**Figure 10–14.** Morphological changes associated with LTP. A. LTP is accompanied by a delayed increase in the proportion of synapses in which the presynaptic bouton makes contact with more than one spine on a single dendrite. The graph plots the proportion of multiple spine boutons in the overall population of tetanized synapses as a function of time after the induction of LTP (5 to 120 minutes). A  $Ca^{2+}$  precipitation technique was used to label tetanized spines (arrowheads in the electron micrograph). (Source: Toni et al., 1999.) B. Spine growth following the induction of LTP is restricted to those spines that contain polyribosomes (PR), indicated by arrows in the electron micrograph. Analysis of three-dimensional reconstructions showed that the mean area of the postsynaptic density in spines lacking polyribosomes was the same before (open bars) and 2 hours after (gray bars) induction of LTP, whereas spines that contained polyribosomes were significantly larger after induction. LTP was also associated with a redistribution of polyribosomes from dendritic shafts to spines. (Source: Harris et al., 2003; adapted from Ostroff et al., 2002.) C. Spine density is not affected by the induction of LTP (left), but there are changes in the distribution of spine types (right), with an increase in the proportion of thin spines and a decrease in the proportion of stubby and shaft spines. Data were obtained from three-dimensional electron microscopic (EM) recon-

structions of dendritic segments from the medial molecular layer of the dentate gyrus. Three groups of rats were analyzed: controls (unstimulated, black bars), those with LTP (6 hours after induction of LTP by tetanic stimulation of the perforant path in anesthetized animals, gray bars), and animals that received the same total number of stimuli but in a pattern that did not induce LTP (white bars). (Source: Popov et al., 2004.) D. High-frequency stimulation leads to the appearance of new spines in the potentiated region of CA1 cells in organotypic cultures. Slice cultures were maintained in a solution containing  $Cd^{2+}$  and low  $Ca^{2+}$  to prevent transmitter release. A cell was impaled with a recording pipette containing fluorescent dye, and a small region of its dendritic tree was made competent for synaptic transmission by local perfusion of a solution containing normal ACSF. In the example shown in the left-hand panel, the extent of the perfused area is indicated by shading, with the pipette tip at the lower end. LTP was induced by pairing (see plot of EPSP amplitude, lower right). The two-photon confocal images on the right were obtained 10 minutes before and 0.5, 1, and 12 hours after induction of LTP. The icons below indicate the times at which the two new spines (indicated by arrows) were visible. Note the delay, observed in all cases, between the induction of LTP and the appearance of the new spines. (Source: Engert and Bonhoeffer, 1997.)

transfer (FRET) strategy to estimate the ratio between soluble G-actin and polymerized F-actin in the dendritic spines of pyramidal cells in organotypic hippocampal cultures. Tetanic stimulation increased the F-actin/G-actin ratio, whereas prolonged low-frequency trains caused a decrease in the ratio. These changes were correlated with increases and decreases in spine width, suggesting a model in which bidirectional, activity-dependent changes in F-actin control synaptic efficacy through changes in synaptic morphology. Because the size of the presynaptic bouton is closely matched to the size of the spine (Harris and Stevens, 1989), there must be a corresponding change in the presynaptic side. Evidence for an activity-dependent increase in the size and number of presynaptic boutons was uncovered by Colicos et al. (2001) in a study on dissociated hippocampal neurons transfected with GFP-actin. As we saw above, the EM evidence is more consistent with an increase in the size than the number of synapses during LTP. Which of the possible models (no change in spine size or number, or changes in one or both) more accurately describes the activity-driven changes that may occur *in vivo* is another goal for future research.

## 10.5 LTP at Mossy Fiber Synapses

In this section we consider the very different form that LTP takes at the largest synapses in the hippocampus, indeed, among the largest in the mammalian brain—the synapses made by granule cell axons (the mossy fibers) on CA3 pyramidal cells. These synapses also support LTD, a topic that is covered in see Section 10.7. Mossy fibers make most of their connections not on CA3 pyramidal cells but on inhibitory interneurons in the hilus and stratum radiatum. We discuss plasticity at these connections in Section 10.8.

### 10.5.1 Mossy Fiber Synapses Display Striking Short-term Plasticity

Mossy fiber boutons make giant, interdigitating synapses at complex spines (Cajal's "thorny excrescences") on the proximal dendrites of CA3 pyramidal cells. Giant synapses contain up to 35 release sites (Henze et al., 2000) and show a greater degree of short-term plasticity (paired-pulse facilitation and frequency potentiation during repetitive stimulation) than associational-commissural (A/C) synapses linking ipsilateral and contralateral CA3 pyramidal cells (Salin et al., 1996). These properties are mediated, at least in part, by synaptically released glutamate acting on presynaptic kainate receptors that are positively linked to transmitter release (Lauri et al., 2001; Schmitz et al., 2001). In addition, at mossy fiber synapses *in vitro*, PTP of several hundred percent can be elicited by long tetani (Langdon et al., 1995); in the anesthetized rat, in contrast, PTP is typically not seen with similar tetanus protocols (Derrick and Martinez, 1994b).

### 10.5.2 Basic Characteristics of NMDA Receptor-independent LTP at Mossy Fiber Synapses

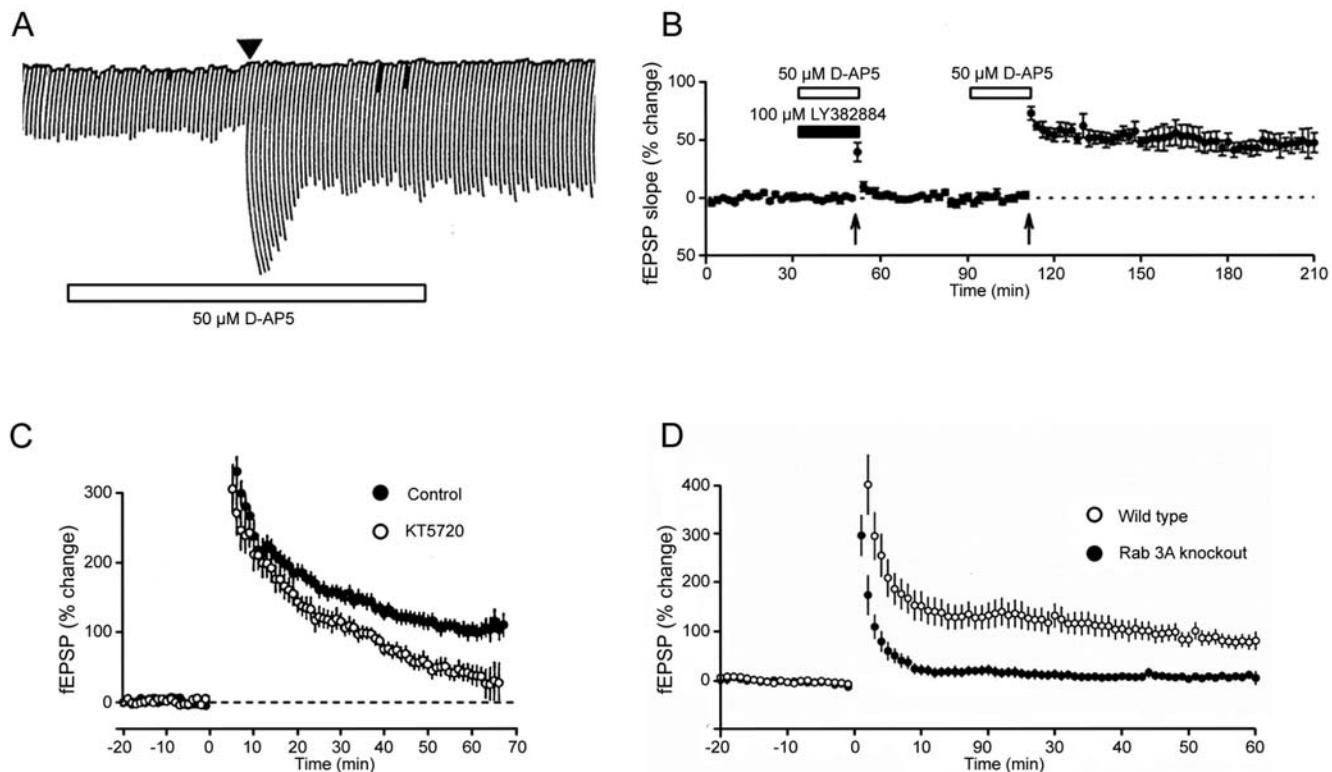

Long-term potentiation in the mossy fiber projection was first documented by Schwartzkroin and Wester (1975). A striking feature of this form of LTP is its immunity to NMDA receptor antagonists (Harris and Cotman, 1985) (Fig. 10–15A), consistent with the relatively sparse distribution of NMDA receptors in stratum lucidum, the mossy fiber terminal zone (Monaghan and Cotman, 1885). (Note that synaptically evoked NMDAR-mediated currents can nevertheless be recorded from CA3 cells following mossy fiber stimulation, a property that has been exploited to provide evidence for a presynaptic expression mechanism in mossy fiber LTP (Weisskopf and Nicoll, 1995) (see below). Although there is wide agreement that the expression of mossy fiber LTP is presynaptically mediated, there has been a persistent and unresolved debate about whether the induction of LTP in this pathway is triggered by presynaptic or postsynaptic processes—a curious reversal of the controversies that invigorate discussion on induction and expression in other regions of the hippocampus. Mossy fiber LTP *in vitro* shows input specificity (Zalutsky and Nicoll, 1992) and associativity (Schmitz et al., 2003). In addition, associativity between mossy fiber and A/C fibers has been reported both *in vivo* (Derrick and Martinez, 1994b) and *in vitro* (Kobayashi and Poo, 2004); in the latter case, induction of LTP in A/C synapses could be boosted by trains to a single mossy fiber. Cooperativity (see Section 10.1.1) has been reported *in vivo* (Derrick and Martinez, 1994b) but is not seen *in vitro* (Zalutsky and Nicoll, 1992).

The duration of mossy fiber LTP has not been studied in the freely moving animal, but with multiple trains at 100 Hz LTP lasting for several hours has been recorded *in vivo* (Henze et al., 2000). Most of what follows is based on a survey of the much larger slice literature, but the *in vivo* data should be borne in mind when considering the functional consequences of mossy fiber plasticity.

### 10.5.3 Induction Mechanisms of Mossy Fiber LTP

#### A Continuing Controversy: The Locus of Induction of Mossy Fiber LTP

The Hebbian characteristics of LTP in the Schaffer-commisural and perforant path projections arise from the voltage-dependent properties of the NMDA receptor. It is a matter of continuing controversy as to whether induction is also Hebbian in the mossy fiber projection. The most straightforward way of settling the issue would be to establish whether postsynaptic maneuvers, such as injection of a  $\text{Ca}^{2+}$  chelator into the target cell or voltage-clamping the cell at hyperpolarized potentials, blocks induction of LTP. Both experiments have been done, and different groups have come up with different answers. According to Johnston and colleagues, mossy fiber LTP is blocked by hyperpolarizing the CA3 pyramidal

**Figure 10-15.** Properties of mossy fiber LTP. *A*, Mossy fiber LTP in vitro is readily induced during blockade of NMDA receptors. The graph plots fEPSP amplitude vs time and shows that a tetanus (delivered at the time indicated by the arrowhead) induced LTP in the presence of D-AP5 (applied for 35 min. Mean baseline amplitude of fEPSPs was 0.4 mV. (*Source:* Harris and Cotman, 1986.) *B*, The induction of mossy fiber LTP in vitro can be prevented by kainate receptor antagonists. The graph plots fEPSP amplitude versus time and shows that the GluR5-containing kainate receptor antagonist LY382884 blocks the induction of mossy fiber LTP in a

reversible manner. A tetanus (100 Hz, 1 second, test intensity) was delivered in the presence of D-AP5 at the times indicated by arrows. (*Source:* Bortolotto et al., 1999.) *C*, Inhibition of PKA prevents the full expression of mossy fiber LTP in vitro. The graph plots fEPSP versus time to show the effects of the PKA inhibitor KT5720 and control experiments. A tetanus was delivered at  $t = 0$ . (*Source:* Weisskopf et al., 1994.) *D*, Mossy fiber LTP in vitro is absent in the Rab 3A knockout. The effects of a tetanus ( $t = 0$ ) on fEPSPs is compared for Rab 3A knockout and wild-type mice. (*Source:* Castillo et al., 1997a.)

neuron (Jaffe and Johnston, 1990) or by injecting the calcium chelator BAPTA (Williams and Johnston, 1989). A report by Zalutsky and Nicoll (1990), working with guinea pig rather than rat hippocampus, disputed both these findings; induction of LTP was insensitive to membrane potential and to intracellular injections of BAPTA. LTP in the A/C projection, however, was blocked by BAPTA. Because these synapses are located more distally on CA3 cells than the complex spines on which mossy fibers terminate, Zalutsky and Nicoll argued that the concentration of BAPTA was likely to have been sufficient to chelate free  $\text{Ca}^{2+}$  in complex spines. They concluded that the induction of mossy fiber LTP was not controlled postsynaptically and was therefore non-Hebbian (Nicoll and Schmitz, 2005).

A subsequent in vitro study offered a partial resolution of the controversy (Urban and Barrio Nuevo, 1996). Brief trains of high-frequency stimulation (B-HFS) (typically 8 stimuli at 100 Hz, repeated eight times at 5-second intervals), as normally used by Johnston and his colleagues, led to a Hebbian

form of mossy fiber LTP, the induction of which was blocked by a number of postsynaptic maneuvers, including hyperpolarization, internal perfusion with BAPTA, and ionotropic glutamate receptor blockade with kynurenone (which prevents synaptically evoked depolarization). In contrast, long trains of high-frequency stimulation (L-HFS) (typically 100 stimuli at 100 Hz, repeated three times at 10-second intervals), as favored by Nicoll and his colleagues, produced a non-Hebbian form of LTP that was not affected by hyperpolarization, kynurenone, or BAPTA.

Johnston's laboratory reentered the arena in 1999, reporting that B-HFS and L-HFS were associated with an increase in dendritic  $\text{Ca}^{2+}$  concentration; moreover, induction of both forms of LTP could be blocked by postsynaptic injection of BAPTA (Yeckel et al., 1999). However, the source of the increase in  $\text{Ca}^{2+}$  was different in the two cases. LTP induced by brief trains was associated with an influx of  $\text{Ca}^{2+}$  through voltage-gated  $\text{Ca}^{2+}$  channels because, as shown earlier (Urban and Barrio Nuevo, 1996), it could be blocked by kynurenone, by

hyperpolarization, and by  $\text{Ca}^{2+}$  channel blockers (Kapur et al., 1998). LTP and the rise in dendritic  $\text{Ca}^{2+}$  induced by long trains was insensitive to membrane potential and to kynurenone (confirming the observation of Zalutsky and Nicoll, 1990) but could be blocked by mGluR1 antagonists and by agents such as ryanodine and thapsigargin, which compromise release of  $\text{Ca}^{2+}$  from internal stores. These results suggest that a build-up of glutamate in the synaptic cleft leads to activation of type 1 mGluRs, stimulation of PLC, and a consequent IP3-induced release of  $\text{Ca}^{2+}$  from internal stores. Both forms of LTP could be blocked by an inhibitor of PKA, indicating that elevation of  $\text{Ca}^{2+}$  by the two routes converges on a PKA-dependent pathway to drive the expression of LTP. However, Mellor and Nicoll (2001) were unable to confirm these results and so the impasse remains unresolved. We are left with the unsatisfactory conclusion that in certain not precisely defined conditions the induction of mossy fiber LTP requires involvement of the postsynaptic cell, whereas in others, equally imprecisely characterized, it does not. It is notable, however, that a number of subsequent studies have emphasized the importance of the postsynaptic cell in the induction (and in one case the expression) of mossy fiber plasticity. Thus, a protocol in which LTP was induced by pairing mossy fiber stimulation with hyperpolarization of the CA3 neuron was developed by Sokolov et al. (2003). In contrast, Lei et al. (2003) reported that pairing low-frequency stimulation with sustained depolarization of the target CA3 cell led to a form of mossy fiber LTD in which expression as well as induction is postsynaptically driven.

Finally, in experiments that introduced a new dimension to mossy fiber plasticity, Contractor et al. (2002) established that the ephrin–EphB receptor tyrosine kinase signaling system (see Section 10.4.8) plays a critical role in the induction of LTP. The native B-ephrin ligand is expressed in the presynaptic membrane where it can potentially engage with the postsynaptic EphB receptor. Postsynaptic injection of antibodies that compromise protein–protein interaction domains on the intracellular C terminus of the EphB receptor blocks the induction of LTP, as does bath perfusion with a soluble form of B-ephrin. These experiments offer strong evidence for a postsynaptic involvement in the induction of mossy fiber LTP. They also provide a potential mechanism for retrograde transsynaptic signaling by which the presynaptic terminal can be informed about critical postsynaptic induction events. The reduction of mossy fiber LTP in NCAM knockout mice provides another indication of the potential importance of transsynaptic signaling at these synapses (Benson et al., 2000).

### **Role of Kainate Receptors in the Induction of Mossy Fiber LTP**

Kainate receptors are located both presynaptically and postsynaptically at mossy fiber synapses. The presynaptic kainate receptors regulate L-glutamate release (Vignes and Collingridge, 1997), and the postsynaptic kainate receptors contribute a slow component to the synaptic current gener-

ated by stimulation of mossy fibers (Castillo et al., 1997b; Vignes and Collingridge, 1997) (see Chapter 6, Section 6.3). The role of kainate receptors in the induction of mossy fiber LTP has provided another opportunity for lively disagreement. In the first study to use a specific kainate receptor antagonist, Bortolotto et al. (1999) reported that induction of mossy fiber LTP was blocked by LY382884 (Fig. 10–15B). Mossy fiber LTP was also blocked by CNQX and kynurenone, reagents that block both AMPA and kainate receptors. Their results were challenged by Nicoll and colleagues, who pointed to previous experiments of theirs and others in which CNQX and kynurenone had failed to block induction of mossy fiber LTP (see exchange of letters between Nicoll et al. and Bortolotto et al. in *Nature* 2000;406:957). Subsequently, Collingridge's group reported that the kainate receptor antagonist LY382884 acted presynaptically to reduce transmitter release from mossy fiber terminals and that this effect occluded mossy fiber LTP (Lauri et al., 2001). In this view, tetanic stimulation led to activation of presynaptic kainate receptors containing GluR5 subunits (the target of LY382884) and thence by a  $\text{Ca}^{2+}$ -dependent pathway to a persistent increase in transmitter release. A possible reconciliation of the two positions has emerged from later studies by the two groups. Lauri et al. (2003) found that the requirement for kainate receptor activation could be negated if the extracellular  $\text{Ca}^{2+}$  concentration was increased from 2 mM to 4 mM (the level normally employed in Nicoll's laboratory). Lauri and colleagues suggested that, at this concentration, sufficient  $\text{Ca}^{2+}$  entered via L-type  $\text{Ca}^{2+}$  channels to compensate for the block of kainate receptors. However, this cannot be the entire explanation because Schmitz et al. (2003) failed to block mossy fiber LTP with LY382884 even in the presence of 2 mM  $\text{Ca}^{2+}$ . Hence, it appears that multiple factors determine the role of kainate receptors in mossy fiber LTP.

Nicoll's group ascribed a role for presynaptic kainate receptors in mediating associative induction properties, in which neighboring mossy fiber or associational/commissural activity can lower the threshold for induction of mossy fiber LTP (Schmitz et al., 2003). Independent support for a critical role of presynaptic kainate receptors in mossy fiber plasticity has also come from the demonstration that LTP is absent in a knockout mouse lacking a functional GluR6 subunit (Contractor et al., 2001). Somewhat unfortunately for the prospects of reconciliation, the same study showed that mossy fiber LTP was unimpaired in mice lacking the GluR5 subunit. However, these results are not necessarily incompatible with the studies using LY382884 because, first, GluR6 is probably necessary for targeting kainate receptors and, second, there may be compensatory upregulation of other kainate receptor subunits in the knockout (Kerchner et al., 2002a). Furthermore, more recently developed antagonists of GluR5-containing kainate receptors, such as UBP296, also block the induction of mossy fiber LTP (More et al., 2004). The actions of GluR5 antagonists can therefore safely be attributed to their ability to inhibit this subunit. Given that LY382884 inhibits GluR5-containing heteromeric kainate receptors, the most likely ex-

planation for the discordant results is that the presynaptic kainate receptor may, but does not invariably, contain the GluR5 subunit.

#### **Role of mGluRs in the Induction of Mossy Fiber LTP**

As we saw in Section 10.3.10, one of the many controversies that enliven the study of hippocampal plasticity concerns the role of metabotropic glutamate receptors in LTP. In the case of mossy fiber LTP, it has been claimed that mGluR antagonists (Bashir et al., 1993), or the targeted deletion of mGluR1 (Conquet et al., 1994), severely impairs induction of LTP at mossy fiber synapses. However, both these findings have been disputed (Hsia et al., 1995; Selig et al., 1995b). In a subsequent study, it was reported that antagonism of both ionotropic and group 1 metabotropic receptors is required before LTP induced by long high-frequency trains (L-HFS) is blocked (Yeckel et al., 1999). Clearly, further work is needed to elucidate the involvement of mGluRs in mossy fiber LTP.

#### **Mossy Fiber LTP Requires Activation of the cAMP/PKA Pathway**

There is convincing evidence that the cAMP and cAMP-dependent protein kinase (PKA) pathway is involved in the generation of mossy fiber LTP. First, bath application of PKA inhibitors blocks the induction of mossy fiber LTP (Huang and Kandel, 1994; Weisskopf et al., 1994) (Fig. 10–15C). Second, bath application of membrane-permeable cAMP analogues or of forskolin, an activator of adenylyl cyclase, induces a form of LTP that occludes with tetanus-induced LTP (Huang and Kandel, 1994; Weisskopf et al., 1994). Third, mutant mice with a targeted deletion of type I adenylyl cyclase show impaired mossy fiber LTP (Wu Z-L et al., 1995). These observations do not directly address the question of pre- versus postsynaptic locus of induction or expression. Forskolin-induced LTP is probably expressed presynaptically for the following reasons: First, there is a reduction in paired-pulse facilitation (Huang and Kandel, 1994; Weisskopf et al., 1994); second, there is no change in the response evoked by iontophoretic glutamate (Weisskopf et al., 1994); and third, there is an increase in the coefficient of variation of synaptic responses, indicative of a presynaptic change (Weisskopf et al., 1994) (see Box 10.1). However, postsynaptic involvement of the PKA signal cascade in mossy fiber LTP has also been suggested by reports that injection of a cAMP analogue into the postsynaptic cell can facilitate induction of LTP (Hopkins and Johnston, 1988) and, conversely, that postsynaptic injection of a PKA peptide inhibitor can impair induction (Yeckel et al., 1999).

#### **Role of Opioid Peptides in Mossy Fiber Plasticity**

Mossy fiber terminals, like the terminals of the lateral perforant path, co-release the opioid peptides enkephalin and dynorphin in a frequency-dependent manner. The involve-

ment of opioid peptides in mossy fiber LTP is yet another area of dispute, with opioid receptor antagonists reportedly blocking mossy fiber LTP in vivo (Derrick and Martinez, 1994a, 1996) but not in vitro (Salin et al., 1995). In vivo, mossy fiber LTP can be induced by a combination of strong activation of A/C fibers, low frequency mossy fiber activation, and injection of  $\mu$  receptor agonists. Any combination of two of these procedures yields mossy fiber LTD rather than LTP (Derrick and Martinez, 1996).

#### **Role of Zinc in Mossy Fiber LTP**

Vesicles in mossy fiber glutamatergic terminals sequester large amounts of  $Zn^{2+}$  (Haug, 1967; Danscher et al., 1976; reviewed by Frederickson and Danscher, 1990). There is good evidence that  $Zn^{2+}$  can be released from mossy fibers during synaptic stimulation, where it may be co-released with L-glutamate (Assaf and Chung, 1984; Howell et al., 1984; Quinta-Ferreira and Matias, 2004).  $Zn^{2+}$  can modulate the function of a variety of ligand-gated and voltage-gated ions channels (Harrison and Gibbons, 1994), via which it may modulate synaptic plasticity. For example,  $Zn^{2+}$  inhibits NMDA receptors, providing a route by which it could affect the induction of NMDAR-dependent LTP (Xie and Smart, 1994; Ueno et al., 2002). There is also a body of evidence suggesting that  $Zn^{2+}$  is involved (Weiss et al., 1989). For example, a variety of  $Zn^{2+}$  chelators can inhibit the induction of mossy fiber LTP (Budde et al., 1997; Lu et al., 2000b; Li et al., 2001), as can chronic deficiency of dietary zinc (Lu et al., 2000b). Conversely, exogenous application of  $Zn^{2+}$  can induce long-lasting potentiation of mossy fiber transmission (Li et al., 2001). Mossy fiber LTP seems to require the entry of  $Zn^{2+}$  from the extracellular space into the postsynaptic neuron, entering via  $Ca^{2+}$ -permeable AMPA or kainate receptors or via voltage-gated ion channels (Li et al., 2001; Jia et al., 2002). Its target in the postsynaptic cell is not known.

#### **LTP at Connections Between Mossy Fibers and Interneurons**

In addition to the large excitatory synapses made by mossy fibers on CA3 pyramidal cells, at least two kinds of connections to inhibitory interneurons in the stratum lucidum have been described (see Chapter 4). LTP at these synapses is considered in Section 10.8.1.

#### **10.5.4 Expression of Mossy Fiber LTP Is Presynaptic**

There is general agreement that the locus of expression of mossy fiber LTP is presynaptic, in contrast to the long-running dispute concerning its locus of induction. Evidence for a presynaptic locus of expression was first presented by Zalutsky and Nicoll (1990), who found that paired-pulse facilitation (PPF) of responses evoked by mossy fiber stimulation was reduced after induction of LTP. However interpretation of this result as

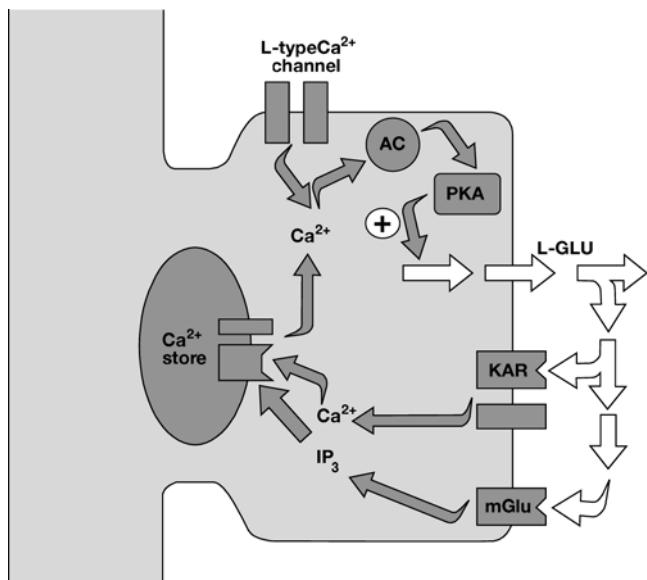

evidence of a presynaptic change is itself based on the assumption that PPF is wholly presynaptic, a claim for which there is no incontrovertible evidence in the mossy fiber pathway and that cannot be taken for granted (see Box 10–1). However, related evidence for a presynaptic locus has come from the demonstration that presynaptic kainate receptors mediate a component of synaptic facilitation that occludes with mossy fiber LTP (Lauri et al., 2001).

Further support for a presynaptic locus of expression has emerged from a comparison of the decay constant of NMDAR-mediated currents in the presence of the activity-dependent blocker MK801 in potentiated and nonpotentiated synapses. Potentiated mossy fiber synapses show a more rapid block than nonpotentiated mossy synapses, in contrast to A/C synapses where the decay rate is unaffected by potentiation (Weisskopf and Nicoll, 1995). This result implies an increase in mean Pr following the induction of LTP (see Section 10.4.4), which could be achieved by an increase in Pr at preexisting release sites or by activation of silent synapses with a mean Pr higher than that of the pretetanus population. Activation of silent synapses could occur by the insertion of receptor clusters or by the awakening of previously silent release sites. In cultured granule cells making autaptic synapses onto themselves, there is evidence that the latter is more likely to be the case (Tong et al., 1996). The existence of NMDAR-independent LTP at granule cell autapses establishes that the CA3 pyramidal cell is not an obligatory component of the LTP machinery at granule cell terminal boutons. As discussed in section 10.4.4, Kawamura et al. (2003), using an optical method to detect glutamate-induced glial depolarization, also reached the conclusion that LTP at mossy fiber synapses, but not at A/C synapses, was associated with an increase in glutamate release.

Quantal analysis has been applied to mossy fiber LTP in slices (Xiang et al., 1994) and in a culture system (Lopez-Garcia et al., 1996); in both studies there was an increase in the coefficient of variation and a reduction in failures at initially nonsilent connections, indicating a presynaptic locus for the expression of LTP (but see Yamamoto et al., 1992). Confocal imaging of excitatory postsynaptic calcium transients (EPSCaTs) at single complex spines is also consistent with a presynaptic locus of expression. LTP is accompanied by an increase in the number of active release sites and/or an increase in Pr at already active sites (Reid et al., 2004).

Some insight has been gained into the mechanisms underlying expression of mossy fiber LTP. Thus, mossy fiber LTP is absent in mice lacking the synaptic vesicle protein Rab3a (Castillo et al., 1997a) and the GTP-dependent Rab3a binding partner RIM1 $\alpha$  (Castillo et al., 2002). RIM1 $\alpha$  is located at the active zone and is a substrate for PKA. Therefore LTP could involve a PKA-dependent interaction between Rab3a and RIM1 $\alpha$  to enhance transmitter release. Surprisingly, however, forskolin-induced potentiation, which occludes with mossy fiber LTP, is not affected in either knockout. Therefore, the relation between PKA-dependent signaling and the role of these two proteins in mossy fiber LTP is unclear.

Another possible mechanism was suggested by the finding that mossy fiber LTP occludes the facilitation of synaptic

**Figure 10–16.** Mechanisms involved in the expression of mossy fiber LTP. Synaptically released L-glutamate can feed back onto presynaptic receptors. Under certain circumstances, at least, this may involve kainate receptors, group I mGlu receptors, and Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release. A possible scheme to link these components is illustrated, which involves convergence of Ca<sup>2+</sup> and IP<sub>3</sub> at the ryanodine receptor. Ca<sup>2+</sup> entry via voltage-gated Ca<sup>2+</sup> channels can provide an alternative source of Ca<sup>2+</sup>. Increases in Ca<sup>2+</sup> stimulate adenylyl cyclase (AC) to activate PKA, and this modifies L-glutamate release. Other mechanisms, including a postsynaptic component, could also be involved in mossy fiber LTP.

transmission induced by depolarization with K<sup>+</sup> (Lauri et al., 2001). This suggests that mossy fiber LTP may alter an ion channel to affect the resting membrane potential of mossy fiber boutons. One candidate is the hyperpolarization-activated cation channel Ih (Mellor et al., 2002, but see Chevaleyre and Castillo, 2002). Thus, a wide range of evidence indicates a presynaptic locus of expression for mossy fiber LTP (Fig. 10–16).

### 10.5.5 E-LTP and L-LTP at Mossy Fiber Synapses Can Be Distinguished by the Effects of Protein Synthesis Inhibitors

Repeated long trains of high-frequency stimulation result in L-LTP lasting undiminished for 6 hours or more at mossy fiber synapses *in vitro* (Urban and Barrionuevo, 1996). In the presence of transcriptional and translational inhibitors, potentiation is initially similar, but responses decline to baseline levels over the following 3 to 4 hours (Huang YY et al., 1994). As is the case elsewhere in the hippocampus, mossy fiber LTP can therefore be subdivided into L-LTP, requiring gene expression and protein synthesis, and E-LTP, which is independent of protein synthesis. The cAMP-dependent protein kinase cascade is implicated in both early and late mossy fiber LTP. PKA inhibitors block both phases, and bath application of forskolin, an activator of adenylyl cyclase, induces both

early protein synthesis-independent and late protein synthesis-dependent potentiation. Moreover, early tetanus-induced LTP occludes forskolin-induced LTP and vice versa (Huang YY et al., 1994; Weisskopf et al., 1994). Early LTP is associated with a conspicuous reduction in paired-pulse facilitation (Zalutsky and Nicoll, 1990); interestingly, this effect attenuates over time, suggesting a switch to mechanisms of potentiation that do not depend on an increase in  $P_r$  at individual release sites but, instead, require either postsynaptic changes or an increase in the number of synapses or active zones (Huang and Kandel, 1994).

### 10.5.6 Summary

Despite its independence of the NMDA receptor, it is evident that LTP at mossy fiber synapses requires an increase in intracellular  $\text{Ca}^{2+}$ ; but whether the critical compartment is the presynaptic terminal or the postsynaptic spine remains unresolved and may depend on the pattern of the plasticity-inducing stimulation. What is clear is that the increase in  $\text{Ca}^{2+}$  is not achieved by activation of NMDA receptors. Instead, increases in  $\text{Ca}^{2+}$  are achieved by a variety of alternative routes, including the opening of voltage-dependent  $\text{Ca}^{2+}$  channels following depolarization (caused by the presynaptic action potential in the case of the presynaptic terminal and by binding of glutamate to postsynaptic AMPA receptors in the case of the postsynaptic cell) and the binding of glutamate to type I mGluRs, leading to release of  $\text{Ca}^{2+}$  from intracellular stores. The finding that kainate receptor antagonists, and philanthotoxin which blocks  $\text{Ca}^{2+}$  permeation, can block mossy fiber LTP under similar experimental conditions raises the possibility that  $\text{Ca}^{2+}$  entry through these receptors may also regulate plasticity at mossy fiber synapses.

Finally, little is known about the role of mossy fiber LTP in the behaving animal. The long (1 second) trains at 100 Hz that are required to produce robust mossy fiber LTP are not likely to be mimicked by granule cells in vivo, and it remains to be established that naturally occurring patterns of granule cell activity lead to LTP at mossy fiber synapses.

## 10.6 LTP Can Be Modulated by Other Neurotransmitters, Neuromodulators, and Effectors and by Endogenous and Circadian Rhythms

The degree and duration of LTP produced by a standard induction protocol is influenced by a multitude of factors in addition to the frequency and duration of the tetanus. We have already discussed the effects of prior activity (metaplasticity) and the critical role of inhibitory circuits in setting the threshold for LTP. A good example of the importance of inhibition is seen in the dentate gyrus of the hippocampal slice, where LTP usually cannot be elicited at all unless the slice is perfused with a GABA<sub>A</sub> antagonist. We now examine the role of some of the more important of the many other neuro-

transmitters and neuromodulators that can affect the threshold for induction or the magnitude and/or duration of LTP. We also consider cyclical influences on LTP, including sleep and circadian rhythms. In this section also we discuss the evidence that newborn granule cells in the dentate gyrus contribute to synaptic plasticity.

### 10.6.1 Modulation by Other Neurotransmitters and Neuromodulators

#### Acetylcholine

Both the early literature (reviewed in Segal and Auerbach, 1997) and more recent studies support the conclusion that the septal cholinergic input can facilitate the induction of hippocampal LTP. Evidence includes (1) inhibition of LTP by broad-spectrum muscarinic antagonists and (2) reduction in the threshold for LTP by muscarinic agonists or by stimulation of the septum. A revealing study in the freely moving rat demonstrates that these effects depend on the behavioral state of the animal (Leung et al., 2003). Basal LTP in the immobile or sleeping rat is not affected by muscarinic antagonists; but if tetanic stimulation is delivered to the Schaffer-commissural projection when the animal is generating cholinergically driven theta activity as it moves around its environment, an enhanced level of LTP is induced in area CA1. Pretreatment with the muscarinic antagonist scopolamine reduced the level of LTP to near-baseline levels, as did injection into the medial septum of the neurotoxin immunoglobulin G (IgG)-saporin, directed against cholinergic neurons. These experiments demonstrate that LTP can be modulated by an endogenous, behaviorally driven cholinergic input from the septum. The effect is probably mediated by high-affinity postsynaptic M2 receptors (Segal and Auerbach, 1997). It is notable that afferent cholinergic fibers and M2 receptors are both present at higher density in the stratum oriens than in the stratum radiatum of area CA1. Activation of muscarinic receptors in the hippocampus leads to G protein-mediated block of a number of  $K^+$  channels, including  $I_{\text{AHP}}$ ,  $I_M$ , and  $I_L$ , as well as enhanced NMDA receptor function (Segal and Auerbach, 1997). Interestingly, direct potentiation of the NMDA receptor conductance occurs at lower concentrations of ACh than that usually required to block  $K^+$  channels (Harvey et al., 1993). Any or all of these effects may contribute to the positive modulation of LTP induction by ACh acting on muscarinic receptors.

#### Monoamines

**Norepinephrine (Noradrenaline).** Noradrenergic innervation of the hippocampus originates primarily from neurons in the locus coeruleus (see Chapter 8, Section 8.1.2). In the first study of the role of monamines in LTP, Bliss et al. (1983) investigated the effects of the depletion of norepinephrine and serotonin. Depletion of norepinephrine was achieved by injecting the neurotoxin 6-hydroxydopamine (6-OHDA) into the locus coeruleus, leading to a reduction in the magnitude of LTP of the fEPSP in the dentate gyrus (Bliss et al., 1983).

Curiously, LTP of the population spike was not affected, a result mirrored in a study showing that  $\beta$ -adrenergic receptor antagonists block LTP of the fEPSP but not of the population spike in the dentate gyrus (Munro et al., 2001, but see Stanton and Sarvey, 1985). There is also evidence that norepinephrine can promote late LTP: Stimulation of adrenergic neurons in the locus coeruleus by injection of glutamate produces a delayed protein synthesis-dependent potentiation of perforant path-evoked responses in the dentate gyrus (Walling and Harley, 2004). A similar pattern of results is seen in area CA1. Depletion of norepinephrine or bath application of  $\beta$ -adrenergic receptor antagonists blocks LTP, and bath application of norepinephrine lowers the threshold for the induction of LTP (Izumi and Zorumski, 1999). Enhancement or reduction of LTP by drugs that respectively stimulate or block  $\beta$ -adrenergic receptors has also been reported in the mossy fiber projection (Hopkins and Johnston, 1988). Because  $\beta$ -adrenergic receptors are positively linked to adenylate cyclase, the mechanism of action of norepinephrine is likely to be similar to that of dopamine, leading (via an increase in cAMP) to activation of PKA.

**Serotonin.** The modulatory effects of serotonin (5-hydroxytryptamine, 5-HT) on LTP have been relatively less studied, and there is little consensus among studies. Selective depletion of serotonin reduced the magnitude of LTP in the dentate gyrus *in vivo* (Bliss et al., 1983), but this result was not replicated in an *in vitro* study (Stanton and Sarvey, 1985). At commissural-associational synapses in area CA3 *in vitro*, bath application of 5-HT was reported to inhibit LTP (Villani and Johnston, 1993), whereas depletion of serotonin in area CA1 was without effect (Stanton and Sarvey, 1985). The role of serotonin receptor subclasses in LTP has received some attention. Injection of ondansetron, a selective antagonist of 5-HT<sub>3</sub> receptors, significantly enhanced the magnitude of LTP in area CA1 in the freely moving rat, probably by suppressing the excitability of interneurons mediating feedforward inhibition (Staubli and Xu, 1995). Support for the notion that the predominant effect of 5-HT is to suppress LTP comes from studies showing that the 5-HT uptake inhibitor fluvoxamine reduces LTP via activation of 5-HT<sub>1A</sub> receptors (Kojima et al., 2003), whereas injection of a 5-HT<sub>4</sub> receptor agonist into the lateral ventricle inhibited LTP, an effect that was blocked by a selective 5-HT<sub>4</sub> antagonist (Kulla and Manahan-Vaughan, 2002). The cellular distribution of the relevant 5-HT receptors and the downstream signaling pathways by which 5-HT exerts its effects on LTP remain largely unexplored.

**Dopamine.** Dopaminergic projections to the hippocampus (primarily to the hilus and stratum radiatum lacunosum) originate in the ventral tegmental area (VTA) and substantia nigra (Scattton et al., 1980; Gasbarri et al., 1997). There is persuasive evidence that dopamine plays an important modulatory role in the induction of protein synthesis-dependent L-LTP in area CA1 (reviewed by Lisman and Grace, 2005). Knockout of the D1 dopamine receptor produces mice that lack L-LTP while displaying normal E-LTP (Matthies et al.,

1997). Bath-applied dopaminergic antagonists similarly block L-LTP when given during, but not after, a strong tetanus applied to induce L-LTP (Frey et al., 1990). Moreover, bath-applied phosphodiesterase inhibitors, which prolong the action of cAMP and so enhance the action of the principal downstream effector of dopamine, protein kinase A, can convert E-LTP into L-LTP (Navakkode et al., 2004). Stimulation of the dopamine receptor-mediated signaling cascade with D1/D5 dopamine receptor agonists or with the cAMP activator forskolin induces protein synthesis-dependent late potentiation that occludes with L-LTP in area CA1 *in vitro* (Frey et al., 1993; Huang and Kandel, 1995; but see Mockett et al., 2004). Thus, in area CA1, dopamine receptor activation appears to be both necessary and sufficient for the induction of L-LTP. This is not, of course, to say that the release of dopamine or of any other neuromodulator is the primary cause of NMDAR-dependent LTP. D1/D5 agonists can lower the threshold for input-specific tetanus-induced LTP *in vitro* (Otmakhova and Lisman, 1996) and *in vivo* (Kusuki et al., 1997). When bath applied at high doses, it can under some circumstances produce L-LTP nonspecifically at many synapses; but this cannot be what happens in the context of input-specific L-LTP. Here, its action may be, rather, to convert or consolidate E-LTP into L-LTP by facilitating gene expression via enhanced PKA activity. Dopamine exerts its effects through activation of PKA, which as we have seen is intimately involved in the dendrite-to-nucleus signaling that triggers gene transcription, and in local dendritic protein synthesis (see Section 10.4.9). In this model, then, dopamine, via cAMP and PKA, is directly involved in the synthesis of plasticity-related proteins (Navakkode et al., 2004). An intriguing aspect of dopamine signaling in area CA1 is that it drives the enhancement of LTP in novel environments (Li et al., 2003; see Lisman and Grace, 2005 for a model of how the hippocampal-VTA loop controls entry of novel experiences into long-term memory). Interestingly, noradrenergic rather than dopaminergic signaling appears to be responsible for novelty-dependent modulation of LTP in the dentate gyrus (Straube et al., 2003).

### Brain-derived Neurotrophic Factor

There is abundant evidence that the neurotrophic peptide, brain-derived neurotrophic factor (BDNF), is released as a result of synaptic activity at hippocampal synapses. Extracellular BDNF can act on its receptor trkB, a member of the tropomysin-related family of receptor tyrosine kinases, to enhance synaptic efficacy at excitatory synapses and diminish efficacy at inhibitory synapses (for reviews, see Schinder and Poo, 2000 and Ernfors and Bramham, 2003). BDNF can probably be released from both pre- and postsynaptic sites at hippocampal synapses and act on populations of pre- and/or postsynaptic trkB receptors whose numbers are regulated by activity. At Schaffer-commissural synapses in area CA1, BDNF can act as a potent excitatory transmitter (Kafitz et al., 1999).

BDNF appears to play a critical role in the induction of LTP. LTP is impaired in BDNF-null mice (Korte et al., 1995), and the deficit can be rescued *in vitro* by BDNF administered

directly (Patterson et al., 1996) or by viral transfection (Korte et al., 1996). BDNF can also produce LTP. Bath application of BDNF to hippocampal slices induces slow-onset, protein synthesis-dependent LTP in area CA1 (Kang and Schuman, 1995), whereas in the dentate gyrus repeated pairing of weak synaptic stimulation with focal dendritic application of BDNF leads to rapid-onset LTP that occludes with tetanus-induced LTP (Kovalchuk et al., 2002). This form of LTP satisfies the criterion for postsynaptic induction, as it is blocked by postsynaptic injection of calcium chelators. A late-onset, transcription-dependent potentiation of synaptic transmission has also been described in the dentate gyrus of the anesthetized rat following transient perfusion with BDNF (Messaoudi et al., 2002) (Fig. 10–2D). The synaptic response climbs gradually after perfusion and persists for many hours thereafter. BDNF-induced late LTP occludes with late tetanus-induced LTP; but in contrast to the rapid-onset LTP observed in the dentate gyrus *in vitro*, it is not NMDAR-dependent. However, because it leads to CREB phosphorylation via activation of ERK1/2 and upregulation of immediate early genes in granule cells, bath application of BDNF activates, at least in part, the normal late LTP-inducing machinery in the postsynaptic cell downstream from the NMDA receptor (Ying et al., 2002). Changes in CREB phosphorylation in the entorhinal cortex, where the perforant path projection to the dentate gyrus originates, suggests there may also be presynaptic involvement (Gooney et al., 2004).

Little information is available on whether the expression of BDNF-induced LTP is pre- and/or postsynaptically mediated in the hippocampus. In hippocampal cultures, neurotrophin-induced potentiation lasting 10 to 15 minutes carries the hallmarks of a presynaptic mechanism: reduced paired-pulse facilitation, increased mini-EPSP frequency without an increase in amplitude, a reduction in the coefficient of variation, and comparable enhancement of both AMPAR- and NMDA-mediated responses (Schinder and Poo, 2000). Whether endogenous BDNF acts as a retrograde messenger released from the postsynaptic cell to act on presynaptic TrkB receptors remains to be established. A presynaptic component of LTP induced at Schaffer-commissural synapses on CA1 pyramidal cells by theta-burst stimulation requires BDNF. However, analysis of two mutant lines—one expressing a mutant form of BDNF in both CA3 and CA1 cells and the other only in CA1 cells—disclosed an impairment of theta-burst LTP only in the former mutant, suggesting that the source of BDNF is in presynaptic neurons (Zakharenko et al., 2003). In other systems, however, such as the neuromuscular junction, there is clear evidence that BDNF acts as a retrograde messenger (Schinder and Poo, 2000).

### Cytokines

A variety of cytokines have been found to interact with LTP. For example, interleukin-1 $\beta$  (IL-1 $\beta$ ) reduces mossy fiber LTP (Katsuki et al., 1990) and NMDA receptor-dependent LTP in area CA1 and the dentate gyrus (Bellinger et al., 1993; Cunningham et al., 1996). It has been suggested that endoge-

nous levels of IL-1 $\beta$  are elevated in response to stress, infection, the amyloid peptide A $\beta$ , and aging, and that this may partly account for the neurodegeneration and cognitive deficits sometimes observed in such circumstances (Murray and Lynch, 1998; Minogue et al., 2003). The mechanism by which IL-1 $\beta$  exerts its effects is not fully established but may involve activation of c-Jun N-terminal kinase (JNK) and p38MAPK as well as caspase-1 and NK $\kappa$ B (Vereker et al., 2000a,b; Curran et al., 2003; Kelly et al., 2003). IL-1 $\beta$  also seems to stimulate superoxide dismutase to increase reactive oxygen species (Vereker et al., 2001). In addition to a role in pathology, however, studies with an IL-1 receptor antagonist and an IL-1 receptor knockout have suggested that IL-1 may be required for the induction of LTP under physiological conditions (Avital et al., 2003; Ross et al., 2003; Maher et al., 2005).

Other interleukins, such as IL-2, IL-6, IL-8, and IL-18, also inhibit the induction of LTP (Tancredi et al., 1990; Bellinger et al., 1995; Li et al., 1997; Curran and O'Connor, 2001; Xiong et al., 2003). However, certain interleukins have complex interactions in their regulation of LTP. For example, IL-10 blocks the inhibitory effect of IL-1 $\beta$  on LTP (Kelly et al., 2001). Other cytokines that have been reported to inhibit LTP include the interferons (D'Arcangelo et al., 1991; Mendoza-Fernandez et al., 2000) and tumor necrosis factor alpha (TNF $\alpha$ ) (Tancredi et al., 1992). TNF $\alpha$  inhibits early LTP, but not late LTP, via activation of a p38MAPK cascade (Butler et al., 2004) and may mediate its actions via an effect on the trafficking of AMPA receptors (Beattie et al., 2002).

### Corticosteroids

The effects of stress on hippocampal plasticity were first explored by Foy et al. (1987). Rats were subjected to mild inescapable stress by confining them in a restraining tube for 30 minutes. Hippocampal slices cut from the brains of animals killed immediately afterward displayed significant impairment in LTP relative to control animals. It later became apparent that an important factor is whether the stress is avoidable; slices from animals that were given shocks but had control over the termination of the shock showed greater LTP than an unshocked group, whereas those that had no control over termination showed less LTP (Shors et al., 1989). Hippocampus-dependent learning is also modulated by stress (see Chapter 15). Later it was found that mild stress can facilitate the induction of LTD (Xu et al., 1997; Manahan-Vaughan, 2000).

In rodents, stress is associated with an increased plasma concentration of the adrenal hormone corticosterone. The hippocampus is richly endowed with the two types of corticosteroid receptor: the high-affinity mineralocorticoid (or type I) receptor and the low-affinity glucocorticoid (type II) receptor. Activation of mineralocorticoid receptors promote LTP, whereas high corticosterone levels activate the glucocorticoid receptor, which is the primary mediator of stress-induced impairment of LTP and spatial learning. Thus, there is an inverted-U relationship between the plasma concentration of corticosterone and its effects on LTP and learning. At

low concentrations of corticosterone (as occurs following adrenalectomy) the occupancy of mineralocorticoid receptors is low, whereas at high levels (as during severe stress) the glucocorticoid receptors are fully occupied; both conditions are associated with a reduction of LTP, promotion of LTD, and impaired learning. Consequently, LTP and learning are maximal at intermediate levels of circulating corticosterone (Diamond et al., 1992; Kim and Diamond, 2002). It is an oversimplification, however, to assume that corticosterone is the only mediator of the effects of stress on LTP and behavior; in fact, corticosterone is neither necessary nor sufficient for these effects to occur. For example, stress can still suppress LTP in rats deprived of corticosterone by adrenalectomy, and lesions of the amygdala block the stress-induced impairment of LTP even though corticosterone levels remained high in lesioned animals (Kim and Diamond, 2002; Kim et al., 2005c). Priming stimuli delivered to the basolateral amygdala has a biphasic effect on LTP in the dentate gyrus *in vivo*, enhancing LTP at short priming-tetanus intervals and suppressing LTP if given an hour before the tetanus to the perforant path. The mechanisms by which activity in the amygdala is able to block LTP in the hippocampus have yet to be worked out, but these findings reflect the intimate manner in which hippocampal plasticity is modulated by the amygdala's view of a stress-filled world (Kim et al., 2005c).

There is evidence that stress engages some of the same signaling pathways that are involved in synaptic plasticity. For example, phosphorylation of the MAP kinase signaling molecules ERK1/2 is markedly increased by stress, and the inhibitory effects of stress on learning and LTP can be blocked by inhibitors of ERK1/2 phosphorylation (Yang et al., 2004). This raises the possibility that the reduction in tetanus-induced LTP during stress reflects potentiation caused by stress itself, pushing the affected synapses toward saturation. However, neither applied corticosterone nor stress has been reported to enhance baseline levels of hippocampal evoked responses. Because NMDA receptor antagonists given at the time of the stressful experience can block the subsequent reduction in LTP, it is likely that the impairment of LTP is due to a metaplastic effect mediated by NMDA receptor activation rather than saturation of LTP (Abraham, 2004).

Hippocampal regulation of the hypothalamic-pituitary-adrenal axis is discussed in Chapter 15.

### **10.6.2 Cyclical Influences Modulate Induction of LTP**

#### **Sex Hormones and LTP**

During proestrus in female rats, when levels of estrogens reach a peak, the number of spines on CA1 pyramidal cells is as much as 30% higher than during estrus (Woolley et al., 1990) (see Chapter 9). Are there corresponding changes in the magnitude of LTP and/or LTD during the estrus cycle? There have been two reports that LTP in area CA1 of female rats with chronically implanted electrodes is enhanced during proestrus

(Warren et al., 1995; Good et al., 1999). Subsequent experiments have largely been conducted on ovariectomized animals where the total absence of estrogen has not always led to the reduction in LTP that the experiments in normally cycling animals might have predicted. For example, Day and Good (2005) saw no change in LTP following ovariectomy but did observe impaired LTD that was reversed by chronic estrogen replacement. Whether these estrogen-induced effects on synaptic plasticity are an indirect result of changes in spine numbers or reflect an action of the hormone on signaling pathways or protein synthesis remains to be seen. Puberty in male rats is associated with a bias toward LTD (Hebbard et al., 2003). The effect of pregnancy on LTP does not appear to have been specifically examined, although a greater flexibility in behavior in the watermaze has been noted (Bodensteiner et al., 2006).

#### **Sleep, Circadian Rhythms, and LTP**

Sleep is necessary for normal cognitive processing. In particular, it seems likely that during sleep the brain sorts newly acquired information to determine what needs to be committed to long-term storage and then assimilates it with previously learned experiences. The brain is therefore performing complex cognitive processing during sleep that is probably crucial for the consolidation of memories. Several groups have wondered if LTP is modulated during sleep, and in particular during dreaming in REM sleep. Our memory for dreams is surprisingly tenuous, given the vividness of the dreaming experience. Can this be linked to suppression of LTP during REM sleep? It seems not. In the dentate gyrus, the magnitude of LTP induced during REM sleep is similar to that obtained during the alert state (Bramham and Srebro, 1989), although there is a significant reduction in magnitude during slow-wave sleep (Leonard et al., 1987).

Other studies have found that sleep deprivation (12–72 hours) can impair the ability to induce LTP (Campbell et al., 2002; Davis et al. 2003; McDermott et al. 2003; Kim et al., 2005b), possibly because of the stress that is associated with sleep deprivation. However, even when precautions are taken to minimize stress, short periods (4 hours) of REM sleep deprivation result in selective impairment in the maintenance of L-LTP in the perforant path (Romcy-Pereira and Pavlides, 2004).

A clue to what sleep might be doing has been obtained by mapping plasticity using the expression of the immediate early gene *zif268* (Ribeiro et al. 2002). The induction of LTP in the perforant path, which is associated with a rapid increase in the expression of *zif268*, also leads to upregulation of *zif268* expression during subsequent episodes of REM sleep in extrahippocampal regions, predominantly in the amygdala, entorhinal, and auditory cortices during the first REM sleep episode and the somatosensory and motor cerebral cortices as REM sleep recurs. These observations support the hypothesis that sleep enables the spread of memory traces from hippocampus to the cerebral cortex.

Exercise promotes LTP at CA1 synapses: LTP is greater when induced in walking rats than in awake but immobile animals or during slow-wave or REM sleep (Leung et al., 2003). The enhanced synaptic plasticity in walking animals is promoted by the septal cholinergic input to the hippocampus.

The pyramidal and granule cell subfields respond differently to night–day variations. In the dentate gyrus, LTP is significantly greater when induced during the dark, active stage of the rat's diurnal cycle (Harris and Teyler, 1983; Dana and Martinez, 1984), consistent with the reduction in LTP observed during slow-wave sleep and perhaps reflecting the greater baseline fEPSPs obtained in the dark (Barnes et al., 1977). In CA1, in contrast, LTP is greater during the light, behaviorally inactive stage. The reasons for this difference and its functional significance are unknown.

### Hibernation

The temperature of hibernating animals can fall to a value at which synaptic transmission fails. As temperature rises on arousal from hibernation, the magnitude of LTP is greater than in control animals maintained at the same temperature (Spangenberger et al., 1995). This no doubt provides a welcome boost to its cognitive faculties at a generally trying time for the hamster.

### 10.6.3 Neurogenesis and LTP

Neurogenesis proceeds at a truly astonishing rate in the dentate gyrus of adult animals (see Chapter 9). In the rat, approximately 9000 new granule cells are born each day. (Box 9–1), approaching 1% of the total number of granule cells in the each dentate gyrus (Section 3.4.1). Performance in some (but not all) hippocampus-dependent tasks (e.g., trace eyeblink conditioning) is blocked by administration of methylazoxymethanol, a toxin that kills dividing cells (Shors et al., 2001). One explanation for this observation is that newborn granule cells are necessary for encoding the learned task. What is the physiological evidence that would support such a conclusion? First, although most newborn cells die, those that survive are incorporated into the neural network of the dentate gyrus, sending axons toward the stratum pyramidale of area CA3 (Hastings and Gould, 1999; Markakis and Gage, 1999) and extending dendrites into the molecular layer where they make synaptic contact with axons of the perforant path (Song et al., 2002). Second, neurogenesis and LTP are enhanced by running (van Praag et al., 1999). Third, immature granule cells have a lower threshold for LTP than do adult cells (Schmidt-Hieber et al., 2004). The reason for this seems to be the much higher input resistance of immature cells (leading to greater depolarization for a given synaptic current) and the expression by immature cells of T-type  $\text{Ca}^{2+}$  channels that support  $\text{Ca}^{2+}$  spikes following relatively small depolarizations. These characteristics lead, on the one hand, to greater relief of the  $\text{Mg}^{2+}$  block of the NMDA receptor and, on the other, to enhanced  $\text{Ca}^{2+}$  entry, both of which promote the

induction of LTP (Schmidt-Hieber et al., 2004). However, there is clearly some way to go before we can conclude that neurogenesis contributes to the cellular basis of learning. Among the basic questions that await answers are (1) what is the lifetime of newborn cells that mature into fully connected members of the adult granule cell network, (2) how does the hippocampus maintain a stable representation of stored events in the face of a continuing turnover of granule cells, and (3) why is adult neurogenesis confined to the dentate gyrus and olfactory bulb. As Schinder and Gage (2004) have pointed out, the tool needed to establish a causal role for neurogenesis in learning is a genetic model in which neurogenesis can be turned on and off at will.

## 10.7 Long-term Depression and Depotentiation: Properties and Mechanisms

### 10.7.1 Overview

If activity-dependent plasticity operated only to enhance synaptic weights, saturation of synaptic efficacy would eventually ensue. A neural net composed of Hebbian synapses all of whose synaptic weights were maximal would be incapable of learning. Although many, if not all, potentiated synapses may eventually decay to baseline through the passage of time, an activity-driven mechanism to allow erasure, or depotentiation, of LTP would enhance the computational flexibility of the network. An additional mechanism permitting activity-dependent LTD from baseline values of synaptic efficacy, and independent of LTP, so-called de novo LTD, would further enhance the flexibility of the system and increase its storage capacity (Dayan and Willshaw, 1991). Another important consideration is the balance of excitation and inhibition that determines the overall stability of the network. Unbridled potentiation would carry the danger of disrupting this balance and driving the system to instability and seizure. The homeostatic checks and balances that the hippocampus deploys at both the cell and network levels to guard against runaway excitation are described in Section 10.3.14; in this light, both the homosynaptic properties of LTD and depotentiation, and the heterosynaptic depression that in some cases accompanies the induction of LTP, may be considered additional weapons in the network's homeostatic armory.

A word on nomenclature: In what follows, by LTD we mean de novo LTD. The depression of a potentiated response we refer to as depotentiation, and the repotentiation of a depressed response as de-depression. It is important to keep these terms distinct because, as we shall see, they embody different mechanisms. Depotentiation, for example, is true reversal or erasure of LTP, not the superposition of depression on a still potentiated background.

Heterosynaptic forms of LTD and depotentiation provided the first indication that, in addition to LTP, hippocampal synapses could support long-term, activity-dependent reduc-

tions in synaptic efficacy (Lynch et al., 1977; Levy and Steward, 1979) (Fig. 10–17A,B). Later work also established that during the first few minutes after its induction (but not at later times) LTP could be “destabilized” (depotentiated) by low-frequency stimulation (Barriosuevo et al., 1980; Staubli and Lynch, 1990; Fujii et al., 1991) (Fig. 10–17B). Further progress was slow, largely because of the lack of a reliable protocol for inducing LTD. The discovery by Dudek and Bear (1992) that prolonged trains of low-frequency stimulation (LFS), typically 900 stimuli at 1 Hz, induced both homosynaptic LTD and homosynaptic depotentiation in hippocampal slices from juvenile rats provided a major impetus to research (Fig. 10–17D, Fig. 10–19A). Progress in studying LTD in the adult animal, however, whether *in vivo* or *in vitro*, is still hampered by the lack of effective stimulus protocol(s) that produce LTD most of the time in most laboratories. This has led to speculation that de novo LTD is a form of synaptic plasticity whose major role lies in the sculpting and pruning of synaptic connections during development of the nervous system. Nevertheless, to prevent network saturation and to preserve an overall mean level of excitability in the network, the conclusion seems unavoidable that mechanisms to decrease synaptic weights must also be available to the fully developed hippocampus.

Initial uncertainties about whether the induction of LTD in area CA1 was NMDAR-dependent (Dudek and Bear, 1992) or mGluR-dependent (Bashir et al., 1993) were resolved when Oliet et al. (1997) showed that it was possible to obtain either result by manipulating the induction protocol, thus confirming the existence of two independent forms of homosynaptic LTD. In both area CA1 and the dentate gyrus, mGluR-dependent LTD is reliably induced at all ages by exposure to the group 1 agonist DHPG (Palmer et al., 1997) (Fig. 10–17E) or by low-frequency trains of pairs of pulses at an appropriate inter-pulse interval (Kemp et al., 2000) (see Section 10.7.5). A third form of LTD has been reported at mossy fiber synapses early in postnatal development that requires neither NMDA nor mGlu receptors (Domenici et al., 1998).

The two major forms of LTD have different developmental profiles: *In vitro*, both NMDAR- and mGlu receptor-dependent LTD occur in area CA1 in the neonate, giving way to predominantly mGluR-LTD in the adult (Kemp et al., 2000). Pharmacological blockade of the uptake of L-glutamate facilitates induction of NMDAR-dependent LTD in perirhinal cortex (Massey et al., 2004) and in area CA1 (Yang et al., 2005). This suggests that mechanisms exist for NMDAR-dependent LTD but that normal uptake processes limit their deployment. Because uptake mechanisms are strongly temperature-dependent, they are likely to be more effective *in vivo* than *in vitro*, where experiments are rarely performed at physiological temperatures. This might be one reason why LTD is often not observed *in vivo*. However, NMDAR-dependent LTD can be induced in area CA1 of the adult rat *in vivo* by low-frequency trains of paired-pulse stimuli with a brief 25 msec interpulse interval (Thiels et al., 1994; Doyère et al., 1996; Thiels et al., 2002).

The molecular mechanisms responsible for the expression of NMDAR-dependent LTD have been extensively studied; induction is postsynaptic, and postsynaptic components of expression include dephosphorylation of GluR1 subunits and internalization of GluR2-containing AMPA receptors. Expression of mGluR-LTD appears to involve both presynaptic and postsynaptic components.

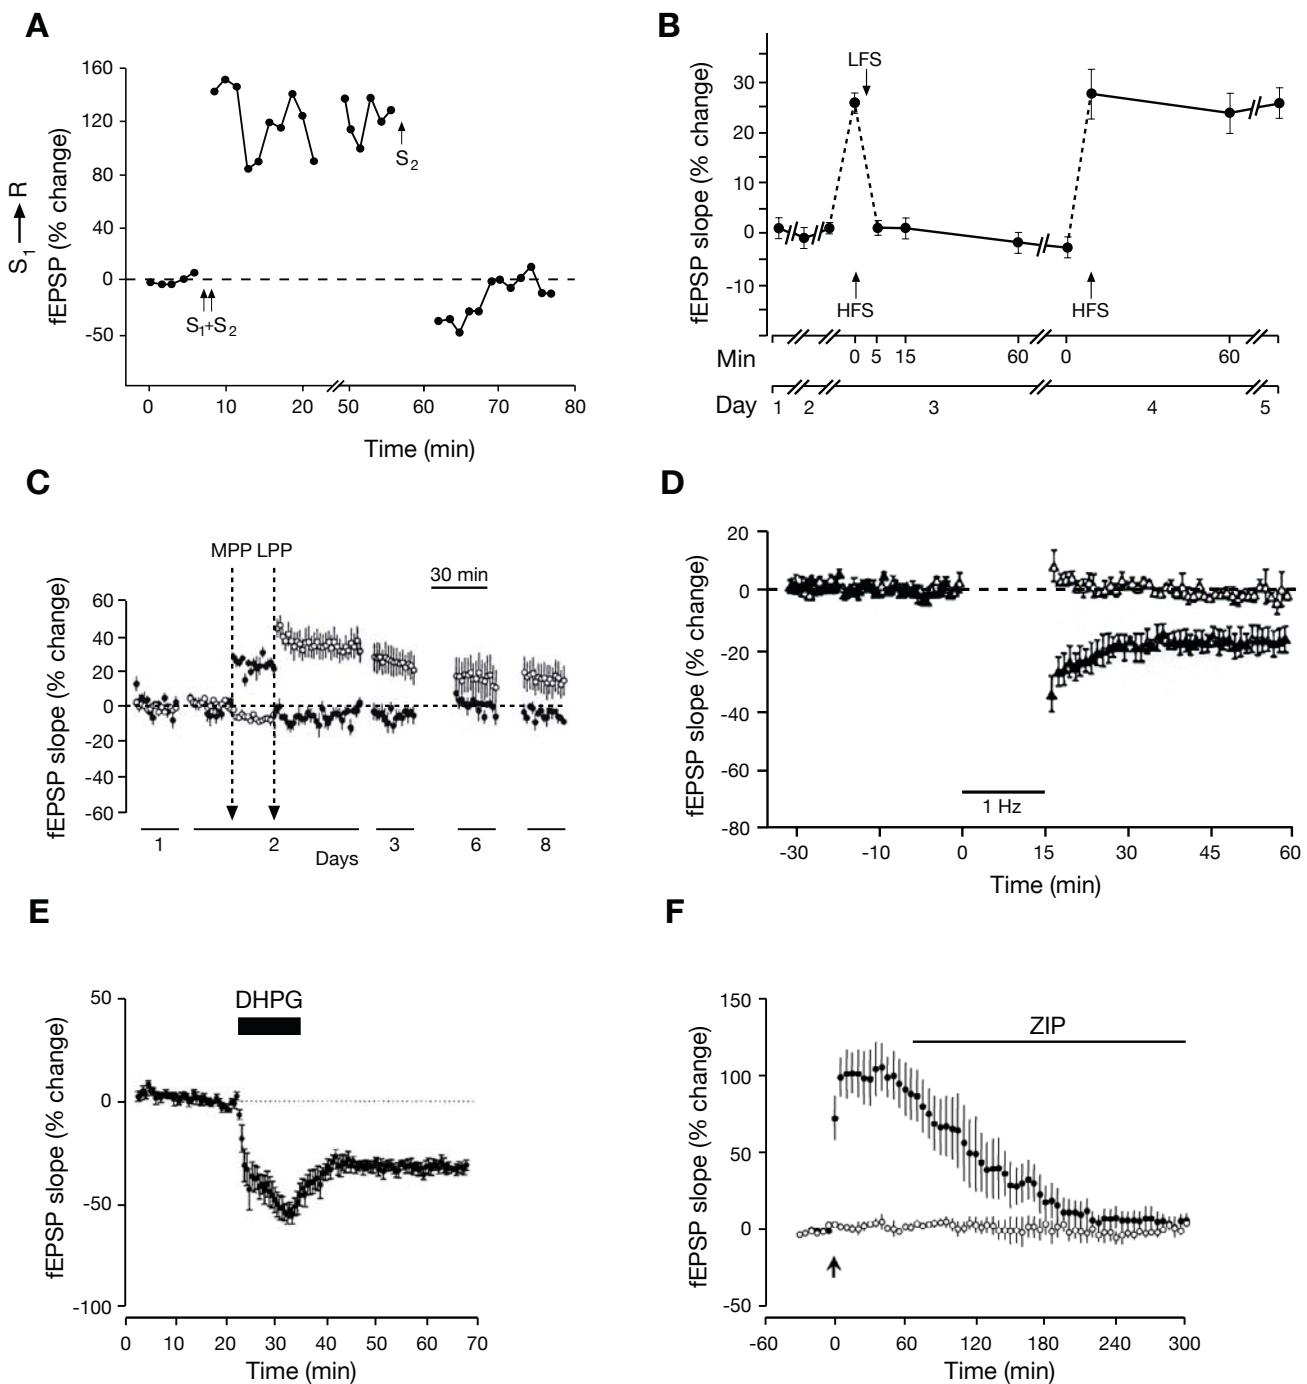

In this section, we deal first with homosynaptic forms of synaptic depression and then go on to examine heterosynaptic LTD and depotentiation. Different hippocampal subfields display substantial differences in the types of homosynaptic and heterosynaptic LTD and depotentiation they can sustain. Although the number of *in vivo* studies on LTD is growing, most of the experiments have been conducted on hippocampal slices from young animals in area CA1, and the text necessarily reflects this bias. Separate sections are devoted to LTD and depotentiation in the mossy fiber projection (see Section 10.7.8) and LTD at connections to and from interneurons (see Section 10.8). For a wide-ranging review of LTD and depotentiation see Kemp and Bashir (2001); mGluR-dependent LTD has been reviewed by Bashir (2003).

### **10.7.2 NMDAR-dependent LTD: Properties and Characteristics**

#### **In Vitro Studies**

The first report that LTD could be achieved with low-frequency stimulation (LFS) (e.g., 100 stimuli at 1 Hz) was published by Dunwiddie and Lynch (1978). However, it was not until several years later when Dudek and Bear (1992) (Fig. 10–17D) found that prolonged trains of LFS reliably produced LTD in young animals that experimental interest in LTD began to accelerate. LTD is routinely obtained with the Bear-Dudek protocol (typically 900 stimuli at 1 Hz) only when slices are prepared from juvenile rats (Dudek and Bear, 1993; O’Dell and Kandel, 1994; Wang and Alger, 1995). LTD induced with this protocol is long-lasting, input-specific, NMDAR-dependent, apparently saturable, and reversible by tetanic stimulation (“dedepression”) (Dudek and Bear, 1992).

Dudek and Bear went on to develop the notion of graded bidirectional synaptic modifiability (Dudek and Bear, 1993) (Fig. 10–19A). In this model, with appropriate high- or low-frequency stimulation, a synapse could be potentiated, depotentiated, depressed, or de-depressed, thus allowing its efficacy to be set anywhere within a range of approximately  $\pm 50\%$  of its base level. The difficulty often encountered of depotentiating a pathway once LTP has been stabilized in the adult animal implies that there are temporal constraints on bidirectionality. A proposed molecular basis for bidirectionality is discussed below. [An alternative hypothesis to graded bidirectional changes is that a modifiable synapse can switch only between three digital levels: resting, potentiated, and depressed. Electrophysiological evidence in favor of a binary all-or-none model of LTP at single synapses was presented by Petersen et al. (1998), but confirmatory studies have not been published.

**Figure 10-17.** Types of hippocampal long-term homosynaptic and heterosynaptic depression. *A*. Heterosynaptic depotentiation of crossed perforant path responses ( $S_1 \rightarrow R$ ) in the anesthetized rat. The graph plots the amplitude of fEPSPs evoked in the dentate gyrus of an anesthetized rat by test stimuli ( $S_1$ ) to the contralateral perforant path. LTP of the contralateral input is induced only by associative tetanization of both ipsilateral and contralateral inputs (double arrow,  $S_1 + S_2$ ). The potentiated contralateral response was then heterosynaptically depotentiated by a tetanus to the ipsilateral pathway ( $S_2$ ). A subsequent combined tetanus restored the potentiated response (not shown). (Source: Levy and Steward, 1979.) *B*. Persistent homosynaptic depotentiation in a freely moving rat. Low-frequency trains (1 Hz for 100 to 250 seconds) given 10 to 15 minutes after the induction of LTP in area CA1 caused a rapid return to baseline. A second tetanus delivered 24 hours later, when the response was still at baseline, led to the reinstatement of LTP.

(Source: Staubli and Lynch, 1990.) *C*. Heterosynaptic depotentiation of the medial perforant path in the freely moving rat after tetanic stimulation of the lateral perforant path. The response remains depotentiated over the following days. (Source: Doyère et al., 1997.) *D*. Prolonged low-frequency stimulation (1 Hz for 15 min) induces LTD in area CA1 in vitro. This is the protocol now most commonly used to induce LTD. It is most effective in young animals. (Source: Dudek and Bear, 1992.) *E*. LTD induced in area CA1 in vitro by bath application of the type 1 mGluR agonist DHPG. The perfusion fluid contained picrotoxin and AP5; hence, under these conditions the effect is NMDA receptor-independent. Synaptic responses were recorded using a grease gap technique (Source: Palmer et al., 1997). *F*. ZIP, a membrane permeable substrate inhibitor of PKM $\zeta$ , reverses LTP in area CA1 in vitro when applied 60 min after induction (filled circles) without affecting the nontetanized control pathway (open circles) (Source: Ling et al., 2002).

Optical studies of transmission at single visualized synapses probably offer the best approach to the issue.]

When LTP is saturated and then depotentiated by LFS, it can subsequently be reinstated from the depotentiated level by high-frequency stimulation. This experiment demonstrates that depotentiation is not simply a superposition of LTD on a continuing but now hidden LTP because if that were the case LTP would remain saturated and thus be incapable of enhancement. Rather, depotentiation is genuine erasure of LTP, returning the pathway to a state in which LTP can again be elicited (Dudek and Bear, 1992, 1993). However, LTD and depotentiation are not the same phenomenon (in the sense that they are generated by a common mechanism) because different phosphatases are involved in the two cases (Lee et al., 2000) (see Fig. 10–19B); and in cortex at least, induction is controlled by different NMDA receptor subunits (NR2B for LTD and NR2A for depotentiation) (Massey et al., 2004). Moreover, in knockout mice lacking the  $\alpha$  catalytic subunit of calcineurin, LTD can be elicited but depotentiation cannot (Zhuo et al., 1999). The limited time window for depotentiation following the induction of LTP also suggests that it is mechanistically different from LTD, which can be induced, in principle, at any time in naïve synapses.

### In Vivo Studies

In general, *in vivo* experiments confirm that it is considerably more difficult to obtain LTD and depotentiation in the intact adult rat than in younger animals. Nevertheless, both LTD and depotentiation can be induced with low-frequency trains in area CA1 of the intact animal, although modifications of the standard protocol are often necessary. There is also evidence that susceptibility to LTD is strain-specific, with Wistar and Sprague-Dawley rats showing a lower threshold for LTD than hooded Listers (Manahan-Vaughan, 2000). The standard 900 pulses/1Hz protocol has been successfully used by some (Heynen et al., 1996; Manahan-Vaughan, 1997), whereas others have found it necessary to use trains at higher frequencies (2–5 Hz) (Doyle et al., 1997) or paired-pulse trains consisting of pairs of stimuli at 0.5 Hz, with a 25-ms interpulse interval chosen to maximize paired-pulse depression (Thiels et al., 1994; Doyère et al., 1996). The incidence of LTD is greater in freely moving animals if they are subjected to mild stress (Xu et al., 1997). LTD has been particularly elusive in the dentate gyrus (Errington et al., 1995; Abraham et al., 1996) where in the freely moving rat it has been elicited only under conditions of stress or following perfusion with mGluR agonists (reviewed by Brauneckell and Manahan-Vaughan, 2001). It is, of course, possible that the optimal patterns of activity for inducing LTD in the dentate gyrus have yet to be identified. Depotentiation in the intact animal is discussed below.

How long is the “long” in long-term depression? Homosynaptic LTD can persist for days in chronically implanted animals (Doyère et al., 1996), and depotentiation has been

followed for more than 24 hours (Kulla et al., 1999). Heterosynaptic depression can also last for days (Abraham et al., 1994; Doyère et al., 1997) (Fig. 10–17C). A late, protein synthesis-dependent component of LTD has been described for NMDAR-dependent LTD in area CA1, induced by low-frequency stimulation both *in vivo* (Manahan-Vaughan et al., 2000) and in hippocampal slice cultures (Kauderer and Kandel, 2000). An early protein synthesis-dependent phase of mGluR-dependent LTD is seen in acute slices (Hüber et al., 2000). An experimentally useful equivalence has been established between LTD induced by the mGluR group 1 agonist DHPG and by a low-frequency paired-pulse protocol; these two stimulus protocols both produce long-lasting, protein synthesis-dependent forms of LTD that when saturated mutually occlude each other, strongly suggesting a shared mechanism (Hüber et al., 2001).

### 10.7.3 NMDAR-dependent LTD: Induction Mechanisms

Long-term depression is defined as NMDAR-dependent if it is blocked by D-AP5 or other NMDA antagonists. There is convincing evidence that the induction of NMDAR-dependent LTD requires a rise in postsynaptic  $\text{Ca}^{2+}$  and that the polarity of the change in synaptic efficacy is determined by the amplitude and time course of the  $\text{Ca}^{2+}$  transient. First, the induction of LTD can be prevented by dialyzing CA1 pyramidal cells with a  $\text{Ca}^{2+}$  chelator (Mulkey and Malenka, 1992). Second, lowering external  $\text{Ca}^{2+}$  transforms a protocol that normally induces LTP into one that produces LTD (Mulkey and Malenka, 1992). Third, Cummings et al. (1996) manipulated  $\text{Ca}^{2+}$  entry into the postsynaptic cell in a number of ways, including the application of low doses of AP5 to limit  $\text{Ca}^{2+}$  entry during the tetanus, which again converted LTP to LTD. These observations indicate that the level of the increase in intracellular  $\text{Ca}^{2+}$  is a critical parameter in determining the direction of change in synaptic strength. They provide support for an influential scheme proposed by Lisman (1989) that exploits the fact that certain protein phosphatases have a higher affinity for  $\text{Ca}^{2+}$  than most protein kinases. This suggests a potential mechanism whereby low elevations of  $\text{Ca}^{2+}$  activate protein phosphatases to yield LTD, whereas higher concentrations activate protein kinases to yield LTP. In Lisman’s scheme, activated protein kinases, in particular autophosphorylated  $\alpha$ CaMKII, enhance synaptic efficacy by phosphorylating receptor subunits, while this process is reversed by activation of phosphatases. Phosphorylation of AMPA receptors is known to increase AMPA receptor-mediated currents, which could account at least in part for the increase in synaptic efficacy in LTP (see Section 10.4). Phosphorylated CaMKII is a substrate for a protein phosphatase (PP1) but PP1 is not itself  $\text{Ca}^{2+}$ -sensitive. To account for LTD, Lisman therefore invoked a phosphatase cascade that begins with activation of the  $\text{Ca}^{2+}$ -sensitive protein phosphatase calcineurin (also known as protein phosphatase 2B, or PP2B). Activated calcineurin then dephosphorylates a phos-

phoprotein called inhibitor 1 (I1), which in its activated state inhibits PP1. Activation of calcineurin thus leads to the activation of PP1 by disinhibition, allowing CaMKII to be dephosphorylated. A critical feature of this scheme is that calcineurin has a higher sensitivity for  $\text{Ca}^{2+}$  than CaMKII, consistent with the hypothesis that small increases in intracellular  $\text{Ca}^{2+}$  lead to LTD and larger increases to LTP. Note also that the scheme provides for a feedback, or gating, mechanism in which the PKA/inhibitor 1 pathway counteracts the effects of the calcineurin pathway when  $\text{Ca}^{2+}$  levels rise to levels that lead to autophosphorylation of CaMKII and LTP (Lisman, 1989; Blitzer et al., 1998).

As is the case for LTP, there is evidence that specific NMDAR subtypes are involved in LTD. A requirement for the NR2B-containing NMDARs was suggested by a knockout of this subunit (Kutsuwada et al., 1996). These animals lacked LTD but had major developmental problems and died young. Several groups have subsequently used NR2B subtype-specific NMDAR antagonists, such as ifenprodil and its more selective derivatives Ro-25-6981 and CP-101,606, to investigate the role of this subunit more directly, but no clear picture has yet emerged. Thus, at one extreme LTD is reported to be enhanced by NR2B inhibitors (Hendricson et al., 2002) and at the other blocked by these compounds (Liu et al., 2004a). Other pharmacological evidence has instead provided evidence for a role of NR2C and/or NR2D receptors in LTD (Hrabetova et al., 2000). There is also evidence that NR2D receptors can mediate a very slow component of the synaptic response at hippocampal synapses (Lozovaya et al., 2004). The very slow kinetics of this channel coupled with its low sensitivity to  $\text{Mg}^{2+}$  means that the NR2D component of the NMDAR-mediated EPSC will summate effectively at the low frequencies of stimulation that are typically used to induce LTD. Presumably, the relative roles of the different NR2 subunits in LTD is determined by a variety of factors. Interestingly, in this context, Pro-BDNF has been shown to facilitate LTD via activation of p75 leading to up-regulation of NR2B receptors (Woo et al., 2005).

Support for the Lisman hypothesis has come from experiments by Malenka and colleagues, who found that LTD was blocked by injecting specific inhibitors of PP1 and calcineurin into CA1 neurons (Mulkey et al., 1993, 1994). On the other hand, a study of transgenic mice expressing an inducible calcineurin inhibitor failed to confirm the importance of calcineurin for LTD; although LTP was enhanced, LTD was not affected (Malleret et al., 2001), suggesting either that the inhibitors were acting on another phosphatase or that another high-affinity phosphatase can take over the role normally played by calcineurin. Overall, there is good evidence that the amplitude and kinetics of the synaptically evoked  $\text{Ca}^{2+}$  transient is critical for setting the sign of synaptic change. As predicted by the model, lower  $\text{Ca}^{2+}$  charge transfer through the NMDA receptor channel is associated with LTD and higher transfer with LTP (Cho et al., 2001; Wu et al., 2001).

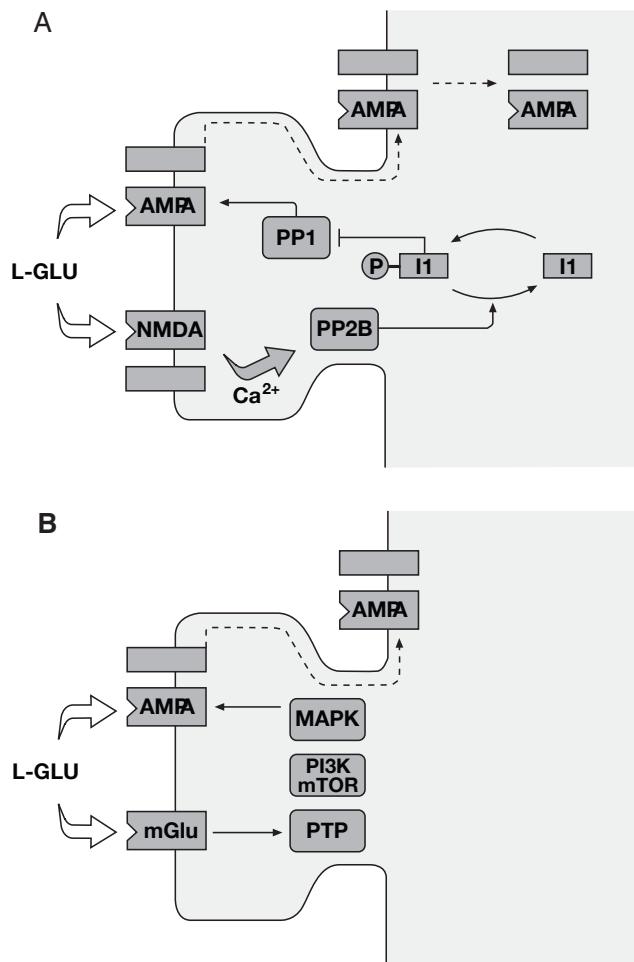

Depolarizing pulses delivered to the postsynaptic cell to draw  $\text{Ca}^{2+}$  into the cell via L-type  $\text{Ca}^{2+}$  channels is itself suffi-

cient to induce persistent LTD (Cummings et al., 1996). This approach was taken further by Yang et al. (1999), who used graduated photolysis of a caged  $\text{Ca}^{2+}$  compound, DM-EGTA, to control the level and rate of rise of cytosolic calcium. These studies made the important point that the rate of rise and the magnitude of the  $\text{Ca}^{2+}$  transient are jointly involved in determining the polarity of the change in synaptic efficacy. Large, rapid rises in  $\text{Ca}^{2+}$  invariably produced persistent potentiation, whereas small, prolonged increases always induced persistent depression. In both cases calcium-induced plasticity occluded activity-induced LTP or LTD, suggesting a convergence of cellular mechanisms. The importance of the prolonged duration of the  $\text{Ca}^{2+}$  transient for the induction of LTD in area CA1 has been further underlined in experiments by Mizuno et al. (2001); pharmacological manipulations were used to control the magnitude of the  $\text{Ca}^{2+}$  transient produced by 1 Hz stimulation, but under no circumstances were trains of less than 200 stimuli successful in inducing LTD. A model of the probable signaling cascades involved in NMDAR-dependent LTD is shown in Figure 10–18A.

### Spike Timing-dependent Induction of LTD

As we saw in Section 10.3, when plasticity is induced by conjoint presynaptic stimulation and a back-propagating spike in the postsynaptic neuron, it is the interval between the onset of the two events that determines the sign of the persistent change. In hippocampal slices, potentiation results when the EPSP precedes the back-propagating action potential (AP) in CA1 pyramidal neurons by 0 to 10 ms (Magee and Johnston, 1997). This result was confirmed in experiments on pairs of connected hippocampal neurons in organotypic culture (Debanne et al., 1998) (Fig. 10–19C) or in dissociated culture (Bi and Poo, 1998) (Fig. 10–19D). Moreover, LTD was induced if the order was reversed, with the back-propagating AP preceding the EPSP, extending to the hippocampus a pattern first established in neocortical neurons (Markram et al., 1997). The pattern of excitation and inhibition is more complex in hippocampal slices (Nishiyama et al., 2000). Potentiation results when the onset of the EPSP and back-propagating AP occur within 10 ms of each other, irrespective of order. Symmetrically placed on either side of the window of potentiation are two 20-ms intervals, between –10 and –30 ms (AP preceding EPSP) and 10 and 30 ms (EPSP preceding AP), within which paired activity results in homosynaptic LTD. The latter is probably explained by the recruitment of feedforward inhibition (Bi and Rubin, 2005). Furthermore, in contrast to the usual absence of heterosynaptic depression in area CA1 following tetanus-induced LTP, heterosynaptic depression occupied the same intervals and displayed the same magnitude as homosynaptic depression; notably absent, however, was any indication of heterosynaptic LTP.

Spike timing-dependent LTD is also NMDAR-dependent, but it is far from clear how it relates to conventional LTD induced by prolonged low-frequency stimulation (Lisman and Spruston, 2005). The rules of induction are very different,

**Figure 10-18.** Mechanisms involved in the induction of LTD. A. NMDA receptor-dependent LTD. The entry of  $\text{Ca}^{2+}$  via NMDA receptors leads to activation of calcineurin (PP2B). This inhibits inhibitor-1 (I1), which in turn results in activation of protein phosphatase 1 (PP1). This leads to the internalization of AMPARs, probably after they have moved laterally away from the synapse. B. mGluR-dependent LTD. Activation of mGlu receptors, in particular mGlu5, also leads to removal of AMPARs from synapses. Here the signaling mechanisms involve protein tyrosine phosphatases (PTPs), mTOR, PI3K and MAPKs. How these enzymes interact is not known. See text for further details.

and it is possible that their expression mechanisms are different too. Do they occlude? Is spike timing-dependent LTD blocked by the same subtype selective NMDA receptor antagonists as conventional LTD? What is the age dependence of spike timing-dependent LTD? What are the relative roles of conventional LTD and spike timing-dependent LTD in the behaving animal? These are questions for future research.

#### 10.7.4 NMDAR-dependent LTD: Expression Mechanisms

In their characterization of two forms of LTD referred to above, Oliet et al. (1997) concluded that NMDAR-dependent

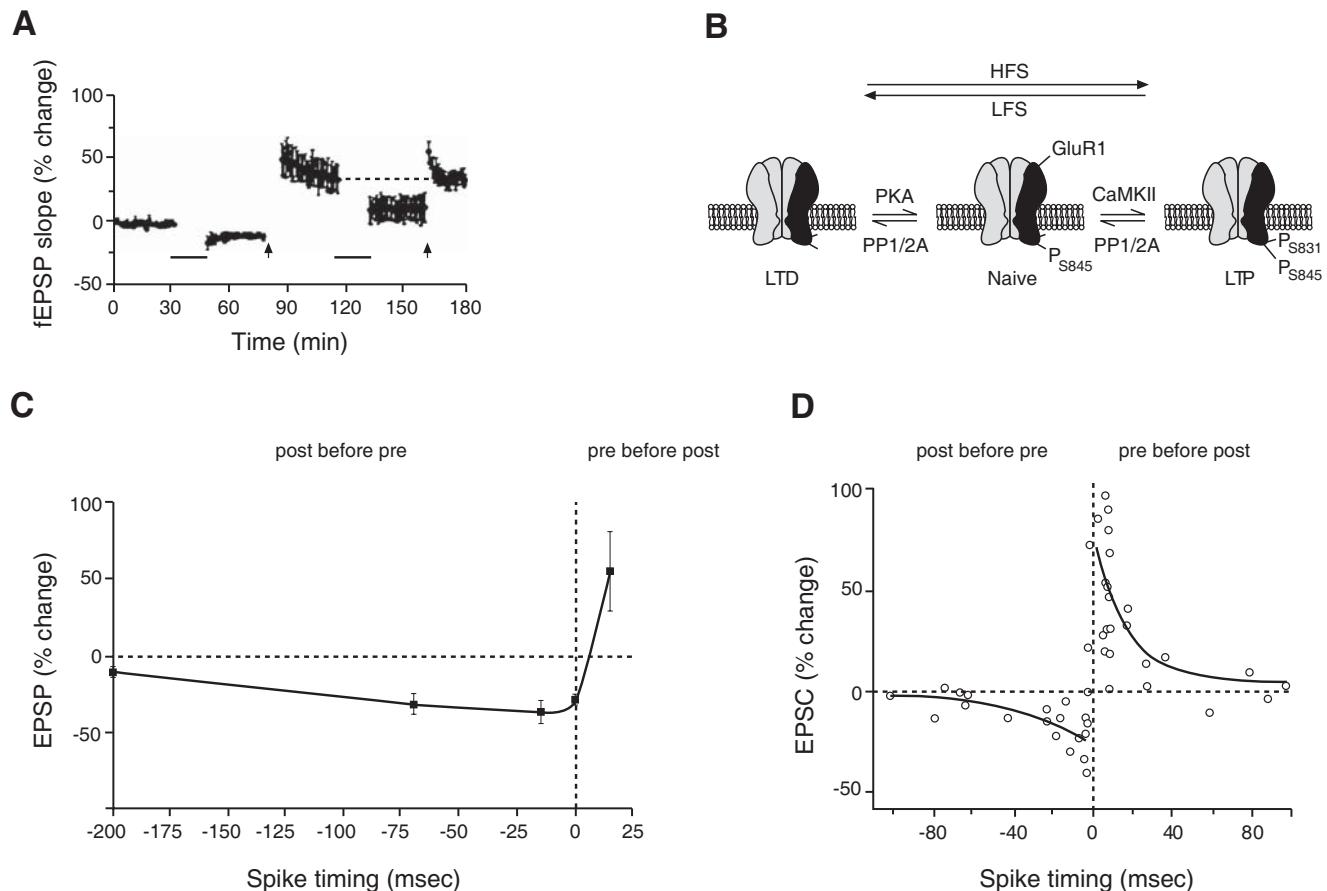

LTD, which was accompanied by a decrease in quantal size, is probably mediated by a postsynaptic mechanism; mGluR-dependent LTD, in contrast, is more likely to be presynaptically expressed (see below). Subsequently, dephosphorylation of AMPA receptor subunits and internalization of both AMPA and NMDA receptors have emerged as mechanisms contributing to the early expression of NMDAR-dependent LTD. There is also evidence for a presynaptic component of expression.

#### Presynaptic Expression Mechanisms

NMDAR-mediated and AMPAR-mediated currents are equally downregulated in LTD (Xiao et al., 1995), a finding that is compatible with a reduction in transmitter release or with internalization of both receptor types. The evidence for downregulation of AMPA receptors is strong and, together with other evidence for postsynaptic changes discussed above, makes an overwhelming case for a postsynaptic contribution to NMDAR-dependent LTP. However, this does not exclude a presynaptic contribution. Evidence for presynaptic involvement in the expression of NMDAR-dependent LTD has emerged from imaging studies of vesicular turnover using the fluorescent styryl dye FM1-43 (Stanton et al., 2001, 2003). The rate of release from a rapidly releasing pool of vesicles was significantly less after the induction of LTD than it was before induction. The effect was NMDAR-dependent and required NO release and activation of presynaptic cGMP, raising the possibility that NO is acting as a retrograde messenger (see Section 10.4.7).

#### Postsynaptic Expression Mechanisms

A unitary mechanism for bidirectional changes in synaptic efficacy has obvious attractions (Dudek and Bear, 1993). However, an illuminating study on the phosphorylation of GluR1 residues in LTP and LTD, although confirming the view that depotentiation is a reversal of LTP, suggests that LTP and LTD involve phosphorylation and dephosphorylation at different residues on GluR1 (Lee et al., 2000). In this scheme (Fig. 10-19B), AMPA receptors in the baseline state are phosphorylated at serine residue 845. High-frequency stimulation leads to activation of CaMKII and phosphorylation of ser831, a state associated with increased single-channel conductance of the receptor (Derkach et al., 1999). Depotentiation by low-frequency stimulation reverses this process by activation of protein phosphatases PP1 and PP2A. Low-frequency stimulation in the naïve slice activates the same okadaic acid-sensitive protein phosphatases, but in this condition it is ser845 that is dephosphorylated, leading to a subunit that is phosphorylated at neither serine residue. High-frequency stimulation in this state activates PKA to rephosphorylate the receptor on ser845 and restore it to its baseline state. Continued high-frequency stimulation would then progress to activation of  $\alpha$ CaMKII via phosphorylation of S831 and hence to LTP. Note that this scheme cannot explain the relative immunity to depotentia-

**Figure 10-19.** Bidirectional plasticity. *A*, Bidirectional plasticity in area CA1 in vivo. LTD induced by low-frequency stimulation (LFS) (1 Hz for 15 minutes) (bar) followed by induction of LTP by high-frequency stimulation (HFS) (100 Hz for 1 second) (arrow), partial depotentiation by LFS, and repotentiation by HFS. (*Source*: Heynen et al., 1996.) *B*, Model of changes in the phosphorylation state of the GluR1 subunit of the AMPA receptor that underlie NMDA receptor-dependent early LTP, depotentiation, early LTD and dedepression. In the naïve state, the receptor is phosphorylated at serine 845 (S845). Early-LTP is expressed via  $\alpha$ -CaMKII-mediated phosphorylation of serine 831. Depotentiation involves the dephosphorylation of S831 via protein phosphatases PP1 and/or PP2A. Early LTD involves dephosphorylation of S845, again by PP1/PP2A, and dedepression after LTD brings the receptor back to the naïve

state via PKA-mediated phosphorylation of serine 845. (*Source*: Lee et al., 2000.) *C, D*, Two examples of bidirectional spike timing-dependent synaptic plasticity (STDP). *C*, STDP elicited by activating pairs of interconnected CA3 cells in organotypic cultures. LTD was induced if an action potential in the presynaptic cell was repeatedly evoked 15 ms before an action potential in the postsynaptic cell; at zero delay or when the postsynaptic spike preceded the presynaptic spike by 15 to 70 ms, LTP was induced. (*Source*: After Debanne et al., 1998.) *D*, STDP in pairs of interconnected pyramidal cells in dissociated hippocampal cultures. Again, LTP is induced if the presynaptic cell fires shortly before the postsynaptic cell, and LTD ensues if the timing is reversed. Each circle represents a single pairing experiment. (*Source*: Bi and Poo, 1998.)

tion once LTP has become stabilized, perhaps by protein synthesis-dependent mechanisms. Subsequent studies have shown that results from the intact animal are compatible with the model. Similar post-translational changes in GluR1 phosphorylation levels on ser845 occur in visual cortex following monocular deprivation (Bear, 2003) and transgenic animals with point mutations on serine residues 831 and 845 (rendering them nonphosphorylatable) exhibit impaired spatial memory, deficits in LTP, and complete suppression of NMDAR-dependent LTD (Lee et al., 2000). The latter result must be reconciled with the evidence for a protein synthesis-dependent component of this form of LTD, discussed below (Kauderer and Kandel, 2000).

A number of techniques have been used to demonstrate downregulation of both AMPA and NMDA receptors in NMDAR-dependent LTD. They include photolytic uncaging of caged glutamate (Kandler et al., 1998; Rammes et al., 2003), iontophoresis of NMDA (Montgomery and Madison, 2002), and immunocytochemical estimates of both AMPA and NMDA populations in tissue from animals in which LTD was induced in vivo (Heynen et al., 2000). The use of antibodies that recognize extracellular epitopes of AMPA receptors on living neurons (Collingridge et al., 2004) has allowed direct demonstration of AMPA receptor internalization during LTD in cultured hippocampal neurons (Beattie et al., 2000). Subsequent studies using pHluorin-GluR2 have suggested that

internalization occurs at extrasynaptic sites and that this precedes removal of AMPA receptors from the synapse (Ashby et al., 2004). The simplest model therefore is one in which endocytosis at an extrasynaptic site is followed by lateral diffusion of AMPA receptors from synaptic to extrasynaptic locations.

Many of the proteins that control the cycling of GluR2 between cytoplasm and synaptic membrane have been identified, and details of their modes of action are beginning to emerge (Collingridge et al., 2004). The concept of subunit-dependent regulation of synaptic plasticity arose from the finding that NSF binds selectively to the GluR2 subunit of AMPA receptors (Nishimune et al., 1998; Osten et al., 1998; Song et al., 1998). Of note were the observations that blockade of the GluR2 interaction with NSF leads to a run-down in AMPAR-mediated synaptic transmission (Nishimune et al., 1998; Song et al., 1998), a reduction in the surface expression of AMPA receptors (Lüscher et al., 1999; Noel et al.; 1999), and occlusion with NMDAR-dependent LTD (Lüscher et al., 1999; Lüthi et al., 1999). It was subsequently discovered that AP2 binds to a region of GluR2 that overlaps with the NSF site (Lee et al., 2002). Selective block of the GluR2 interaction with NSF caused a run-down in synaptic transmission, and selective block of the GluR2 interaction with AP2 resulted in suppression LTD. This suggests a mechanism whereby NSF is normally bound to GluR2 subunits to stabilize AMPA receptors at the synapse. However, in response to an LTD-inducing stimulus, AP2 exchanges with NSF, and this initiates clathrin-dependent endocytosis (Collingridge et al., 2004). This scheme requires a mechanism to initiate the exchange of NSF for AP2. One possibility is that  $\text{Ca}^{2+}$  entry during the induction of LTD interacts with the neuronal  $\text{Ca}^{2+}$  sensor hippocalcin (Burgoyne, 2004). On binding  $\text{Ca}^{2+}$ , hippocalcin undergoes a conformational change to expose a myristoylated region that can target the molecule to the plasma membrane. It also binds both AP2 and GluR2 subunits in a  $\text{Ca}^{2+}$ -dependent manner (Palmer et al., 2005). Thus, hippocalcin is well placed to actively promote the exchange of NSF for AP2. Consistent with this idea, a dominant negative form of hippocalcin blocks induction of NMDAR-dependent LTD (Palmer et al., 2005). Thus, hippocalcin is a strong contender for the role of  $\text{Ca}^{2+}$  sensor in LTD. It is likely, however, that other  $\text{Ca}^{2+}$ -sensing proteins are also involved in the induction of LTD, and the full mechanistic details have yet to be elucidated.

Scaffolding proteins such as GRIP/ABP (Dong et al., 1997; Srivastava and Ziff, 1999) and the PKC-targeting protein PICK (Dev et al., 1999; Xia et al., 1999) also bind to the C terminal tail of the GluR2 subunit, where they may tether AMPA receptors at the plasma membrane or at intracellular sites. There is evidence that PICK1 is directly involved in LTD (Kim et al., 2001). The proposal is that GRIP/ABP normally anchors AMPA receptors at the synapse. However, LTD leads to activation of PICK1, which phosphorylates GluR2 subunits, causing them to dissociate from GRIP/ABP so they can be removed from the synapse. Indeed, it has been shown that PICK1 binds  $\text{Ca}^{2+}$ , facilitating its interaction with AMPA receptors (Hanley

and Henley, 2005). Furthermore, a  $\text{Ca}^{2+}$ -insensitive PICK1 mutant blocks NMDA-induced internalization of AMPA receptors, implicating this interaction in LTD. However, another idea is that GRIP/ABP binds the GluR2 subunit to maintain a store of AMPA receptors intracellularly (Daw et al., 2000). In this scheme, when PICK1 phosphorylates GluR2 it untethers AMPA receptors and so provides a pool near the synapse, ready for membrane insertion. It is possible that these diametrically opposed roles of PICK1, via its interaction with GRIP/ABP, can both operate under different conditions. Considerable work still needs to be done to understand the relation between the various proteins involved in AMPA receptor trafficking and LTD.

Although the role of the GluR2 subunit in LTD is well established, it is not the only mechanism that supports NMDAR-dependent LTD in the hippocampus. This is shown by studies using knockouts, where NMDAR-dependent LTD has been observed in both the GluR2 knockout and the GluR2/GluR3 double knockout (Jia et al., 1996; Meng et al., 2003). Moreover, as we have seen, the dephosphorylation of ser845 of GluR1 can also result in LTD (Kameyama et al., 1998), suggesting that there are multiple mechanisms for the induction of LTD. Further studies are required to understand the relative contributions of these various mechanisms to LTD in wild-type animals *in vivo*.

### A Protein Synthesis-dependent Phase of NMDAR-dependent LTD

Three investigations published in 2000 established that NMDAR-dependent LTD can sustain a late, protein-dependent phase. Different preparations were used in each of these studies: organotypic cultures (Kauderer and Kandel, 2000), acute slices (Hüber et al., 2000), and freely moving rats (Manahan-Vaughan et al., 2000). In all three preparations, late LTD lasting several hours could be induced by prolonged low-frequency stimulation, and in each case it was blocked by protein synthesis inhibitors. However, only in organotypic culture was late LTD blocked by transcriptional inhibitors. Local protein synthesis may therefore provide the message captured by the tags set by LTD-inducing stimulation (Kauderer and Kandel, 2000; Sajikumar and Frey, 2004b) (see Section 10.4.9).

### 10.7.5 mGluR-dependent LTD

#### mGluR-dependent LTD Induced by Synaptic Activity

Homosynaptic LTD using low-frequency stimulation is blocked by NMDA receptor antagonists (Dudek and Bear, 1992; Mulkey and Malenka, 1992). Before long, however, it was shown that certain forms of LTD and depotentiation were prevented by mGluR antagonists rather than by NMDA antagonists (Bashir et al., 1993; Bashir and Collingridge, 1994; Bolshakov and Siegelbaum, 1994; Yang et al., 1994), thereby

demonstrating two mechanistically distinct forms of synaptic depression. Both types were pathway-specific. The mechanistically distinct nature of these two forms of LTD was confirmed by the lack of occlusion between the two (Oliet et al., 1997; Palmer et al., 1997). Oliet et al. (1997) also observed a decrease in the quantal size of miniature EPSCs without a change in miniature frequency in NMDAR-dependent LTD, suggesting a postsynaptic expression mechanism. In contrast, in mGluR-LTD there was a reduction in miniature frequency, with no change in quantal size, suggesting a presynaptic expression mechanism. Finally, induction of mGluR-dependent LTD did not erase LTP, as was the case with depotentiation produced by the stimulus protocol that produced NMDAR-dependent LTD but, rather, was superimposed on LTP. These experiments confirmed the existence of two distinct types of LTD at Schaffer-commissural–CA1 pyramidal synapses with distinct induction and expression mechanisms.

Low-frequency trains to Schaffer-commissural fibers in slices from neonatal rats induce a form of mGluR-dependent LTD that is blocked by postsynaptic injection of calcium chelators but is, at least in part, expressed as an increase in transmitter release (Bolshakov and Siegelbaum, 1994)—a combination that immediately suggests the need for a retrograde messenger (see Section 10.4.7). Strong, if incomplete, evidence that a lipoxygenase metabolite of arachidonic acid, 12(S)HPETE, may be the retrograde messenger in this case has been presented by Feinmark et al. (2003).

A study by Kemp et al. (2000) illustrates the complexity of LTD induction mechanisms. The effects of two protocols in area CA1 were compared: trains of single stimuli at 1 Hz and trains of paired pulses also at 1 Hz. In slices from young animals, LTD produced by either protocol was blocked by AP5. Adult animals showed a shift toward mGluR-dependent LTD and in general required longer trains, but it remained possible, by varying the stimulus parameters, to obtain either mGluR-dependent or NMDAR-dependent LTD. Again, the two forms of LTD did not occlude, indicating the independence of the associated expression mechanisms. The mechanisms behind the age- and activity-related shift from NMDAR-mediated to mGluR-mediated LTD are unknown but may reflect the developmental regulation of receptor subtypes. Whatever the reasons, these observations make it clear that the precise details of activity-induced changes in synaptic efficacy depend on the fine temporal structure of the patterns of neural activity itself.

Although the paired-pulse protocol introduced by Kemp et al. (2000) (900 pairs at 1 Hz with an interpulse interval of 50 msec) generates mGluR-dependent LTD in area CA1 *in vitro* (see also Hüber et al., 2000), it has not been shown to be effective *in vivo*. The subtly different paired-pulse protocol formulated by Thiels et al. (1994), in which the interpulse interval is set at 25 ms to maximize inhibitory feedback, produces a depression that is NMDAR-dependent rather than mGluR-dependent (Thiels et al., 2002). Furthermore, although group I mGluR antagonists are generally more effective at blocking mGluR-dependent LTD in area CA1 *in vitro*, group II antago-

nists depress the late component of LTD *in vivo* (Manahan-Vaughan, 1997).

### **mGluR-dependent LTD Induced by Exposure to mGluR Agonists**

Brief exposure to the group I mGluR agonist dihydroxyphenylglycine (DHPG) induces a reassuringly robust LTD in adult slice preparations in both area CA1 (Palmer et al., 1997) (Fig 10.17E) and the dentate gyrus (Camodeca et al., 1999). This form of LTD, probably mediated by mGluR5 receptors, is blocked by group I or broad-spectrum mGluR antagonists but not by NMDA receptor antagonists. Experiments to probe the induction site of mGluR-LTD point toward a postsynaptic locus of induction. Intracellular injection of a G protein inhibitor into CA1 pyramidal cells suppressed the ability of DHPG to induce LTD (Watabe et al., 2002). Intracellular injection of BAPTA, on the other hand, had no such effect (Fitzjohn et al., 2001b), suggesting a  $\text{Ca}^{2+}$ -insensitive induction process. The experiments of Hüber et al. (2000) led to the conclusion that mGluR-LTP depends on rapid activation of local postsynaptic protein synthesis. In the presence of the protein synthesis inhibitor anisomycin, the depression induced by DHPG quickly attenuates, and responses recover to baseline within 60 minutes (Hüber et al., 2000). LTD induced by mGluR agonists thus quickly becomes dependent on protein synthesis. Consistent with the rapid action of anisomycin, mGluR-induced LTD survived in an isolated *in vitro* preparation, from which both pre- and postsynaptic cell bodies had been removed by appropriate scalpel cuts. This result implies that local protein synthesis at synaptic sites is required early in the expression of mGluR-induced LTD. Given that protein synthetic machinery has not been described at presynaptic boutons, it seems safe to conclude that the induction of this early form of protein synthesis-dependent LTD is located in dendrites. Synaptically driven mGluR-dependent LTD induced by low-frequency trains of paired pulses was also blocked by anisomycin (Hüber et al., 2000).

There is less agreement concerning the locus of expression of this form of LTD. On the one hand there is evidence that it is presynaptically mediated because (1) there is no postsynaptic change in response to flash photolysis of caged glutamate (Rammes et al., 2003), (2) NMDA and AMPA receptor components of synaptic responses are equally depressed (Watabe et al., 2002), (3) paired-pulse facilitation is increased (Fitzjohn et al., 2001), and (4) DHPG produces a persistent decrease in the frequency of miniature EPSCs with no change in amplitude in tetrodotoxin-treated cultured hippocampal neurons (Fitzjohn et al., 2001b). However, there is also evidence that DHPG-induced LTD involves removal of both AMPA and NMDA receptors from synapses (Snyder et al., 2001). These disparate observations may be reconciled by the finding that mGluR-dependent LTD, induced by DHPG, is blocked by postsynaptically applied inhibitors of protein tyrosine phosphatases (PTPs) and of the actin cytoskeleton (Moult et al.,

2006). These postsynaptic manipulations blocked the changes in paired-pulse facilitation and miniature frequency, suggesting a retrograde signaling process that is dependent on PTPs and the actin cytoskeleton. An alternative explanation is that AMPA receptors are removed to create silent synapses. If this occurs preferentially at high-Pr synapses owing to the requirement for activity to drive the movement, the changes in paired-pulse facilitation would simply reflect this postsynaptic alteration (see Box 10–1). The lack of change in the response to uncaged glutamate, which act on both spines and dendrites, can be reconciled with a postsynaptic model if, instead of being internalized, AMPA receptors diffuse laterally to extrasynaptic sites (Moult et al., 2006).

#### **Signaling Pathways in mGluR-dependent LTD**

DHPG-induced LTD has been widely used as a model to explore the signalling mechanisms involved in mGluR-dependent LTD. By definition, mGluRs are coupled to G-proteins, and as expected DHPG-induced LTD requires activation of G-proteins (Watabe et al., 2002; Huang CC et al., 2004). Since group I mGluRs are positively linked to PLC, and thereby the generation of diacylglycerol and IP<sub>3</sub>, it might have been anticipated that inhibitors of PKC and/or release of Ca<sup>2+</sup> from stores would block mGluR-dependent LTD. However, a variety of potent PKC inhibitors and blockers of Ca<sup>2+</sup> stores, applied alone or in combination, failed to affect DHPG-induced LTD (Camodeca et al., 1999; Schnabel et al., 2001). Furthermore, DHPG-induced LTD is insensitive to inhibitors of PKA (Camodeca et al., 1999; Schnabel et al., 2001), while inhibitors of CaMKII cause a modest enhancement of the effect (Schnabel et al., 1999). It has been suggested that DHPG-induced LTD is blocked by PTK inhibitors in the dentate gyrus (Camodeca et al., 1999) but this finding was not replicated in area CA1 (Moult et al., 2002), suggesting the possibility of regional differences. Whilst there is general agreement for a role of MAPK cascades, there is some contention as to whether the mechanism involves the Ras-activated ERKs (Gallagher et al., 2004) or the Rap-activated p38 MAPK (Rush et al., 2002; Huang CC et al., 2004). Finally, so far as kinases are concerned, there is evidence for a role of the PI3K-Akt-mTOR signalling pathway in DHPG-induced LTD (Hou and Klann, 2004). With respect to phosphatases, inhibitors of the ser/thr phosphatases that are involved in NMDAR-dependent LTD (PP1/PP2A and PP2B) do not inhibit DHPG-induced LTD; rather, PP1/PP2A inhibitors cause a small facilitation of the effect (Schnabel et al., 2001). However, inhibitors of tyrosine phosphatases completely eliminate DHPG-induced LTD (Moult et al., 2002; Huang CC and Hsu, 2006), a result that identifies a major signalling pathway for this robust form of LTD.

Less is known about the signalling pathways involved in synaptically-induced mGluR-dependent LTD. The report that the DHPG-induced and synaptically-induced forms mutually occlude each other suggests a common underlying pathway

(Hüber et al., 2001), and, as we have seen, both are blocked by protein synthesis inhibitors (Hüber et al., 2000). However, unlike DHPG-induced LTD, synaptically-induced mGluR-dependent LTD appears also to be sensitive to PKC inhibitors (Oliet et al., 1997). Whether this reflects a heterogeneity in the synaptic forms is unknown.

How the various signalling components that have been identified in mGluR-dependent LTD (e.g., PI3K-Akt-mTOR, MAPKs, PTPs) interrelate is not known. What is clear, however, is that the signalling mechanisms involved in mGluR-induced LTD are very different from those involved in NMDAR-dependent LTD (see schemas in Fig. 10–18A and B).

#### **10.7.6 Homosynaptic Depotentiation**

Long-term potentiation *in vitro* can be reversed by low-frequency stimulation when it is given within a few minutes of the tetanus used to induce LTP (Barrioñuevo et al., 1980; Staubli and Lynch, 1990; Fujii et al., 1991), a process sometimes referred to as destabilization of LTP. Destabilization is a specific example of the more general phenomenon of depotentiation, which refers to the reversal of LTP at any post-tetanus interval. Whereas destabilization is a robust phenomenon observed in all hippocampal pathways and at all ages, depotentiation at longer intervals after induction is less easily induced in adult animals.

In all hippocampal subfields and in both adult and juvenile animals, LTP can be depotentiated by a prolonged low-frequency train (e.g., 900 stimuli at 1 Hz) beginning immediately after induction. The time window for induction and the input specificity of depotentiation have been documented. The efficiency of the depotentiating train quickly declines after the LTP-inducing event; and many, though not all, *in vitro* studies suggest that depotentiation can be induced only if low-frequency stimulation is applied within minutes of LTP induction. A similar time window is seen in the dentate gyrus of the intact animal (Martin, 1998; Kulla et al., 1999; Straube and Frey, 2003). In area CA1 of the awake animal, however, Doyle et al. (1997), using 900 stimuli at 5 to 10 Hz, succeeded in depotentiating LTP at a range of intervals from 10 minutes to 24 hours after induction in area CA1. Lower stimulus frequencies were ineffective, and Doyle et al. were unable to induce LTD at any frequency. Another question is how long depotentiation lasts. In the dentate gyrus of the unanesthetized rat, depotentiation has been reported to persist for 24 hours (Kulla et al., 1999). This raises the question of the stability of the depotentiated response: Do depotentiated synapses, like their potentiated counterparts, retain the potential for reversed plasticity only during a limited time window after induction? In other words, is de-depression, like depotentiation, time-limited? The essence of “bidirectional plasticity” is that synaptic efficacy can be reset up and down at will, but this may be the case only within specific time windows. There is some evidence to suggest that, at least in area CA1, depotentiation appears to be input-specific (Bortolotto et al.,

1994; Huang CC et al., 2001; but see Muller et al., 1995). However, in the dentate gyrus *in vivo* and at mossy fiber synapses, heterosynaptic effects become apparent (see below).

According to the model of early LTP and LTD expression proposed by Lee et al. (2000), potentiation occurs as a result of the phosphorylation of S831 on GluR1, leading to an increase in channel conductance (Derkach et al., 1999). Depotentiation results when this residue is dephosphorylated (Lee et al., 2000; Huang CC et al., 2001). Consistent with this idea, it has been shown that depotentiation can be, but is not invariably, accompanied by a decrease in single-channel conductance (Lüthi et al., 2004). Indeed, there is a precise relation between the type of LTP and depotentiation observed; when LTP is the result of an increase in single-channel conductance, the increase is reversed in depotentiation. However, in cases where there is no change in single-channel conductance during LTP, neither is there any change in this parameter during depotentiation. With the latter form of bidirectional plasticity, the most likely explanation is changes in the number of AMPA receptors expressed at synapses. Both the protein kinase (CaMKII) and protein phosphatases (PP1/2A) involved in these processes are calcium-dependent; and, adapting the Lisman hypothesis, strong, rapid increases should favor phosphorylation and potentiation, whereas prolonged, modest increases in calcium should favor dephosphorylation and depotentiation (Yang et al., 1999; Mizuno et al., 2001). There is disagreement about the pharmacology of depotentiation. Some authors have reported that AP5 blocks depotentiation in area CA1 *in vitro* (Fujii et al., 1991; Selig et al., 1995b; Huang CC et al., 2001; Lüthi et al., 2004), whereas others have found it is blocked by Gp 1/II mGluR antagonists, and not by NMDAR antagonists, in both area CA1 in acute slices (Bashir and Collingridge, 1994; Fitzjohn et al., 1998) and between pairs of CA3 pyramidal cells in organotypic hippocampal cultures (Montgomery and Madison, 2002). As with LTD, the data suggest that two forms of depotentiation exist: one depending on activation of NMDA receptors, and the other on mGluRs. The extent to which each form is accessed is likely to depend on the experimental conditions employed.

The extent to which different NR2 subunits are involved in the NMDA receptor-dependent form of depotentiation in the hippocampus is unknown. The possibility that there may be differences between depotentiation and LTD in this regard is however suggested by experiments performed in perirhinal cortex (Massey et al., 2004). Depotentiation was not affected by selective NR2B inhibitors whilst LTD, recorded in the presence of an uptake inhibitor, was fully blocked by these compounds. Conversely, a partially selective NR2A antagonist, NVP-AAM007, blocked depotentiation whilst having no effect on LTD.

An interesting twist to the depotentiation story was uncovered by Woo and Nguyen (2003). Multiple trains of tetanic stimulation not only produce maximal LTP but protect against depotentiation by low-frequency stimulation beginning 5 minutes after induction. Surprisingly, this rapidly

mounted protection is provided through local protein synthesis. The protein synthesis blockers emetine and anisomycin block the protection and do so in slices in which a cut is made between the cell body layer and the recording and stimulating sites in the stratum radiatum of area CA1. The protection is input-specific, but within 40 minutes heterosynaptic protection against depotentiation is extended to synapses throughout the cell by a transcriptional-dependent process. These results are reminiscent of the finding of Huber et al. (2000) that mGluR-dependent LTD involves rapid local protein synthesis as well as the tagging experiments of Frey and Morris (1997) and Kauderer and Kandel (2000). In none of these cases have the effector molecules responsible or their mode of action yet been identified.

Depotentiation exhibits an intriguing form of state dependence in newly unsilenced connections between CA3 pyramidal cells in organotypic cultures. In this preparation, about 20% of connected cells are originally silent (that is, the postsynaptic cell does not respond to an action potential generated in the presynaptic cell) but can be made active by an LTP-inducing pairing protocol. For the first few minutes or so after unsilencing, these new functional connections are immune to re-silencing. After 30 minutes, the newly activated connections enter a state in which they can be depressed by low-frequency stimulation and after LTP induction can be depotentiated in the usual way by low-frequency stimulation (Montgomery and Madison, 2002).

We end this section with the reminder that a potent chemical activator of depotentiation, which appears to be effective at arbitrarily long intervals after induction, exists in the form of a membrane permeable inhibitor of the autonomously active PKC isoform PKM $\zeta$  (Serrano et al., 2005; see Section 10.4.9).

### **10.7.7 Heterosynaptic LTD and Depotentiation: Activity in One Input Can Induce LTD in Another**

Heterosynaptic LTD and depotentiation were the first forms of long-term activity-dependent depression to be discovered in the hippocampus. In two-pathway experiments in area CA1 of the hippocampal slice, Lynch et al. (1977) noticed that a strong tetanus to one pathway was sometimes accompanied by a depression of the population spike in the second, nontetanized pathway. However, even when present, heterosynaptic depression rarely lasted for more than a few minutes in slices from adult animals. Two years later, in a study in the dentate gyrus of the anesthetized rat, Levy and Steward (1979) showed that previously potentiated responses evoked by stimulation of the contralateral perforant path were depressed by tetanic stimulation of the ipsilateral perforant path (Fig. 10–17A). Depression could also be induced in the naïve contralateral pathway. The crossed perforant path thus exhibits both heterosynaptic LTD and heterosynaptic depotentiation.

More recently, heterosynaptic LTD in area CA1 has been documented in slices from young animals, induced by a tetanus (Scanziani et al., 1996; Nagase et al., 2003) or by low-

frequency stimulation (Wasling et al., 2002) delivered to another pathway. Others have been able to elicit heterosynaptic depression only if the heterosynaptic pathway was first potentiated (heterosynaptic depotentiation) (Muller et al., 1995). Evidence that cytoplasmic  $\text{Ca}^{2+}$  is a trigger for heterosynaptic depression has been provided by a detailed study of spike timing-dependent plasticity in slices from 1-month-old rats (Nishiyama et al., 2000). When an LTD-inducing protocol was delivered to the first pathway (that is, when the afferent input was repeatedly paired with a back-propagating action potential, the latter preceding the former by ~20 ms), LTD was also induced in a second, unpaired pathway. The effect was blocked by injection of an antibody to the IP3 receptor, and it was not seen in IP3 receptor knockout mice (see also Nagase et al., 2003). Nishiyama et al. (2000) attributed the spread of LTD to the propagation of IP3 receptor-mediated  $\text{Ca}^{2+}$  waves propagating via the endoplasmic reticulum to neighboring synaptic sites. These experiments, together with the work of Daw et al. (2002), suggest that “input specificity in synaptic modification is not an intrinsic property ... but a dynamic variable linked to the pattern of long-range  $\text{Ca}^{2+}$  signaling in the postsynaptic dendrite” (Nishiyama et al., 2000). In complementary work, Daw et al. (2002) found that the input specificity of LTD was lost in the presence of an inhibitor of IP3, leading to heterosynaptic depression. This result is in line with the conclusions of Nishiyama et al. (2000), since a likely consequence of PI3 kinase inhibition is an increase in IP3 concentration.

A novel, unsuspected form of heterosynaptic depression has emerged as a result of the growing interest in the effects of cannabinoids and their receptors in the hippocampus. Tetanic stimulation of the Schaffer-commissural pathway in hippocampal slices induces a powerful and persistent depression of neighboring GABAergic terminals projecting to the same target CA1 pyramidal cells (Chevaleyre and Castillo, 2003). The effect relies on release of the cannabinoid diacylglycerol (2-AG) from postsynaptic cells; 2-AG binds to cannabinoid CB1 receptors on the terminals of GABAergic interneurons, leading by an unknown route to a reduction in transmitter release. The resulting disinhibition provides a potential mechanism for the phenomenon of E-S potentiation (see Section 10.3.12). This and other examples of cannabinoid-mediated synaptic plasticity are reviewed by Chevaleyre et al. (2006).

#### Heterosynaptic LTD and Depotentiation in the Medial and Lateral Perforant Path of the Intact Rat

The strongest body of *in vivo* evidence relating to heterosynaptic LTD and depotentiation has come from studies of the medial and lateral components of the ipsilateral perforant path (MPP and LPP, respectively) in the intact rat (Abraham and Goddard, 1983; Abraham et al., 1985, 1994; Doyère et al., 1997) (Fig. 10–17B). Though accounts differ as to the relative ease of obtaining heterosynaptic effects in the two pathways,

there is evidence it can work in both directions. Tetanization of the LPP induces persistent LTD in naïve MPP responses and persistent and reversible depotentiation of potentiated MPP responses (Doyère et al., 1997) (Fig. 10–17C). Moreover, in contrast to homosynaptic depotentiation, there is no restricted time window for the induction of heterosynaptic depotentiation; in the freely moving animal, a tetanus to the LPP can depotentiate MPP responses several days after induction. Both heterosynaptic LTD and depotentiation can persist for days, though the depression is in general less persistent than homosynaptic LTP in the same pathways (Doyère et al., 1997). Doyère et al. were not able to produce heterosynaptic LTD in the LPP; but in Abraham’s laboratory, tetanic stimulation of the MPP led to LTD that lasted for days in the LPP (Abraham et al., 1994).

Heterosynaptic depression and depotentiation in the dentate gyrus *in vivo* are largely confined to the fEPSP; Doyère et al. reported small but significant heterosynaptic depression of the population spike but little if any depotentiation. A possible explanation for this seemingly anomalous result is that heterosynaptic depression is accompanied by heterosynaptic E-S potentiation (Abraham et al., 1985).

#### Heterosynaptic Associative LTD: A Rarely Observed Form of Synaptic Plasticity

Because the nontetanized pathway is not—or need not be—active at the time of induction, heterosynaptic LTD represents a mechanism for generalized synaptic depression. With associative heterosynaptic LTD, in contrast, it is only the synapses active at the time of induction that are depressed. Convincing examples of this form of LTD are rare, and it remains to be established if associative LTD exists in the hippocampus of the intact animal. A report by Stanton and Sejnowski (1989) that heterosynaptic associative LTD could be induced in area CA1 *in vitro* by pairing single stimuli to one pathway with out-of-phase brief high-frequency trains to a second pathway could not be replicated by Kerr and Abraham, (1993); or Paulsen et al., (1993). In a variant of this protocol, Christie and Abraham (1992) reported that the lateral perforant path in the dentate gyrus of the anesthetized rat can exhibit associative LTD if it has previously been “primed” by stimulation at theta frequency (Abraham and Goddard, 1983; Christie and Abraham, 1992). However, no evidence of priming was seen in area CA1 in the *in vitro* experiments of Paulsen et al. (1993), suggesting that the effect may be confined to the dentate gyrus or to the intact animal. A homosynaptic variant of the Stanton and Sejnowski protocol has been studied in organotypic hippocampal cultures (Debanne et al., 1994). Repeated pairing of a depolarizing pulse to an impaled CA1 neuron with a single stimulus delivered several hundred milliseconds later to Schaffer-commissural fibers resulted in prolonged depression in the stimulated pathway. The time window during which associative LTD could be obtained was fairly broad: Maximal depression was obtained with a pairing interval of 800 ms, but

1600 ms was almost as effective. The effect is associative because it required both afferent activity and strong depolarizing pulses to fire the postsynaptic cell, and it is input-specific because it was not observed in unstimulated inputs. Associative LTD in organotypic cultures is NMDAR-dependent and is blocked in cells dialyzed with  $\text{Ca}^{2+}$  chelators.

### 10.7.8 LTD and Depotentiation at Mossy Fiber-CA3 Pyramidal Cell Synapses

#### LTD at Mossy Fiber Synapses

Homosynaptic LTD can be induced at mossy fiber synapses *in vitro* by continuous low-frequency stimulation (1 Hz for 15 minutes), at least in young animals (Battistin and Cherubini, 1994; Kobayashi et al., 1996; Domenici et al., 1998; Tzounopoulos et al., 1998). However, homosynaptic LTD in mossy fibers appears to be more readily induced by low-intensity, high-frequency stimulation than by prolonged low-frequency stimulation, possibly reflecting a requirement for the frequency-dependent co-release of dynorphin from mossy fiber terminals. Release of dynorphin can also lead to transient heterosynaptic depression (Weisskopf et al., 1993). In the anesthetized rat, there is evidence that dynorphin acts postsynaptically to modulate both homosynaptic and heterosynaptic LTD (Derrick and Martinez, 1996).

As with mossy fiber LTP, NMDA receptor antagonists do not block mossy fiber LTD, though group II mGluR antagonists are effective (Kobayashi et al., 1996; Tzounopoulos et al., 1998; Chen et al., 2001a). Its induction is not affected by clamping the postsynaptic cell at a hyperpolarized membrane potential or by loading the cell with BAPTA (Kobayashi et al., 1996; Domenici et al., 1998). Given the controversy surrounding similar experiments addressing the mechanism of mossy fiber LTP, it may be premature to conclude that these results provide conclusive evidence for a presynaptic induction mechanism. Tzounopoulos et al. (1998) have presented evidence for a presynaptic model of mossy fiber LTD in which a decrease in the activity of PKA, triggered by a group II mGluR-mediated decrease in adenyl cyclase activity, leads to a persistent decrease in release probability at mossy fiber terminals. Two lines of knockout mice that lack presynaptic proteins are further pointers to a presynaptic expression mechanism for mossy fiber LTD: One lacks the predominantly presynaptic receptor mGluR2 (Yokoi et al., 1996) and shows impairment in LTD; the other, which shows enhanced LTD, lacks RIM $\alpha$ , an active zone protein that binds to Rab3a and is also a PKA substrate (Castillo et al., 2002).

A pairing-induced postsynaptic form of LTD has been uncovered in the mossy fiber projection to CA3 pyramidal cells. Postsynaptic depolarization combined with low-frequency (0.33 Hz) stimulation of mossy fibers causes persistent depression that depends on  $\text{Ca}^{2+}$  entry through L-type  $\text{Ca}^{2+}$  channels in proximal dendrites of CA3 pyramidal cells (Lei et al., 2003). That this is a novel form of mossy fiber LTD is con-

firmed by the fact that it does not occlude with LTD induced by low-frequency stimulation of mossy fibers.

#### Depotentiation at Mossy Fiber Synapses

Low-frequency stimulation applied immediately, but not 30 to 60 minutes, after a tetanus reverses mossy fiber LTP (Tzounopoulos et al., 1998; Chen et al., 2001a). Thus, as in area CA1 and the dentate gyrus, LTP in time becomes immune to depotentiation. Depotentiation is blocked by group II mGluR antagonists, and group II agonists can substitute for low-frequency stimulation in producing time-dependent depotentiation (Chen et al., 2001a). Low-frequency stimulation can induce heterosynaptic depotentiation in a neighboring mossy fiber pathway, perhaps as a result of glutamate spillover (Chen et al., 2001). In contrast to LTD, depotentiation can be readily elicited in adult animals (Huang CC and Hsu, 2001).

Chen et al. (2001a) have made the interesting observation that depotentiation in the mossy fiber pathway is not input-specific. A low-frequency train to a recently potentiated mossy fiber input leads to depotentiation of that input and of a second mossy fiber input, not exposed to low-frequency stimulation, that was potentiated at the same time as the first. This is in contrast to the input specificity of depotentiation that the same group found in area CA1 (Huang CC and Hsu, 2001). Another study (Huang et al., 2002) provided evidence of the involvement of presynaptic mGluR2 receptors in heterosynaptic depotentiation, activated perhaps by spillover from activated fibers. Although these experiments demonstrate the potential for erasing LTP in a nonspecific way in the mossy fiber pathway, it is important to emphasize once again that there is as yet no evidence that this occurs in the intact, behaving animal.

#### Mossy Fiber LTD Is Developmentally Regulated

In slices from young rats (less than 14 days after birth), another form of mossy fiber LTD has been observed that can be induced by high-frequency stimulation (100 Hz for 1 second) and is independent of both NMDA and metabotropic glutamate receptors (Battistin and Cherubini 1994). The induction of this form of LTD is blocked by postsynaptic injection of BAPTA, but its expression remains presynaptic (Domenici et al., 1998). Intriguingly, mGluR-dependent LTD induced by low-frequency stimulation and high-frequency-induced LTD do not occlude, suggesting that both induction and expression mechanisms are different in the two forms of LTD (see Section 10.9.1).

#### LTD: Roles and Rules in the Intact Animal

In the freely moving animal, mild stress promotes LTD and inhibits LTP, though the effect is short-lasting (Xu et al., 1997). Exploration of a novel environment, on the other hand, can promote partial or total depotentiation for an extended

period. In one study, the effect was restricted to a time window of more than an hour but less than 24 hours after induction (Xu et al., 1998). In another study in which a tetanus protocol was adopted that produced a very long-lasting form of LTP, depotentiation could be induced several weeks (but not months) after induction by leaving rats for a few nights in a rodent Disney World with endless possibilities for exploration (Abraham et al., 2002).

What is the function of LTD and its partner depotentiation? Theoretical analysis of distributed neural nets suggests that a network whose synaptic elements are endowed with the property of bidirectional plasticity, including heterosynaptic plasticity, are more stable and have a larger storage capacity than networks where only potentiation (or depression) is possible (Willshaw and Dayan, 1990). It is usually presumed that if the encoding of memories and semantic knowledge is achieved by changes in synaptic weights these changes must be stable, but models where this is not the case have been proposed (Abraham and Robins, 2005). Such models are even more dependent on mechanisms allowing easy reversibility of changes in synaptic weights. What then is the role of LTD? Clearly depotentiation has the potential to disrupt memory circuits and cause active forgetting. What is the evidence that activity-dependent erasure is necessary for forgetting? To put it another way, what sorts of forgetting, if any, could not be explained by the gradual decay of LTP? After all, forgetting on demand is next to impossible.

One consequence of heterosynaptic LTD is to maintain relatively constant the net excitatory drive onto target cells. The observation that there is no increase in the mean firing rate of place cells following the induction of LTP is consistent with this idea (McNaughton et al., 1984; Dragoi et al., 2003).

In the laboratory there are two very different ways of eliciting LTD: (1) with long low-frequency trains tuned to mGluR group I receptors or to NMDA receptors; and (2) by appropriate pairings of presynaptic and back-propagating postsynaptic spikes. There are several fundamental issues to be resolved here. How is the “tuning” realized mechanistically? Do the endogenous patterns of activity provide anything like 1 Hz/900 pulse regimens that are required to obtain sustained LTD? Does LTD or any of the other forms of persistent synaptic depression described in this section occur at all in the hippocampus of the freely moving, behaving animal? The nearest this question has come to receiving a positive answer comes from the experiments in behaving animals discussed above.

## 10.8 Synaptic Plasticity and Inhibitory Pathways

In addition to plasticity at glutamatergic synapses on glutamatergic principal cells, there is a growing body of data on plasticity at synapses where a GABAergic neuron comprises

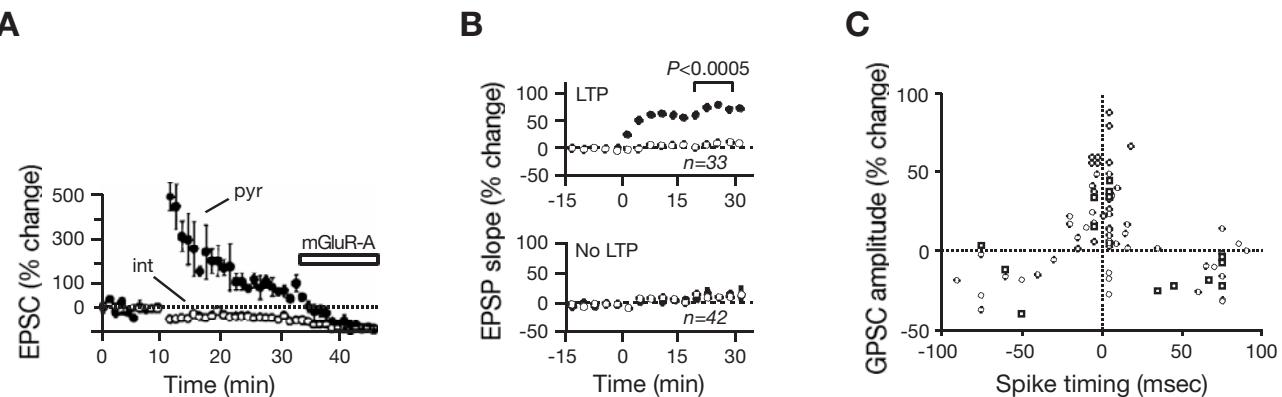

one or other side of the synaptic partnership (Bischofberger and Jonas, 2002; Lawrence and McBain, 2003). In this section we examine LTP and LTD at excitatory synapses onto interneurons and at inhibitory synapses made by interneurons onto excitatory and inhibitory neurons.

### 10.8.1 LTP and LTD at Glutamatergic Synapses on Interneurons

The subunit composition of AMPA and NMDA receptors on interneurons differ in detail from that found on pyramidal cells (see Chapter 5 and Chapter 6, Section 6.3). The dominant NMDA subunit is NR2B, the presence of which prolongs NMDAR-mediated currents (McBain et al., 1999). The AMPA receptor subunit GluR2, which in its edited form limits the calcium permeability of the AMPA receptor ion channel, is generally in low abundance at synapses on inhibitory interneurons, and AMPAR-mediated calcium fluxes are correspondingly higher (Lawrence and McBain, 2003). The distinct assemblage of glutamate receptor subtypes at interneuron synaptic membranes is reflected in the types of plasticity observed; high-frequency trains can, depending on the protocol or cell type, induce either no change, LTP (Maccaferri and McBain, 1996; Perez et al., 2001; Lapointe et al., 2003), or LTD (McMahon and Kauer, 1997). Induction of LTP at excitatory synapses on stratum oriens/alveus (OA) interneurons in stratum oriens is mGluR1-dependent and requires postsynaptic  $\text{Ca}^{2+}$  entry; expression appears to be presynaptic (Lapointe et al., 2003). There are no reports of long-term changes produced by low-frequency trains. However, LTD at feedforward excitatory synapses on CA1 interneurons can be induced by high-frequency stimulation, as first described at Schaffer-commissural inputs to interneurons in stratum radiatum of area CA1 (McMahon and Kauer, 1997). This form of LTD appears not to be input-specific. Functional suppression, via LTD, of excitatory feedforward synapses onto interneurons in stratum radiatum provides a potential mechanism for the phenomenon of E-S potentiation (see Section 10.3.12).

A pairing strategy (depolarizing pulses combined with theta-burst afferent stimulation) has been successfully employed to induce LTP of excitatory afferents to interneurons of stratum oriens in area CA1, but the same protocol is ineffective in the stratum radiatum (Perez et al., 2001). Thus, the magnitude and polarity of activity-induced plasticity at excitatory synapses on CA1 interneurons depends on the stimulus protocol, the location of the interneuron, and presumably the distribution of its receptor subunits.

Mossy fibers provide an interesting example of terminal-specific plasticity. As we have seen, both LTP and LTD are expressed presynaptically at mossy fiber–CA3 pyramidal cell synapses. Filopodial extensions of mossy fiber giant boutons and mossy fibers with en passant boutons make excitatory synapses on dendrites of CA3 interneurons. In stratum radiatum of area CA3, tetanic stimulation of mossy fibers induces LTD in interneurons expressing calcium-permeable AMPA

**Figure 10-20.** Synaptic plasticity of glutamatergic inputs to hippocampal interneurons and at GABAergic inputs from interneurons. **A.** Tetanic stimulation of mossy fibers produces LTP at CA3 pyramidal cells (filled circles) but a mean depression in a population of interneurons (int) (open circles). Note that responses were blocked by an mGluR agonist (mGluR-A), consistent with activation of mossy fibers. (*Source:* Maccaferri et al., 1998.) **B.** With perforated patch recording, input-specific LTP can be induced by pairing in a subpopulation of small feedforward interneurons in the stratum radiatum of area CA1. EPSPs from Interneurons showing LTP are plotted in the upper panel (filled circles are responses from paired input, open circles from unpaired input); responses from

non-potentiating interneurons are plotted in the lower panel. (*Source:* Lamsa et al., 2005.) **C.** Potentiation of GABAergic postsynaptic currents (GPSCs) recorded in dissociated hippocampal cultures following repeated pairing of presynaptic and postsynaptic neurons. LTP of GABAergic transmission is input-specific; and unlike pairing-induced plasticity at glutamatergic synapses, it occurs 20 ms either side of coincident presynaptic and postsynaptic activity. The effect is caused by an L-type calcium channel-dependent local suppression of  $\text{Cl}^-$  transporter activity. The resulting decrease in the reversal potential for  $\text{Cl}^-$  results in an increase in the GPSC when the cell is clamped at a hyperpolarized potential. (*Source:* Woodin et al., 2003.)

receptors; and presynaptic mGluRs but not NMDARs are required for its induction (Maccaferri et al., 1998; Laezza et al., 1999) (Fig. 10–20A). In further work from McBain's group, tetanus-induced LTP was observed in stratum lucidum interneurons expressing  $\text{Ca}^{2+}$ -impermeable GluR2-containing AMPA receptors. The mechanism underlying LTD depends on whether there are calcium-permeable or calcium-impermeable AMPA receptors at that synapse; for both types of synapse, the locus of induction is postsynaptic, although the evidence points to presynaptic expression in the former case and postsynaptic expression in the latter (Lawrence and McBain, 2003). At the mossy fiber–basket cell connection in the dentate gyrus, LTP can be induced by high-frequency stimulation paired with depolarization of the basket cell; LTD is the outcome of tetanic stimulation without depolarisation. Analysis of the number of failures, coefficient of variation, and paired-pulse modulation indicate a presynaptic locus for LTD (Alle et al., 2001). A general conclusion from these studies is that the target cell controls the type and extent of plasticity at mossy fiber terminals.

An intriguing form of E-S potentiation (see Section 10.3.12) at interneurons in the molecular layer of the dentate gyrus has been reported by Ross and Soltesz (2001). Tetanic stimulation of the perforant path leads to a persistent decrease in membrane potential, which increases the probability of the interneuron firing to subsequent stimuli without affecting the amplitude of the EPSP. The effect requires activation of  $\text{Ca}^{2+}$ -permeable AMPA receptors and reflects downregulation in the activity of the electrogenic Na/K ATPase pump.

Two other examples of plasticity at excitatory synapses have been identified at hippocampal interneurons. Lamsa et al. (2005) observed LTP at feedforward excitatory synapses on a subset of interneurons (about half their sample of aspiny interneurons) in area CA1 using perforated patch recordings to preserve the cytoplasmic integrity of the cell. The authors suggest that LTP at this synapse is important for preserving the temporal fidelity of pyramidal cell firing (Fig. 10–20B). McBain and his colleagues have identified a metabotropic switch mediating bidirectional plasticity at synapses made by mossy fibers onto stratum lucidum interneurons (SLINs) (Pelkey et al., 2005). The switch is operated by mGluR7 receptors, which in the resting state are present on presynaptic terminals of mossy fiber–SLIN synapses. Intense activity (such as a high-frequency train) activates the receptors and triggers a sequence of events that leads to LTD, expressed as a reduction in transmitter release from mossy fiber–SLIN terminals. The resulting decrease in feedforward inhibition promotes the firing of CA3 pyramidal cells. Another consequence of the intense activation during the train is that mGluR7 receptors become internalized; now, without the feedback suppression of transmitter release that they control, the mossy fiber terminals onto SLINs display LTP when strongly activated, and feedforward inhibition is restored. By this remarkable meta-plastic mechanism the balance of excitation and inhibition is maintained in the CA3 network. These two sets of results demonstrate a greater potential for plasticity in the inhibitory circuits of the hippocampus than has been generally assumed (McBain et al., 1999).

### 10.8.2 LTP and LTD at GABAergic Synapses

It might be expected that GABAergic synapses would not display plasticity because they lack the equivalent of the voltage-dependent NMDA receptor that for most excitatory synapses is an essential component of the inductive machinery. However, both LTP and LTD have been observed following tetanic stimulation of GABAergic afferents to pyramidal cells in area CA1, under conditions in which all ionotropic glutamate channels are blocked (Caillard et al., 1999; Shew et al., 2000). There is disagreement about whether the postsynaptic cell is (Shew et al., 2000) or is not (Caillard et al., 1999) involved in the induction of LTP, but the evidence points to a presynaptic locus of expression. These experiments were carried out on animals 2 weeks old or less. In a study on hippocampal slices from 4- to 5-week-old rats, tetanic stimulation resulted in LTD of GABAergic responses in CA1 pyramidal cells (Lu et al., 2000a). Here the effect appears to have been induced heterosynaptically by co-activation of convergent excitatory fibers, as induction was blocked by bath application of AP5 or by injecting a calcineurin inhibitor into the postsynaptic cell. A novel form of heterosynaptic LTD at inhibitory synapses in area CA1 has been discovered by Chevaleyre and Castillo (2003). Persistent reduction of evoked IPSCs was induced by brief high-frequency stimulation of Schaffer-commissural fibers, again under conditions in which ionotropic glutamate receptors were blocked. The effect was abolished by antagonists of group 1 mGluRs and cannabinoid CB1 receptors. Chevaleyre and Castillo (2003) concluded that the sequence of events underlying this form of plasticity begins with mGluR-mediated release of the endogenous agonist 2-AG from stimulated pyramidal cells followed by binding of 2-AG to CB1 receptors on the terminals of inhibitory boutons. For further discussion of the results of Lu et al. (2000a) and Chevaleyre and Castillo (2003) in the context of E-S potentiation, see Section 10.3.12.

Woodin et al. (2003) uncovered an unusual form of spike timing-dependent plasticity (STDP) (see Section 10.3.8) that is independent of the order of the pre- and postsynaptic activity at inhibitory synapses onto hippocampal pyramidal cells. Repeated pairings between the presynaptic action potential and the back-propagating dendritic spike at intervals up to 20 ms on either side of coincidence result in long-term reduction in the GABAergic IPSC. The effect is triggered by  $\text{Ca}^{2+}$  entry through L-type  $\text{Ca}^{2+}$  channels, leading to persistent down-regulation of the  $\text{K}^+/\text{Cl}^-$  co-transporter, with a consequent buildup in the concentration of intracellular  $\text{Cl}^-$  and a depolarizing shift in the  $\text{Cl}^-$  equilibrium potential (Fig. 10–20C).

An unsuspected mechanism for potentiation of the GABAergic slow IPSC has been revealed in dendritic spines of CA1 pyramidal cells (Huang CS et al., 2005). The slow IPSC is mediated by  $\text{GABA}_B$  receptors and the G protein-activated inwardly rectifying  $\text{K}^+$  (GIRK) channel, both of which are located on spines as well as dendrites of CA1 neurons. Pairing of single stimuli with depolarization induces LTP of the slow IPSC that is both NMDAR-dependent and  $\alpha\text{CaMKII}-$

dependent. Remarkably, the same induction mechanisms that lead to LTP of excitatory transmission also mediate potentiation of slow GABAergic responses in the same spines. Huang et al. speculate that the temporal window for coincidence detection is sharpened in spines equipped with the  $\text{GABA}_B$ /GIRK system because subsequent excitatory responses are held in check by the slow IPSC.

To conclude this section, we note that to date there have been no studies on plasticity at inhibitory synapses on granule cells or at inhibitory synapses on interneurons.

### 10.9 LTP and LTD in Development and Aging and in Animal Models of Cognitive Dysfunction

Long-term potentiation is often considered as if it were a unitary process. However, as documented elsewhere in the chapter, various factors can greatly influence the properties of LTP, such as the pathway under investigation, the phase of LTP being studied, and the methods used for its induction. Another critical factor is the age of the animal. It is likely that the predominant role for synaptic plasticity early in development is in the formation and refinement of synaptic connections. As animals develop, it can be assumed that LTP and other manifestations of plasticity are involved in modifying synaptic strength at existing synapses, but here too there could be age-dependent alterations in the underlying mechanisms. Juvenile forms of LTP may be less evident but may persist into adulthood in some circumstances, for example during reactive synaptogenesis in response to brain injury and in the dentate gyrus when newborn granule cells are incorporated into the network of mature granule cells (Schmidt-Hieber et al., 2004).

#### 10.9.1 Hippocampal Synaptic Plasticity During Development

##### LTP and the Postnatal Hippocampus

Because they have been the most extensively investigated, more is known about age-dependent changes in LTP at CA1 synapses than elsewhere in the brain. Silent synapses—defined as synapses that have an NMDAR-mediated component of synaptic transmission but no detectable AMPAR-mediated component (Fig. 10–21A)—account for approximately 80% of CA3–CA1 connections during the first 2 days of postnatal life in the rat, decreasing dramatically over the next week or so (Durand et al., 1996) (Fig. 10–21B). By P5 to P6 they account for half this number and continue to decline steeply thereafter. The mechanism of LTP at these synapses involves the rapid unsilencing of silent synapses through the NMDAR-dependent appearance of AMPAR-mediated responses. The simplest mechanism to explain this is the rapid recruitment to the synapse of AMPA receptors, though presynaptic mechanisms have also been proposed (Kullmann, 2003). A reappraisal of

the role of silent synapses may be needed following the observation that synapses are not initially silent; rather, the AMPAR-mediated component disappears as a result of the synaptic stimulation used to obtain baseline responses (Xiao et al., 2004). This activity-dependent silencing is developmentally regulated; it is evident at P3 to P12 but not at P29 to P32, which could account for the developmental profile of silent synapses. Whatever its origin and mechanisms, the unsilencing of silent synapses is best regarded as a juvenile form of LTP; the extent to which it is involved, if at all, during LTP in more mature animals or during reactive synaptogenesis is currently unknown.

NMDA receptors are likely to be the primary trigger for LTP induction throughout life but signaling molecules activated downstream of these receptors may change as the animal matures. We have already alluded in section 10.4.3 to the developmental switch in the kinase dependence of E-LTP that occurs between P7 and P8 when LTP is primarily PKA-dependent, and P27 when LTP acquires its adult dependence on CaMKII (Yasuda et al., 2003) (Fig. 10–21C).

Another study compared LTP mechanisms at CA1 synapses at two stages of development under otherwise identical conditions (Palmer et al., 2004). It was found that LTP involved two mechanisms at P6. The more prevalent form was exhibited by synapses that had an initially low Pr (and showed pronounced PPF); at these synapses LTP was expressed as an increase in Pr (and an associated decrease in PPF) (Fig. 10–21D). The second form displayed no significant change in Pr or PPF but was associated with a decrease in the mean unitary conductance of AMPA receptors. As noted earlier this can most simply be explained by the insertion of additional receptors but with lower single-channel conductance than preexisting receptors. By P12, neither of these mechanisms was present. Instead, LTP was associated with either an increase or no change in the mean unitary conductance, consistent with an increase in the single-channel conductance of preexisting AMPA receptors (or, alternatively, an exchange of high for low conductance receptors) and the insertion of additional receptors of the same unitary conductance as the preexisting receptors, respectively. Regardless of the precise underlying mechanisms, this study illustrates the diversity of LTP mechanisms that can exist at a single type of synapse. The coexistence of more than one mechanism in the same preparation adds further complexity and may reflect the heterogeneity of the developmental state of synapses at any one age.

### LTD and the Postnatal Hippocampus

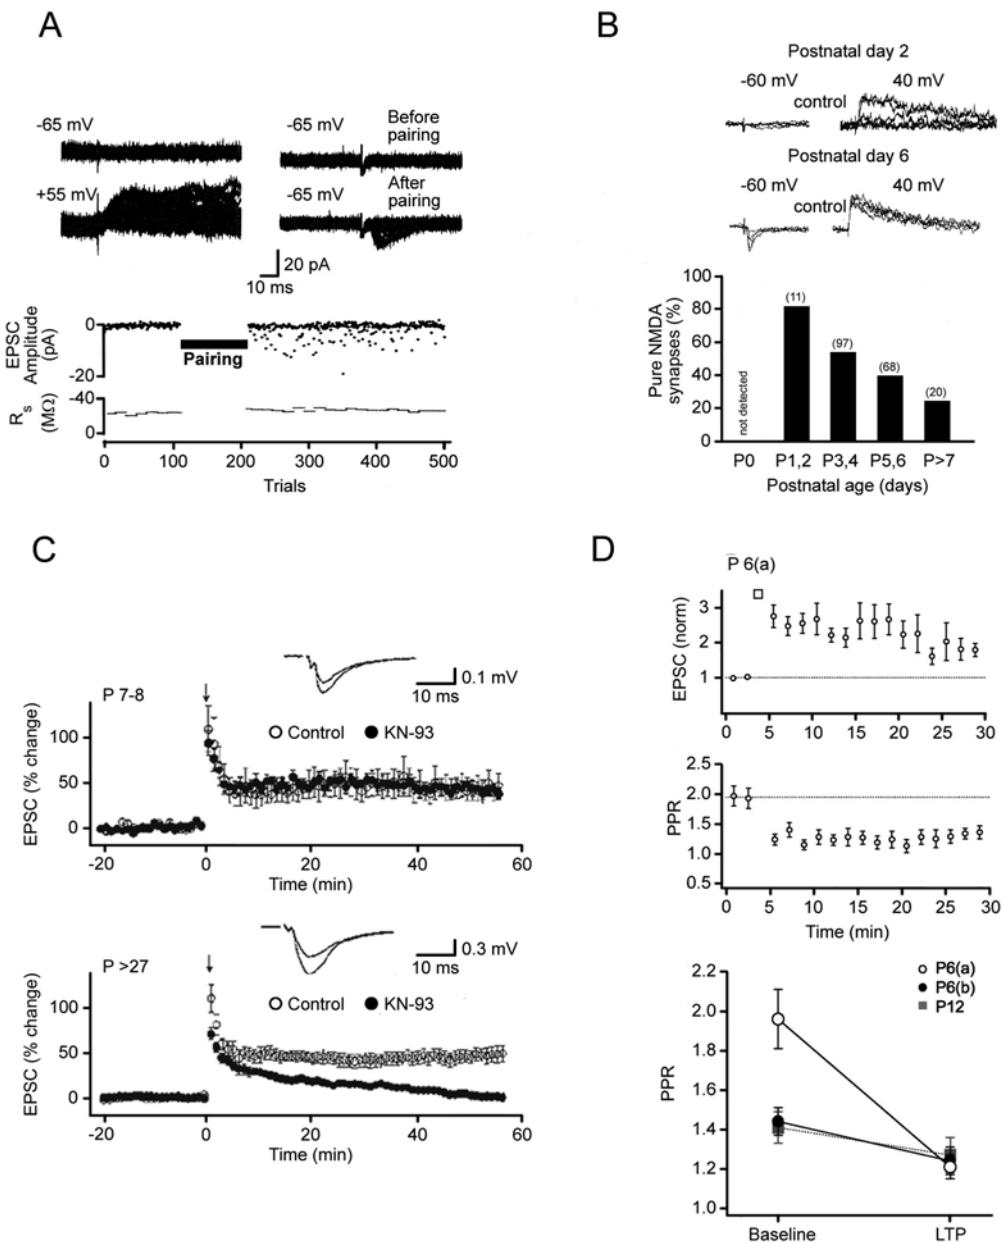

In addition to marked alterations in the properties and mechanisms of LTP during development, there are also significant changes in LTD. At Schaffer-commissural synapses, LTD is often induced by a prolonged period of low-frequency stimulation (e.g., 900 pulses at 1 Hz). As noted in Section 10.7, LTD is more readily induced in juvenile animals than in adults. However, NMDAR-dependent LTD can be induced in adults when glutamate uptake is blocked (Yang et al., 2005), as earlier

described at cortical synapses (Massey et al., 2004). This suggests that the mechanisms for LTD exist in adults but are less readily accessible. These differences in the ability to induce LTD presumably reflect age-related changes in induction mechanisms. For example, in very young animals it seems that mGluRs and voltage-gated  $\text{Ca}^{2+}$  channels are important triggers (Bolshakov and Siegelbaum, 1994). In juveniles and adults, both NMDAR- and mGluR-dependent forms of LTD may coexist, though the relative contributions of each form may change with age (Kemp et al., 2000).

Developmental shifts in the generation of LTD also occur at mossy fiber synapses, as noted in Section 10.7.8. Between the first and second week of life it is possible to induce two forms of LTD (Domenici et al., 1998). One form is induced by a high-frequency train and is independent of both NMDARs and mGluRs. The second form is induced by prolonged low-frequency stimulation and depends on activation of mGluRs. The high-frequency form of LTD, however, is replaced by LTP in rats more than 2 weeks of age (Battistin and Cherubini, 1994).

### 10.9.2 Synaptic Plasticity and the Aging Hippocampus

Changes in the molecular mechanisms of LTP are unlikely to change radically during normal aging: LTP induction, for example, still requires the activation of NMDA receptors (Barnes et al., 1996). However, during aging there are alterations in the LTP process that could contribute to a decline in cognitive function. In general, it can be concluded that aged rats have deficits in both the induction and maintenance of LTP; however, these deficits are complex and depend on the pathway under investigation and the experimental protocol (reviewed by Burke and Barnes, 2006). For example, in aged rats there is an increased rate of decay of LTP at perforant path–granule cell synapses that correlates with the rate of forgetting (Barnes, 1979). A similar deficit in the maintenance of LTP in the perforant path input to CA3 neurons has been reported (Dieguez and Barea-Rodriguez, 2004). There is also an increase in the induction threshold of LTP in aged rats at perforant path–granule cell synapses that is detectable with submaximal induction protocols (Barnes et al., 2000). At CA1 synapses, the primary deficit with aging seems to be a reduction in the magnitude of LTP, which may be explained by less depolarization during induction and presumably therefore less activation of NMDA receptors (Deupree et al., 1991; Moore et al., 1993; Rosenzweig et al., 1997; Tombaugh et al., 2002). Thus, it appears that a major factor in age-related changes in LTP is alterations in conditions affecting NMDA receptor function and its associated  $\text{Ca}^{2+}$  signaling. In turn, alterations in NMDA receptor-dependent plasticity seem to account for many of the alterations in the dynamics of neuronal assemblies that occur with aging. This is indicated by the findings that blockade of NMDA receptors in young rats results in ensemble dynamics that resemble those of old rats (Kentros et al., 1998; Ekstrom et al., 2001).

**Figure 10-21.** Developmental changes in LTP. **A.** Early in development there are silent synapses that display NMDA but not AMPA receptor-mediated EPSCs. These can be rapidly unsilenced by an LTP induction protocol. The traces (left-hand side) show only failures at a negative membrane potential but NMDA receptor-mediated synaptic responses at a positive holding potential. The traces (right-hand side) show only failures before but some AMPA receptor-mediated EPSCs after pairing-induced LTP. The graph plots the amplitude of EPSCs versus time. (*Source:* Liao et al., 1995.) **B.** The incidence of silent synapses dramatically decreases with development. The traces are EPSCs at negative and positive membrane potentials at postnatal day 2 (P2) and P6. At P2 the synapse is silent because only NMDA receptor-mediated responses are observed. At P6 the synapse is no longer silent because both AMPA and NMDA receptor-mediated responses are observed. The graph plots the incidence of silent synapses versus the developmental age

of the animal. Note the dramatic decrease in the incidence of silent synapses with age. (*Source:* Durand et al., 1996.) **C.** Sensitivity to the CaMKII inhibitor KN-93 increases with development. The upper graph shows that KN-93 has no effect on LTP at CA1 synapses in slices obtained from P7 to P8 rats. However, KN-93 blocked the induction of E-LTP in slices obtained from rats at P27 and later. (*Source:* Yasuda et al., 2003.) **D.** The expression mechanisms of LTP, assessed as changes in paired-pulse facilitation, alter during development. The upper graph plots the EPSC amplitude (upper) and paired-pulse ratio (lower) before and following pairing induced LTP (at the time depicted by open square) for a subclass of P6 neurons termed P6(a). The lower graph plots the change in the paired-pulse ratio following LTP for this group of synapses and for another subclass of P6 neurons [P6(b)] and P12 neurons. Note the dramatic decrease in paired pulse facilitation that is specific for P6(a). (*Source:* Palmer et al., 2004.)

In aged animals it once again appears to be easier to induce LTD and depotentiation (Norris et al., 1996).

### 10.9.3 Animal Models of Cognitive Decline

#### Alzheimer's Disease

Memory loss is a prominent aspect of Alzheimer's disease (AD), and given the strong presumptive links between synaptic plasticity and memory, it is not surprising that several groups have asked whether synaptic plasticity is affected in rodent models of the disease (reviewed by Rowan et al., 2003).

The diagnostic, postmortem feature of Alzheimer's disease in humans is the deposition of amyloid plaque in structures of the temporal lobe (see Chapter 16). Whether plaque deposition is the cause or a consequence of the disease has not been resolved, but many believe that excessive levels of amyloid  $\beta$  (A $\beta$ ) is the primary cause of the disease. A $\beta$  is a peptide fragment that is cleaved from the amyloid precursor protein (APP) by the action of secretases. In various familial forms of early-onset AD, there are mutations in APP that result in its misprocessing, leading to deposition of A $\beta$ . Several mouse lines have been created that overexpress these mutant forms of APP. These mice display age-related cognitive deficits and amyloid plaque deposition. With respect to alterations in synaptic function, two main effects have been noted. In some, but not all, studies there is a decrease in LTP (Chapman et al., 1999; Moechars et al., 1999). In other studies the most dramatic effect is a decrease in basal synaptic transmission (Hsia et al., 1999; Larson et al., 1999; Fitzjohn et al., 2001a), which could indirectly affect LTP through the property of cooperativity (see Section 10.3.1). A decrease in LTP was also observed in a mouse that overexpressed an amyloidogenic fragment of the C-terminal of APP (Nalbantoglu et al., 1997). An alternative approach to investigating the role of APP in AD is to generate a mouse with null expression of APP. APP-null mice also display LTP deficits under some, but not all, conditions (Seabrook et al., 1999). In particular, no deficit was seen when GABA inhibition was blocked, suggesting that the effect on LTP is mediated via a relative increase in synaptic inhibition (Fitzjohn et al., 2001a). This raises the possibility that APP is required for normal functioning of GABA-mediated synaptic transmission.

A larger number of cases of familial AD have mutations in *PS1*, a component of the machinery involved in APP processing. Mice expressing *PS* mutations generally have enhanced LTP (Parent et al., 1999; Barrow et al., 2000; Zaman et al., 2000) possibly because Ca $^{2+}$  homeostasis is affected (Schneider et al., 2001). In a conditional forebrain-specific *PS1* knockout mice there were no detectable changes in basal transmission or LTP (Yu et al., 2001), whereas in a mouse underexpressing *PS1* there was a deficit in LTP evoked with multiple tetani (Morton et al., 2002). In humans, the ApoE4 isoform of the lipid-shuttling protein apolipoprotein E (ApoE) is a risk factor for AD. A mouse with the ApoE gene knocked out showed near-normal LTP (Anderson et al., 1998)

even in the aged animal (Valastro et al., 2001), though a deficit in LTP has also been reported (Trommer et al., 2004). Interestingly, a knock-in mouse expressing human ApoE4 showed enhanced LTP when young (Kitamura et al., 2004); LTP dropped back to wild-type levels during adulthood and has not yet been examined in the aged knock-in mice.

The other major approach to investigating the role of A $\beta$  in AD is to apply A $\beta$  exogenously. In most such studies, A $\beta$  has been found to impair LTP. For example, A $\beta$  blocked both E-LTP and L-LTP without affecting baseline transmission in both the dentate gyrus and area CA1 *in vitro* (Lambert et al., 1998; Chen et al., 2000; Wang et al., 2002). Not all studies, however, have reported deficits in LTP following A $\beta$  application. For example, LTP was enhanced in the perforant path input to dentate gyrus (Wu et al., 1995a). There is also generally a block of LTP *in vivo*, though L-LTP appears to be more sensitive than E-LTP (Cullen et al., 1997; Freir et al., 2001). At longer intervals after A $\beta$  injection impairment of baseline transmission also becomes apparent (Cullen et al., 1996; Stephan et al., 2001), resembling the situation in several of the transgenic mouse studies.

Interestingly, studies with A $\beta$  fragments suggest that the active forms responsible for the inhibition of LTP are soluble A $\beta$  oligomers (Walsh et al., 2002). Other studies have addressed the mechanisms responsible for the A $\beta$  impairment of LTP and have uncovered interactions of A $\beta$  with the cholinergic system (Auld et al., 2002), in particular nicotinic receptors and the ERK2 MAPK cascade (Dineley et al., 2001), the GABA system (Sun and Alkon, 2002), NMDA receptors (Wu et al., 1995b), and CREB (Tong et al., 2001).

The first, partially effective, drugs used to treat AD were cholinesterase inhibitors, which exert their effect by potentiating cholinergic function in regions such as the hippocampus. Cholinergic systems facilitate NMDAR-dependent LTP, possibly in part by direct potentiation of the NMDA receptor conductance (see Section 10.6.1). It is feasible, therefore, that their cognitive enhancing effect at the early stages of AD is due to the facilitation of LTP. The next compound to be introduced into the clinic for the treatment of AD was memantine, which is a weak NMDA receptor antagonist (Parsons et al., 1999). It may seem paradoxical that an NMDA receptor antagonist can have cognitive enhancing properties. However, a plausible mechanism of action has been advanced based on studies on hippocampal LTP (Coan et al., 1989). It was found that bathing hippocampal slices in a Mg $^{2+}$ -free medium resulted in the inhibition of LTP. However, if a concentration of AP5 was added to the slices that would ordinarily block LTP, LTP could be obtained. If, however, a higher concentration of AP5 was used, LTP was inhibited. These surprising findings were interpreted as follows. To induce LTP requires either no activation or perhaps a very low level of NMDA receptor activation during baseline stimulation but then a high degree of NMDA receptor activity briefly during a tetanus. When Mg $^{2+}$  was omitted from the bathing medium, the baseline level of NMDA receptor activation both before and following the tetanus was greatly enhanced; this inhibited the LTP process,

probably by preinduction and partial saturation of LTP. The addition of a standard concentration of AP5 substituted for Mg<sup>2+</sup> and suppressed NMDA receptor activation. During the tetanus, however, the concentration was insufficient to block the induction of LTP given the absence of Mg<sup>2+</sup>. That a higher concentration was effective demonstrates that it is NMDAR-dependent LTP that is recovered by AP5 treatment. What is the relevance of this to disease? In various pathological states, such as AD, the general dysfunction could lead to depolarization of neurons, for example due to problems with energy levels affecting glutamate uptake. Indeed, blocking glutamate uptake produces a similar NMDA receptor-dependent inhibition of LTP (Katagiri et al., 2001). Memantine is a weak, high voltage-dependent NMDA receptor antagonist (Parsons et al., 1993) that can also restore the ability of slices bathed in Mg<sup>2+</sup>-free medium to undergo LTP (Frankiewicz and Parson), 1999). So its probable mechanism of action is to inhibit spurious activation of NMDA receptors in modestly depolarized cells; but during strong depolarization (e.g., during a tetanus) it is rapidly displaced from NMDA receptors. In this way it can facilitate LTP. In addition, its ability to inhibit tonic activation of NMDA receptors could endow it with neuroprotective properties (Danysz et al., 2000).

### **Down's Syndrome**

The segmental trisomy mouse (Ts65Dn) has an extra chromosome 16 (corresponding to human chromosome 21) and has accordingly found use as a model for Down's syndrome. The Ts65Dn mouse shows learning impairments and a reduction in LTP at CA1 synapses *in vitro* (Siarey et al, 1997). In a subsequent study, a deficit was found in theta-burst LTP but not in tetanus-induced LTP; the deficit was rescued by blocking GABA inhibition (Costa and Grybko, 2005). A reduction in LTP in the dentate gyrus of the Ts65Dn mouse that was rescued by blockade of GABA inhibition has also been observed (Kleschevnikov et al, 2004). There is also a deficit in LTP in the Ts1Cje mouse model of Down's syndrome (Siarey et al, 2005). In this mouse both the cognitive deficits and the LTP deficits are less severe. Whereas LTP is reduced in mouse models of Down's syndrome, LTD is increased (Siarey et al., 1999, 2005). A mouse expressing most of human chromosome 21, in addition to both copies of the homologous mouse chromosome 16, shows learning deficits and a reduction in LTP in the dentate gyrus *in vivo* (O'Doherty et al., 2005). Thus, all mouse models of Down's syndrome so far studied have displayed alterations in LTP or LTD, consistent with the hypothesis that deficits in hippocampal synaptic plasticity may play a causative role in the cognitive deficits associated with the condition.

### **Huntington's Disease**

Huntington's disease is a progressive neurodegenerative disorder associated with multiple CAG repeats in the gene encoding the protein huntingtin; it usually starts around the third to fifth decade of life. Neuronal loss is primarily in the striatum and cerebral cortex but can involve the hippocampus at later

stages. However, before the onset of classical symptoms, patients often exhibit cognitive deficits. Studies in various mouse models of Huntington's disease have reported deficits in LTP at Schaffer–commissural synapses (Usdin et al., 1999; Hodgson et al., 1999; Murphy et al., 2000). Strikingly, and in contrast to control animals, slices from adult mutant mice readily displayed NMDA receptor-dependent LTD and depotentiation at Schaffer–commissural synapses (Murphy et al., 2000). Expression of the full-length mutated huntingtin in cell lines results in augmentation of NR2B containing NMDA receptors (Chen et al., 1999), which might explain the enhancement of LTD (see Section 10.7.3). Mossy fiber LTP is also reduced in a mouse model of Huntington's disease (Gibson et al., 2005). In this study a similar LTP deficit was observed in mice lacking complexin II, a protein that is reduced in Huntington's disease patients.

### **Schizophrenia**

Schizophrenia is another developmentally regulated disorder that involves cognitive impairment as well as psychosis. There are good reasons to believe that schizophrenia involves pathological alterations in synaptic plasticity, in particular LTP-like processes. Thus, one of the best animal models of schizophrenia involves injection of phencyclidine (PCP). It is a curious coincidence that in the same year that the NMDA receptor was established as the trigger for LTP at Schaffer-commissural synapses (Collingridge et al., 1983), it was also shown that PCP and other dissociative anesthetics such as ketamine are potent blockers of NMDA receptors (Anis et al., 1983) and that PCP blocks induction of LTP at these synapses (Stringer et al, 1983). Since then, the glutamate hypothesis of schizophrenia has gained in popularity and is now the dominant hypothesis in the field. The general notion is that schizophrenia may involve impairment of NMDAR-dependent LTP in the hippocampus and other brain regions affected by the disease, thereby leading to impairment of LTP, cognitive dysfunction, and thought disturbances. Evidence to support the hypothesis that LTP may be affected in schizophrenia is starting to accumulate. For example, in the post-weaning social isolation model of schizophrenia there is a reduction in NMDAR-dependent LTP in the CA1 projection to the subiculum (Roberts and Greene, 2003). There are many ways in which NMDA receptor-dependent LTP could be directly or indirectly affected, and it seems likely that genetic and environmental influences can modify synaptic plasticity in various ways. For example, the schizophrenia-susceptibility gene *neuregulin-1* stimulates the internalization of GluR1-containing AMPA receptors and leads to depotentiation of NMDAR-dependent LTP (Kwon et al., 2005).

### **Diabetes and Other Diseases Associated with Potential Cognitive Deficits**

Cognitive deficits associated with type I diabetes may also involve alterations in hippocampal synaptic plasticity. For example, there is an impairment of LTP at Schaffer–commis-

sural synapses in nonobese diabetic rats and upregulation of NMDA receptors (Valastro et al., 2002). Similarly, rats treated with streptozotocin, a pancreatic beta cell toxin, have impaired LTP and enhanced LTD at Schaffer–commissural synapses (Artola et al., 2005). In contrast, LTP appeared normal at these synapses in Zucker diabetic fatty rats, a model of type II diabetes (Belanger et al., 2004).

## Epilepsy

A link between epilepsy and LTP has long been suspected, but the evidence to date is not compelling. In two animal models of human temporal lobe epilepsy—kindling and pilocarpine-induced seizures—LTP is reduced, probably because synapses become potentiated during the seizures (Schubert et al., 2005). LTP is also impaired in slices prepared from human epileptic dentate gyrus relative to nonepileptic tissue (Beck et al., 2000). Kindling is induced in temporal lobe structures, most readily in the amygdala, by daily repetitions of brief high-frequency sinusoidal stimulation, typically at 60 Hz for 1 second. Initially, stimulation produces no behavioral effects, but eventually, after several daily repetitions, the same protocol leads to generalized convulsions (Goddard, 1967). Is there an LTP component to kindling? Cain (1989) noted several differences between LTP and the pathological processes elicited by kindling stimulation. Thus, the development of kindling may be delayed but is not blocked by NMDA receptor antagonists. During later stages of kindling, evoked responses are often diminished rather than enhanced. Moreover, repeated tetanic stimulation of afferent pathways of the kind that induces LTP does not elicit kindling. The kinetics of onset and persistence are also very different in the two cases; kindling requires several daily sessions to reach full expression and is then effectively permanent. LTP is induced within seconds or minutes but in most cases returns to baseline within days or weeks. Thus, it seems reasonable to conclude that the sorts of stimulation that lead to LTP are not in themselves epileptogenic, and that LTP lies at the benign end of the spectrum of activity-dependent changes in synaptic efficacy.

## Synaptic Plasticity and the Enhancement or Suppression of Memory

Increasing confidence in the existence of a causal link between LTP and memory has encouraged the development of pharmaceutical approaches to the treatment of memory dysfunction based on targets such as glutamate receptors and transcription factors known to be important in LTP and/or LTD. Though still at a relatively early stage of development, these approaches hold great promise for the future (see reviews by Cooke and Bliss, 2005 and Lynch, 2006).

## Summary

A common emerging theme is that a number of diseases involving cognitive deficits have altered hippocampal synaptic

plasticity, in particular changes in NMDAR-dependent LTP and/or LTD. It seems likely, therefore, that synaptic plasticity in the brain of the type represented by LTP and LTD is disrupted in these diseases and contributes to the etiology of cognitive impairment. By extension, it seems likely that alterations in LTP and LTD in the hippocampus and other brain regions may be involved in other neurological and psychiatric disorders, including drug addiction (Hyman and Malenka, 2001) anxiety, depression, bipolar disorders, motoneuron disease, and Parkinson's disease.

## 10.10 Functional Implications of Hippocampal Synaptic Plasticity

What is the function of LTP? Is it a physiological phenomenon that engages the same neural mechanisms that are responsible for certain forms of learning and memory? Or is it a laboratory curiosity of no functional significance? A version of these questions was posed at the end of the first article on LTP (Bliss and Lomo, 1973), and the debate has been with us ever since. In this concluding section of the chapter, we turn to the functional significance of activity-dependent synaptic plasticity in relation to behavior.

### 10.10.1 Synaptic Plasticity and Memory Hypothesis

Most functional studies of LTP and LTD address their possible roles in learning, with the majority of studies focusing on NMDAR-dependent forms of plasticity. The aim of such research has been caricatured by Stevens (1998) in the question “Does LTP equal memory?” There are numerous qualifications to such a question. What type of LTP? What type of learning? What role for LTD and depotentiation? Is the persistence of LTP correlated with and responsible for the persistence of memory? These questions indicate that the debate has moved on from merely recognizing certain analogies between LTP and learning to specific ideas about how the mechanisms of induction and expression of synaptic plasticity relate to the multiple types and processes of memory that we now know to exist (see Chapter 13). These ideas share a common generic theme that has been called the “synaptic plasticity and memory” (SPM) hypothesis (Martin et al., 2000). The SPM hypothesis asserts that synaptic plasticity (1) occurs during ordinary brain activity, and (2) is responsible for memory formation, as follows (Martin et al., 2000).

Activity-dependent synaptic plasticity is induced at appropriate synapses during memory formation, and is both necessary and sufficient for the information storage underlying the type of memory mediated by the brain area in which that plasticity is observed.

With respect to the hippocampus, this implies that some of the neural mechanisms of synaptic plasticity discussed above, such as alterations in AMPA receptor trafficking, should occur

during hippocampus-dependent forms of learning and be necessary for that learning to occur.

Earlier in the chapter, it was pointed out that synaptic plasticity displays physiological properties that are highly suggestive of an information storage device, as many have asserted the hippocampus to be (McNaughton, 1983; Lynch and Baudry, 1984; Goelet et al., 1986; Morris et al., 1990; Bliss and Collingridge, 1993; Barnes, 1995; Jeffery, 1997; Shors and Matzel, 1997). Such classical properties include *associativity*, *input-specificity*, and *persistence*. These may be relevant to associative features of learning and memory, as follows. First, associative induction implies the capacity to relate a pattern of presynaptic neural activity with a pattern of postsynaptic activity, as in the association of ideas. Second, they are relevant to storage capacity because a synapse-specific mechanism endows the network with greater storage capacity than would changes in cell excitability. Third, to store information in the brain, some persistent change in the nervous system has to occur. Whether these changes necessarily have to last as long as memory is debatable. A qualification is that hippocampal-neocortical consolidation mechanisms may become engaged that would obviate the need for long-lasting persistence in the hippocampus, notwithstanding the fact that LTP in the dentate gyrus has been shown to last for more than a year in rodents (Abraham, 2003; Abraham and Robins, 2005).

The pioneering studies implicating LTP in memory were correlational. Barnes (1979) and Barnes and McNaughton (1985) observed, in the course of work on aging, that the persistence of LTP over time was statistically correlated with the rate of learning and/or the degree of retention of spatial memory in a circular arena task (see Chapter 13 for a description of this and other behavioral tasks). Similar correlations have been observed many times, another example arising in studies of the overexpression of human mutant amyloid precursor protein (hAPP) in a murine model of Alzheimer's disease (Hsiao et al., 1996). This is associated with an age-related decline in performance in a delayed spatial alternation task that is correlated with a corresponding decline in LTP, assessed *in vivo* and *in vitro* (Chapman et al., 1999). Lynch (2004) reviewed a number of other cases where similar correlations are observed.

However, it is far from clear that the physiological properties of synaptic plasticity are, in general, likely to be exactly homologous to, and thus correlated with, parameters of learning at the behavioral level. Some properties should be directly related. One example is that the mechanisms of "induction" of LTP and the "encoding" of memory should overlap. Other properties are less likely to be correlated because the overt manifestations of memory are not due solely to synaptic properties—they also depend on the properties of the network in which that plasticity is embedded (see Chapter 14). An example of mismatch is that the temporal contiguity requirements for presynaptic glutamate release and postsynaptic depolarization in the induction of NMDAR-dependent LTP (see Section 10.3) are temporally much tighter than those govern-

ing various forms of associative conditioning. This has sometimes been mentioned as a weakness of the SPM hypothesis (Diamond and Rose, 1994). Associative conditioning depends on the ability of the CS to predict the US (contingency); simply pairing—CS and US (contiguity)—is not sufficient if, for example, many additional unpaired CS and US presentations are also introduced. The studies of spike timing plasticity (see Section 10.3) illustrate the temporal contiguity requirements for LTP, but to date they say nothing about contingency. However, an investigation of amygdalar plasticity reveals that LTP and fear conditioning are indeed both sensitive to CS-US contingency (Bauer et al., 2001). A train of tetanic stimulation of thalamic afferents to the lateral amygdala *in vitro* was paired with a series of depolarizing current pulses to the postsynaptic neuron. This procedure was repeated 15 times at 20-second intervals, resulting in robust LTP. Intriguingly, the addition of unpaired depolarization 10 seconds after each pairing—analogous to unpaired US presentations—resulted in almost no LTP despite the preservation of contiguity. The mechanisms underlying this contingency phenomenon clearly operate over a time scale of at least 10 seconds. These findings illustrate that LTP, at least in the lateral amygdala, reflects a property of learning that might have been expected to arise only at the circuit level.

Synaptic plasticity does, of course, have distinct functions in different parts of the nervous system. In the amygdala, it has been implicated in conditioned fear (LeDoux, 2000), thereby reflecting a feature of the generic SPM hypothesis ("type of memory mediated by the brain area"). However, in the spinal cord, LTP-like changes have been implicated in hyperalgesia to painful stimuli (Fitzgerald, 2005). This illustrates one of the themes of this book—how principles that were first developed for the hippocampus have had a wider significance in neuroscience. LTP and LTD may also have other functions in the hippocampus. Proposals include the "plasticity/pathology continuum" hypothesis (McEachern and Shaw, 1996) and the notion that synaptic changes play a role in attentional rather than memory processes (Shors and Matzel, 1997). Distinguishing between these and alternative hypotheses about the functions of synaptic plasticity is not always easy, and exacting analytical studies are required.

Martin et al. (2000) proposed four criteria for a rigorous test of the SPM hypothesis: detectability, anterograde alteration, retrograde alteration, and mimicry. Broadly speaking, they correspond to correlation, necessity, and sufficiency. The first of these four criteria, *detectability*, states that, in association with the formation of memory lasting any length of time, LTP or LTD must occur at certain synapses in one or more brain areas and should, in principle, be detectable. The limited number of synapses that change with any one learning experience might make this criterion difficult to meet experimentally. The possibility of heterosynaptic LTD in conjunction with learning-induced potentiation poses a similar problem. The second criterion, *anterograde alteration*, asserts that

blocking the mechanisms that induce or express changes in synaptic weights should have the anterograde effect of impairing new learning. The intervention may be achieved in various ways: physiologically, pharmacologically, or through molecular-genetic manipulation. The NMDA receptor has been a particular target, but there is a growing body of work examining interventions that affect the transition from protein synthesis-independent to protein synthesis-dependent forms of LTP and of memory. A separate aspect of necessity—our third criterion, *retrograde alteration*—is that altering the pattern of synaptic weights after learning has taken place should affect an animal's memory of past experience. This arises because altering the spatial distribution of synaptic weights within a distributed associative matrix such as the hippocampus should alter the associations retrieved from such a network. Finally, if changes in synaptic weight are the neural basis of trace storage, their artificial induction in a specific spatial pattern of weights should give rise to an “apparent” memory (mimicry) for a stimulus or event that did not, in practice, actually occur. Although this criterion may seem fanciful, particularly in the hippocampus, it is the ultimate “engineering” criterion that is most likely to convince skeptics of the functional importance of LTP. For reasons we shall come to, it may be easier to meet this criterion in brain areas such as the amygdala than in the hippocampus.

### 10.10.2 Detectability: Is Learning Associated with the Induction of LTP?

The SPM hypothesis requires that synaptic changes must occur during learning. The experimental design is ostensibly straightforward: Synaptic efficacy is compared before and after a variety of learning experiences. The prediction is that a persistent increase in synaptic efficacy should occur at appropriate synapses in association with certain types of learning. Types of learning that engage the hippocampal formation should be associated with synaptic potentiation, whereas other types of learning should not. What is less clear is whether such synaptic changes would be readily detectable in global measures such as fEPSPs.

#### Exploration-induced and Spatial Learning-induced Changes in Hippocampal Field Potentials and Transmitter Release

Considerable excitement surrounded the discovery of what appeared to be striking short-term modulation of perforant-path evoked EPSPs in the dentate gyrus during spatial exploration (Sharp et al., 1989; Green et al., 1990). Exploratory activity was accompanied by an increase in the dentate fEPSP and a decrease in both amplitude and latency of the population spike. However, Moser et al. (1993a) discovered that this unusual pattern of electrophysiological change during exploration is largely due to changes in brain temperature caused by associated muscular activity (Fig. 10–22A). Application of

radiant heat was sufficient to induce changes in fEPSPs. If during exploration the animal's brain was “temperature-clamped” by intermittent infrared heating, exploratory motor activity was no longer associated with changes in the fEPSP. Moser et al. (1993b, 1994) went on to work out the calibration functions relating brain temperature to fEPSP magnitude before placing animals in an environment containing six landmarks. A small temperature-independent component of the increase in fEPSP was observed that was correlated with exploration (Fig. 10–22B). This increased rapidly at the start of exploration and declined gradually to baseline over a short period (15 minutes). Further studies have shown exploratory behavior to be associated with the activation of immediate early genes (IEGs) such as *c-fos* (Gall et al., 1998) and *Arc* (Guzowski et al., 1999). Temperature controls have not, to our knowledge, been conducted in these studies, but these patterns of IEG activation are unlikely to be entirely due to activity-associated changes in brain temperature, as the spatial distribution of *Arc* expression in area CA1 over two exploration sessions is exquisitely sensitive to the spatial similarity of the two enclosures in which testing takes place (Guzowski et al., 1999).

Complementing these studies of fEPSPs in behaving animals have been studies comparing brain tissue (*in vitro*) from animals that have been exposed to a learning situation with tissue from animals that have been left unattended. For example, Green and Greenough (1986) saw enhanced fEPSPs in the dentate gyrus in response to perforant path stimulation in slices taken from adult animals that had been reared in complex environments. This study was particularly well controlled in showing no changes in antidromic potentials or presynaptic fiber volleys. However, it is possible that experience can alter neurogenesis in the dentate gyrus (see Chapter 9). Such changes could contribute to or account for the findings of Green and Greenough (1986); enhanced fEPSPs could reflect the creation of new neurons and synapses.

An increase in glutamate release has also been reported following both LTP (see Section 10.3) and watermaze learning (Richter-Levin et al., 1995; McGahon et al., 1996). Richter-Levin et al. (1997) trained rats in a spatial watermaze task for varying numbers of trials and then induced LTP *in vivo* on one side of the brain; finally, they examined veratridine-induced glutamate release in synaptosomes prepared from the hippocampus of the trained animals. Learning was associated with increased glutamate release. Tissue prepared from the hemisphere in which LTP had been induced showed a greater increase in glutamate release when taken from rats at an early stage of training than at a later stage. Thus, not only were both LTP and learning associated with an increase in glutamate release, but the learning-associated increase occluded the increase normally seen after LTP. This striking result would be in accord with the SPM hypothesis were it not for the further finding that the amount of perforant path-induced LTP *in vivo* was the same in both the undertrained and extensively trained groups. This is puzzling. That the magnitude of elec-

trophysiological induced LTP is unaffected by prior spatial learning is consistent with the idea that an individual learning experience may enhance only a small proportion of synapses in the dentate gyrus. However, if this is the case, why was the LTP seen after extensive learning not associated with an increase in glutamate release? Perhaps learning is associated with a shift in the relative expression of presynaptically mediated and postsynaptically mediated LTP.

One puzzle about detectability concerns the difficulty in observing learning-associated synaptic changes in the hippocampus. Storage capacity could be one factor, particularly in a distributed-associative system such as the hippocampus; another could be that heterosynaptic depression (LTD) may occur at other synapses during learning, rendering field potentials an inappropriate way to investigate the issue. Heterosynaptic LTD might serve a normalizing or scaling function in a distributed associative memory system by ensuring that the sum of the synaptic weights on any given neuron remains roughly constant (Willshaw and Dayan, 1990) see Section 10.3.14; fEPSP amplitude would then remain unchanged. Given this, the issue might be better pursued in other brain structures or with other techniques.

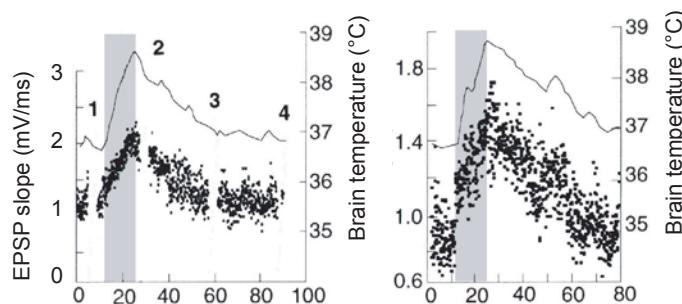

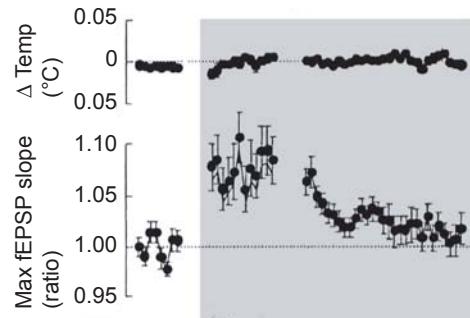

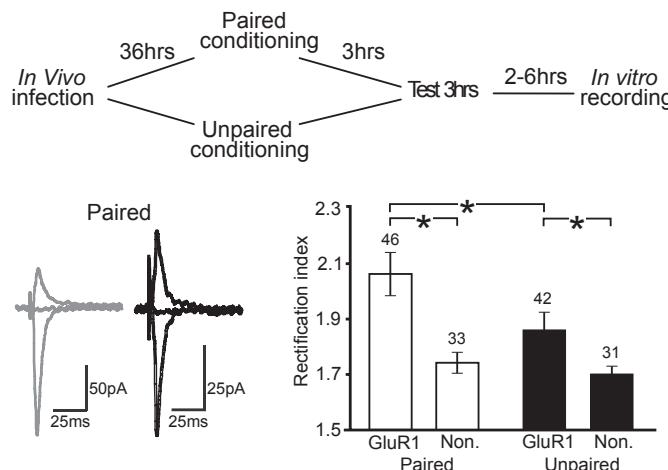

#### **Learning-related fEPSP Changes in Other Brain Areas**

Vindicating this suspicion, the detectability criterion has been spectacularly upheld in studies of amygdala-dependent fear conditioning. Rogan et al. (1997) monitored evoked potentials elicited by an auditory CS in the lateral amygdala *in vivo* before and after auditory fear conditioning. Paired presentations of the auditory CS and foot shock resulted in increased freezing behavior and a parallel potentiation of the CS-evoked potential. Enhancement of electrically evoked responses was also found in brain slices taken from fear-conditioned rats (McKernan and Shinnick-Gallagher, 1997), and an increase in auditory evoked responses following tone fear conditioning has since been reported in freely moving mice (Tang et al., 2001, 2003). Learning-induced changes in evoked responses occlude electrically induced LTP, implying that the two processes engage common mechanisms (Tsvetkov et al., 2002; Schroeder and Shinnick-Gallagher, 2005); such changes can also be persistent, lasting at least 10 days in the latter case. A recent study offers further insights into the mechanisms of learning-related plasticity, providing more direct evidence that the learning-related changes are mechanistically similar to LTP (Rumpel et al., 2005). Using the rectification of AMPA receptor-mediated transmission as an index of mutated GluR1 subunit incorporation, as in the studies of LTP expression described above (see Section 10.4), tone-fear conditioning was shown to be associated with an increase in EPSCs associated with AMPA receptor trafficking in the pathway from the auditory thalamus to the amygdala *in vitro* (Fig. 10–22C). The change was greater when paired conditioning trials were used in which the tone preceded the fear-evoking shock by an optimum CS-US interval but much weaker after

unpaired conditioning. Use of a “plasticity-block” vector (Malinow and Malenka, 2002) to interfere with AMPA receptor trafficking prevented the learning-associated rectification of AMPA-mediated transmission and, in separate experiments, learning itself. Intriguingly, plasticity had to be disturbed in only a small percentage of neurons (approximately 27%) for an effect to be observed, raising the possibility that combinatorial effects may be responsible for the learning of different CS-US pairings.

A phenomenon resembling LTP also occurs in the primary motor cortex (M1) following acquisition of a motor skill in rats. Rioult-Pedotti et al. (1998) trained rats to reach through a hole in a small plastic box with their preferred paw to retrieve food pellets. After a few days of training, recordings from brain slices revealed that EPSPs from layer II/III of the contralateral M1 of trained rats were substantially larger than those recorded in the ipsilateral untrained hemisphere or in untrained animals (Fig. 10–22D). Similar LTP-like changes have since been observed in M1 following motor learning *in vivo* (Monfils and Teskey, 2004). In a follow-up study, repeated trains of either high- or low-frequency stimulation were delivered to saturate LTP or LTD, respectively (Rioult-Pedotti et al., 2000). Strikingly, the capacity for further LTP was reduced (and LTD enhanced) following motor learning despite the synaptic potentials being larger—reflecting no change in the synaptic plasticity range of the synapses affected by or involved in motor learning. This partial occlusion suggests that LTP and skill learning may engage similar neuronal mechanisms. However, a puzzle about these findings is that the increase in EPSPs is typically large (about 50%), and the spatial distribution of the weight changes and their information content are currently unknown. We argued above that, in the hippocampus at least, learning-related changes in EPSPs are likely to be extremely small. This may not be true in the motor cortex, but the result is surprising nonetheless. It is not clear whether such changes actually encode the learned skill—thus constituting a motor engram—or serve some other, less specific role in the information processing that accompanies motor learning. Would similar fEPSP increases be seen for each new skill that is learned? Alternatively, might such a large change occur only when the rodent motor cortex is engaged in skill learning for the first time?

Learning-induced changes in evoked responses have also been observed in several other brain areas. For example, increased fEPSPs have been observed in the piriform cortex in conjunction with olfactory learning (Roman et al., 2004; Sevelinges et al., 2004); and enhancement of LTP accompanied by facilitation of LTD has also been reported (Lebel et al., 2001). Lasting potentiation of transmission at the parallel fiber–Purkinje cell synapse of the cerebellum has been observed following auditory fear conditioning (Sacchetti et al., 2004), and induction of an LTP-like effect during learning has been observed in the connections of the fimbria to the lateral septum (Jaffard et al., 1996). Synaptic changes are also implicated in the experience-dependent reorganization of

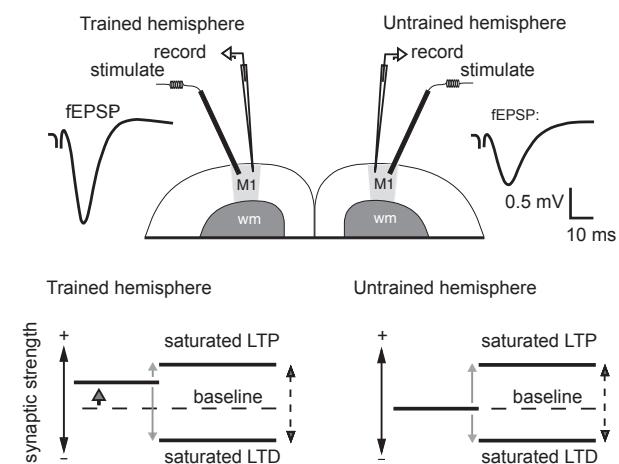

**A Exploration (STEM)****Heating only****B Exploration, with heating subtracted****C AMPA receptor trafficking induced by learning**

**Figure 10–22.** Detectability: induction of LTP-like changes in association with learning? *A, B.* Early studies that explored whether learning is associated with increased fEPSPs revealed some constraints on this approach. For example, novelty exploration is associated with an increase in both fEPSPs and brain temperature. Control studies established that in most cases the temperature change could explain some but not all of the change in fEPSPs that were at first thought to be due to learning-associated LTP induction. A short-lasting temperature-independent component can be detected. (*Source:* Moser et al., 1993a, 1994.) *C.* Fear conditioning in

cortical representations (e.g., Weinberger, 2004), but a detailed treatment of this topic is beyond the scope of this book.

**Associative Conditioning and Hippocampal fEPSPs**

Despite the difficulty of detecting hippocampal LTP-like phenomena after spatial learning, lasting changes in population measures of hippocampal activity have been observed after certain forms of conditioning (see Weisz et al., 1984). For example, an increase in the slope of the CA1 fEPSP has been reported in rat hippocampal slices prepared after contextual fear conditioning (Sacchetti et al., 2001) and in freely moving mice after auditory fear conditioning (Tang et al., 2003) and

**D Induction of LTP by motor learning**

the amygdala is associated with enhanced AMPA receptor trafficking, measured using rectification of AMPA receptor-mediated transmission as an index of mutated GluR1 subunit incorporation. See text for discussion. (*Source:* After Rumpel et al., 2005.) *D.* Motor learning restricted to one limb in rodents (food-pellet collecting) is associated with an increase in the size of fEPSPs in layer III of the contralateral motor cortex, and this increase occludes the extent of subsequent LTP induction relative to the opposite hemisphere. (*Source:* After Rioult-Pedotti et al., 1998, 2000.)

trace eyeblink conditioning (Gruart et al., 2006). In a follow-up to their original study, Sacchetti et al. (2002) found that, as in M1 and piriform cortex, learning results in partial occlusion of subsequent LTP only when assessed up to 1 day after training; the increase in fEPSPs was previously found to last for 7 days. Perhaps synapse formation occurs in tandem with the consolidation of existing memory trace, reestablishing the capacity for normal LTP after several days while preserving established changes in synaptic strength—although metaplastic changes might provide an alternative explanation (Abraham and Tate, 1997; cf. Moser, et al., 1993a; Lebel et al., 2001). Consistent with other early work of Moser et al. (1993b, 1994), mere exploration of a novel context without shock resulted in an increase in the evoked response and partial

occlusion of LTP in slices prepared 10 minutes after exploration but not at later time points. These findings confirm that exploration alone is insufficient to cause lasting potentiation of hippocampal fEPSPs (Sacchetti et al., 2001).

The less than compelling literature on detectability in the hippocampus considered so far received a major boost from two papers published in 2006. In the first study, Gruart et al. (2006) implanted stimulating and recording electrodes in area CA1 of the mouse hippocampus, and monitored Schaffer-commissural responses while animals were trained in a trace eyeblink conditioning task, using an airpuff as the unconditioned stimulus, and a tone as the conditioned stimulus. Trace conditioning is a hippocampus-dependent form of classical conditioning in which a delay is imposed between the end of the CS and the onset of the US. Gruart et al found that the amplitude of the evoked fEPSP significantly increased as training progressed, and then declined as the conditioned response was extinguished. Both learning and the potentiation of the fEPSP were NMDAR-dependent, indicating that the potentiation was LTP rather than some other facilitatory process. In the second study, from Mark Bear's laboratory, Whitlock et al. (2006) used a hippocampus-dependent one-trial learning procedure to look for changes in fEPSPs using an array of 8 recording electrodes implanted in area CA1. In a first recording session baseline responses were collected. The animals were then trained in an inhibitory avoidance conditioning task, in which the rat forms an immediate aversion to the dark compartment of a two-compartment box after receiving a footshock there. Animals were then returned to the recording chamber. Across all trained animals, a significant potentiation of the fEPSP was seen in 27% of electrodes, detectable as soon as recording was begun 15 min after the footshock, and continuing at a stable level for 4 hours. A tetanus was then given to test for occlusion. LTP was significantly greater at non-potentiated than potentiated recording sites; this partial occlusion is powerful evidence that the potentiation observed was LTP. Whitlock et al. wondered if their failure to see LTP at more recording sites was a reflection that learning induces both LTP and LTD. They examined this possibility using an ingenious biochemical approach. LTP and LTD are associated with phosphorylation of AMPA receptors at different residues (see Section 10.7.4); using phospho-antibodies specific to the two sites they were able to obtain a phosphorylation index of the degree of LTP and LTD in hippocampal tissue from trained and control animals. The surprising finding was that training was associated with an increase in phosphorylation at ser831, the LTP-specific residue, but no change at ser845, the LTD specific residue. A question for future work is whether this result can be reconciled with the widely held assumption that stability in the hippocampal network requires LTP at some synapses to be balanced by LTD at others. One possibility is that other forms of persistent depression, such as heterosynaptic depotentiation and depression, which may have different biochemical signatures and which are easier to obtain in adults than de-

novo LTD, provide the counterbalance. But perhaps the most provocative question to arise from this study is this: Given that some electrodes detect potentiation, why don't they all? The finding implies that synaptic weight changes are not uniformly distributed within the network, and suggests instead a "currant bun" model of memory, in which representations are stored in clusters of potentiated cells that are relatively far apart compared to the inter-electrode distance (250  $\mu\text{m}$ ) (see commentary by Bliss et al., 2006).

### **10.10.3 Anterograde Alteration: Do Manipulations That Block the Induction or Expression of Synaptic Plasticity Impair Learning?**

The SPM hypothesis requires that any manipulations that limit or block the induction or expression of synaptic plasticity in the hippocampus should have corresponding effects on hippocampus-dependent learning. Meeting this second criterion has proved a particularly popular approach, with numerous pharmacological, molecular-genetic, and occlusion studies being conducted. Enhancement of LTP might also enhance learning, but this prediction is less straightforward because, as the BCM theory of metaplasticity implies (see Section 10.3.13), LTP and LTD exist in dynamic equilibrium. Disrupting this equilibrium might cause dysfunction, even if the agent of disruption is enhanced LTP. Moreover, perturbations that enhance LTP could arise for several reasons, only some of which would be expected to enhance learning.

#### **Pharmacological Blockade of the NMDA Receptor Impairs Learning**

Morris et al. (1986) showed that chronic intraventricular infusion of the NMDA antagonist D,L-AP5 blocked spatial but not visual discrimination learning in a watermaze (Fig. 10–23A). Later work established that this effect was due to the active D-isomer of AP5 (Davis et al., 1992) and that it occurs with acute intrahippocampal infusions of D-AP5 (Morris et al., 1989) and over a range of intrahippocampal drug concentrations comparable to those that impair hippocampal LTP *in vivo* and *in vitro* (Davis et al., 1992). Numerous studies have since found that competitive NMDA antagonists impair hippocampus-dependent learning. Learning paradigms used include spatial learning, T-maze alternation, certain types of olfactory learning, contextual fear-conditioning, social transmission of food preference, flavor-place paired associate learning (delayed reinforcement of low rates of response—DRL), and other operant tasks (Danysz et al., 1988; Tonkiss et al., 1988; Staubli et al., 1989; Tonkiss and Rawlins, 1991; Bolhuis and Reid, 1992; Cole et al., 1993; Lyford et al., 1993; Caramanos and Shapiro, 1994; Fanselow et al., 1994; Li et al., 1997; Steele and Morris, 1999; Lee and Kesner, 2002; Roberts and Shapiro, 2002; Day et al., 2003; Bast et al., 2005; for reviews see Danysz et al., 1995 and Lynch, 2004). These data strongly sup-

port the SPM hypothesis, but there are problems with the interpretation of these findings associated with sensorimotor side effects of NMDA antagonists and effects of these drugs on neuronal processes other than LTP.

In humans, administration of ketamine results in hallucinations. We cannot know what rats are seeing or smelling under the influence of an NMDA antagonist. However, sensorimotor disturbances are sometimes observed during watermaze training with diffuse NMDA receptor blockade, including falling off the platform during a “wet-dog” shake, thigmotaxis, and failure to climb onto the platform (Cain et al., 1996; Saucier et al., 1996). Motor disturbances induced by NMDA antagonists are also seen during other tasks. Such abnormalities could be due to diffusion of drug to the thalamus disrupting the normal transmission of somatosensory and visual information (Sillito, 1985; Salt, 1986; Salt and Eaton, 1989) or to the striatum causing motor disturbances such as flaccidity (Turski et al., 1990). Clearly, learning cannot proceed when animals can neither sense nor move properly, and equally obviously it would be fallacious to assert that the drug is having a *direct* effect on learning mechanisms per se. Many laboratories have noted that animals treated with non-competitive NMDA antagonists (such as MK-801) show sensory inattention and motor stereotypies (Koek et al., 1988; Tricklebank et al., 1989; Keith and Rudy, 1990; Tiedtke et al., 1990; Mondadori and Weiskrantz, 1991; Danysz et al., 1995; Cain et al., 1996). At high doses, AP5-treated animals also display stereotypies, but these doses are substantially higher than those necessary to block LTP *in vivo* following regionally restricted infusion. These problems are much less apparent with acute intrahippocampal infusion.

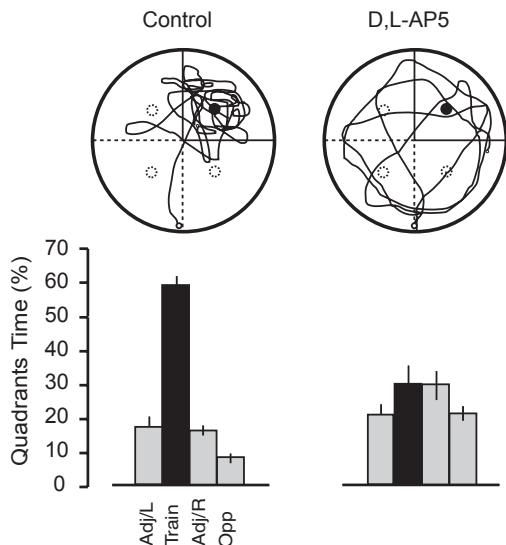

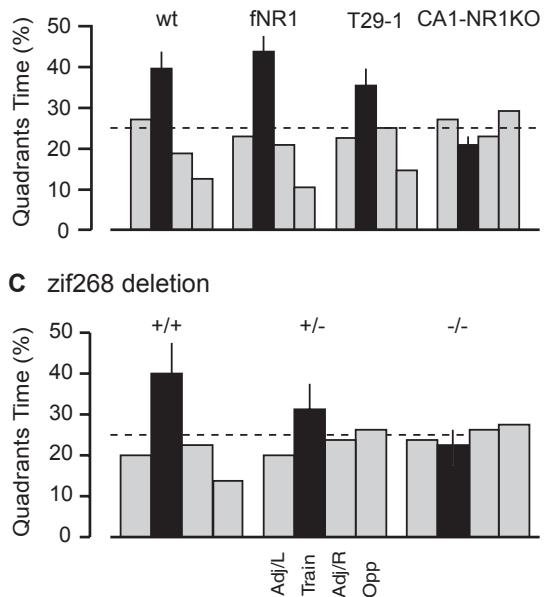

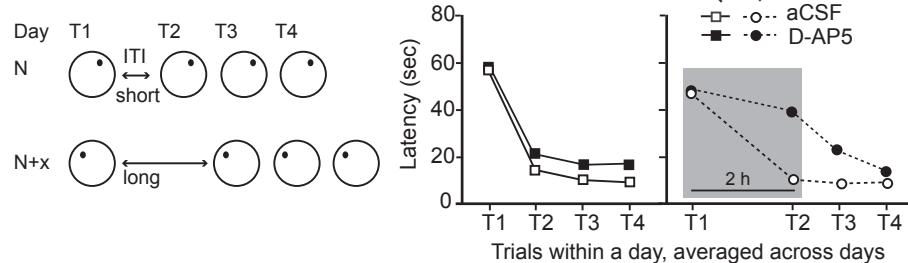

Using peripheral injections of an NMDA antagonist, Cain et al. (1996) showed that the impairment of spatial learning in a watermaze is correlated with the degree of sensorimotor impairment. They asserted that the sensorimotor deficit is primary and the learning deficit merely secondary. Saucier and Cain (1995) also observed that the impairment in watermaze learning that normally occurs following intraperitoneal administration of a competitive NMDA antagonist disappears if the animals are given sufficient pretraining to prevent the drug-induced sensorimotor disturbances seen in experimentally naive animals. Their pretrained animals showed a clear block of LTP after drug treatment, no sensorimotor impairment, and normal rates of spatial learning.

Other data indicate, however, that a deficit in spatial learning can still be observed, relative to appropriate control groups, following nonspatial pretraining (Morris, 1989; Bannerman et al., 1995). Bannerman et al. (1995) discovered that the usual AP5-induced learning deficit all but disappeared in animals trained first as normal animals in one watermaze (“downstairs”) before later being trained in a second watermaze (“upstairs”) under the influence of the drug. However, if training in the downstairs watermaze was non-spatial in character, with sight of extramaze cues occluded, the normal AP5-induced deficit in spatial learning was seen dur-

ing the second task. Sensorimotor disturbances were equally reduced by both procedures. Bannerman et al. (1995) suggested that blocking NMDA receptors dissociated different components of spatial learning—impairing an animal’s ability to learn the required strategy rather than the map of landmarks in the room in which the watermaze is situated. This explanation was apparently refuted by Hoh et al. (1999), who reported that watermaze “strategy learning” is unaffected by intraperitoneal administration of the NMDA antagonist CGS19755 during nonspatial pretraining at a dose that successfully blocks LTP in freely moving animals in both CA1 and the dentate gyrus. The drug-treated rats learned non-spatial strategies adequately and showed equivalent performance in subsequent spatial learning and spatial reversal relative to vehicle-treated control animals. Hoh et al. (1999) suggested that relative task difficulty may explain the different outcome of their study and that of Bannerman et al. (1995)—the latter study involved a larger pool and a smaller escape platform.

Using single-unit recording to study the effects of the NMDA antagonist 3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP) on hippocampal place fields (see Chapter 11), Kentros et al. (1998) showed that previously established firing fields are unchanged, and new place fields are acquired normally when rats are placed in a new environment. These findings are inconsistent with a sensorimotor disturbance hypothesis. Kentros et al. went on to show that the new place fields are unstable over time, implicating LTP induction in the learning of a new spatial context. Temporal instability of place fields was also observed in transgenic mice with altered LTP (Rotenberg et al., 1996). This temporal instability could account for Bannerman et al.’s (1995) finding of poor learning by naive animals trained with one trial per day but not the observation that spatially pretrained AP5-treated animals learn normally in a new environment.

Poor spatial memory over time in the presence of NMDA receptor blockade is unlikely to be specific to novel environments but task-specific in other ways. Steele and Morris (1999) trained rats in a delayed matching-to-place (DMP) task in the watermaze. In this variant of the task, the platform is hidden in a different location each day and stays there for four trials. Normal rats show quite long escape latencies on trial 1 (when they do not know where the platform is hidden) but much shorter latencies on subsequent trials (when they do). Most of the “savings” in escape latency occur between trials 1 and 2, indicative of one-trial learning. Infusion of APV had no effect on performance at a short memory delay (15-second intertrial interval) but caused pronounced impairment at 20 minutes and 2 hours. This delay-dependent deficit occurred irrespective of whether the animals stayed in the training context throughout the memory delay or were returned to the room with their home cages and irrespective of whether the drug was infused chronically into the ventricle or acutely into the hippocampus. If the AP5-induced impairment of the DMP task were sensorimotor or attentional in

**A NMDA receptor blockade impairs spatial learning****B NR1 deletion restricted to CA1****D One-shot spatial memory (DMP)**

**Figure 10–23.** Anterograde alteration of LTP and memory. *A*. Chronic intraventricular infusion of the NMDA receptor antagonist D,L-AP5 blocks LTP induction in the dentate gyrus (not shown) and impairs spatial memory in a watermaze. Swim paths show focused searching in the target quadrant only by aCSF controls. Other experiments established that the drug spared simple visual discrimination learning. (*Source:* After Morris et al., 1986.) *B*. Cell-type and region-specific knockout of the NR1 subunit of the NMDA receptor in area CA1 of the hippocampus blocks LTP induction (not shown) and impairs spatial reference memory. (*Source:* After Tsien et al., 1996.) *C*. Knockout of the immediate early gene

*zif268* impairs LTP and long-term memory in the watermaze. Other experiments established that short-term memory was intact. (*Source:* After Jones et al., 2001.) *D*. One-shot learning in the watermaze can be studied using the DMP paradigm (see Figure 13–23 for explanation). Intrahippocampal D-AP5 infusion blocks memory of a one-time experience after 2 hours but leaves short-term (15 seconds) memory unaffected. (*Source:* After Steele and Morris, 1999.) *E*. Region-specific knockout of NR1 in area CA3 leaves spatial reference memory intact but impairs one-shot memory. (*Source:* After Nakazawa et al., 2003.)

nature, a deficit would be expected at all delays. The delay-dependent memory impairment is inconsistent with Kentros et al.'s (1998) proposal that temporal instability occurs only in a novel context.

In addition to addressing the potential sensorimotor side effects of AP5, the study by Steele and Morris (1999) indicated that rapid spatial learning remains sensitive to NMDA receptor blockade, even after pretraining. (The animals tested in this study received several days of “pretraining” on the DMP task prior to surgery and drug infusion). It may be significant that the DMP task requires the trial-unique encoding of novel locations, whereas the reference memory task involves the

incremental learning of a single location over multiple trials. Consequently, the reference memory task may require little hippocampal synaptic plasticity in experienced animals, whereas substantial NMDAR-dependent plasticity might remain essential for one-trial encoding, even after extensive training. Consistent with this, selective impairment for rapid learning has been observed after several genetic interventions. Mice lacking the GluRI (GluR-A) subunit of the AMPA receptor, for example, have profound deficits in CA1 LTP, but acquisition of a watermaze reference memory task is normal; severe impairments are found in spatial working memory, however, such as T-maze nonmatching to place (see Chapter 7

for a detailed discussion). Similar results have also been obtained after targeting an entirely different component of the hippocampal circuitry—the recurrent collateral system of CA3. Mice with a CA3-specific knockout of the gene coding for the NR1 subunit of the NMDA receptor lack associative LTP in this subregion (although the direct entorhinal input to CA3 is probably also compromised), but the acquisition of a standard watermaze reference memory task remains unaffected, at least when all cues are present during retrieval (Nakazawa et al., 2002). Performance in a DMP version of the task, in contrast, is markedly impaired (Nakazawa et al., 2003). Molecular-genetic approaches are discussed below.

The NMDA receptor is implicated in the induction but not the expression of LTP (see Section 10.3). By analogy, one may predict that NMDA antagonists should impair the encoding of new memory “traces” (induction) but have no effect on memory retrieval (expression). Consistent with this idea, Staubli et al. (1989) found that administering AP5 to animals after they had been trained in odor discrimination learning had no effect on retention, although the drug did impair new learning. Entorhinal cortex lesions, on the other hand, cause rapid forgetting of olfactory information (Staubli et al., 1984). Likewise, Morris (1989) and Morris et al. (1990) found that APV had no effect on retention of a previously trained watermaze task, whereas lesions of the hippocampal formation were disruptive when given shortly after the end of training. Similar deficits in encoding but not retrieval were noted in the DMP task of Steele and Morris (1999). Using a one-trial paired-associate learning paradigm, Day et al. (2003) showed that intrahippocampal infusion of D-AP5 prior to the “sample” trial when two novel stimuli were paired for the first time caused subsequent choice performance in the memory “retrieval” trial to fall to chance. Delaying the infusion of D-AP5 by 20 minutes until after the sample trial, such that memory retrieval was also conducted with dorsal hippocampal NMDA receptors blocked, had no effect on memory. Both effects were seen at doses sufficient to block LTP *in vivo*. Similar recent results were recently obtained in a purely spatial version of the task (Bast et al., 2005).

Long-term memory retention can, however, be impaired by the blockade of hippocampal NMDA receptors soon after, as well as during, learning (Izquierdo et al., 1993, 1998; Packard and Teather, 1997; McDonald et al., 2005). These findings suggest that the early stabilization of memory requires additional “offline” episodes of NMDA receptor activation after initial encoding. The involvement of NMDA receptors in systems consolidation and long-term information is less well understood. Shimizu et al. (2000) used the tTA and Cre/loxP systems to develop a mouse with an apparently CA1-specific (but see Fukaya et al., 2003) inducible deletion of the NMDA NR1 subunit. Deletion of this subunit by application of doxycycline 1 to 7 days after training on a watermaze reference memory task caused subsequent impairment in retention of the platform location. However, chronic blockade of hippocampal NMDA receptors during the days after spatial

training by either daily injections of CPP in rats (Villarreal et al., 2002) or intraventricular minipump infusions of D-AP5 in both rats and mice (Day and Langston, 2006) does not impair retention. In fact, Villarreal et al. (2002) reported enhancement of spatial memory after posttraining NMDA receptor antagonism, consistent with their additional finding that chronic NMDA receptor blockade prevents the decay of LTP that usually occurs over a period of several days. Modest enhancement of retention was also found by Day and Langston (2006). Perhaps the blockade of synaptic plasticity after training reduces retroactive interference from ongoing experience that might otherwise degrade the original memory (see also Rosenzweig et al., 2002).

Several studies have indicated that low doses of NMDA receptor antagonists can, paradoxically, enhance the learning of certain tasks, such as step-down inhibitory avoidance (Mondadori et al., 1989) and social learning (Lederer et al., 1993). These findings do not challenge the SPM hypothesis because the effects are observed at doses far too low to block LTP *in vivo*, and different mechanisms are likely to be involved in antagonist-induced facilitation of learning. For instance, the facilitation of inhibitory avoidance by low doses of NMDA antagonists is sensitive to pretreatment by steroids such as aldosterone or corticosterone, whereas the impaired inhibitory avoidance caused by high doses is steroid-insensitive (Mondadori and Weiskrantz, 1993; Mondadori et al., 1996). Work with the noncompetitive NMDA receptor antagonist memantine has also led to counterintuitive findings by virtue of its rapid on-and-off kinetics of channel blocking. At therapeutic doses, memantine does not impair learning or LTP, but it does limit neurotoxicity and so prevent impairments in cognitive function or their accumulation over time (Parsons et al., 1999).

Studies targeting the NMDA receptor are now complemented by many pharmacological manipulations directed at the diversity of receptors and intracellular signaling pathways that play a role in synaptic plasticity. To take just one example, there is considerable evidence that blockade or knockout of group I mGluRs, a class of receptor implicated in both LTP and LTD (see Section 10.3), can impair a variety of forms of memory, including spatial learning, contextual fear conditioning, and inhibitory avoidance (for reviews see Holscher et al., 1999; Riedel et al., 2003; Simonyi et al., 2005). For a fuller account of pharmacological interventions targeting sites other than the NMDA receptor, see Lynch (2004).

#### **Targeted Disruption of the NMDA Receptor and Downstream Signal-transduction Pathways Impairs Hippocampus-dependent Learning**

Some of the earliest uses of targeted molecular engineering in neuroscience were in relation to synaptic plasticity and learning in studies of downstream signal-transduction pathways (Silva et al., 1992a,b; Grant et al., 1995). These early studies revealed intriguing correlations between LTP and

hippocampus-dependent learning. They set the pattern for a host of subsequent studies in which homologous recombination was used to delete genes in all cells of the body for the lifetime of the animal (Capecci, 1989). The approach is often characterized by cell biological evidence that the deletion has been successful, followed by electrophysiological and behavioral analyses of the phenotype of the mutant progeny. The array of generally positive findings obtained from well over 100 relevant knockouts developed since 1992 lends general support to the SPM hypothesis (see Table 5 in Lynch (2004).

Numerous problems, however, were soon identified. For certain critically important proteins, there can be a catastrophic outcome such as embryonic or perinatal lethality. This occurred with an attempted deletion of the NR1 subtype of the NMDA receptor (Chen and Tonegawa, 1997), although deletion of the NR2A ( $\epsilon 1$ ) subunit using conventional homologous recombination could be successfully carried forward to adults, and these mice showed a deficit in both hippocampal LTP and spatial learning (Sakimura et al., 1995). Other mutants display the opposite problem, a null phenotype, though it is hard to believe that key brain enzymes have no function. Either inappropriate behavioral assays have been used, or there has been compensation by other closely related genes (Grant et al., 1995). Another problem is interanimal variability; for example, it is puzzling that some slices from the  $\alpha$ CaMKII mutants studied by Silva et al. (1992a) show normal LTP, whereas most show none unless parallel biochemical pathways can be activated in a probabilistic fashion. Hinds et al. (1998) reported a yet higher proportion of  $\alpha$ CaMKII mutants showing normal LTP and suggested that the  $\beta$  enzyme may have been upregulated. Hinds et al.'s (1998) study involved animals cross-bred with C57/BL6 mice. The issue of genetic background is important: The embryonic stem cells most widely used to make mutants are derived from a specific strain of mice—the Sv129 strain; and when these mice are cross-bred with strains such as C57/BL6, a number of “flanking” genes derived from the 129 strain are still expressed alongside the mutated gene. Aspects of the resulting phenotype may reflect these flanking genes (Gerlai, 1996). Residual Sv129 genes have unpredictable effects and are undesirable because the Sv129 strain is notoriously poor at learning (Lipp and Wolfer, 1998). Recommendations about the desirability of back-crosses into more suitable strains (such as C57/BL6) were subsequently discussed in the gene-targeting community and a set of guidelines published (Anonymous, 1997).

Another issue is that many studies examine LTP only using *in vitro* brain slices. This is insufficient and a separate consideration concerns the value of looking at LTP *in vivo*. Nosten-Bertrand et al. (1996) found that *thy-1* mutants had normal LTP in area CA1 but no LTP in the dentate gyrus when measured in anesthetized animals *in vivo*. Further studies revealed, however, that normal LTP could be obtained in dentate slices when bicuculline was added to reduce inhibition, implying that the machinery for inducing LTP must still be present in *thy-1* mutants. When bicuculline was infused locally *in vivo* in

small quantities (to avoid seizure activity), the now disinhibited area of the dentate showed normal LTP. Errington et al. (1997) also found that LTP in freely moving *thy-1* mutants was compromised but not totally abolished, with a wide range of variability among individual animals. An important general message of the *thy-1* study for the field is that electrophysiological results in brain slices are not infallible predictors of what might happen to synaptic plasticity in the whole animal. The study also highlights the value of assessing both learning and LTP in the same animals.

A third problem when using mice to assess the SPM hypothesis has been the inappropriate interpretation of behavioral studies. Some studies using the watermaze with transgenic mice have used an apparatus that is too small to study spatial learning effectively (< 1.2 m) or failed to use posttraining probe tests. In a careful factor analysis of hundreds of experiments, Wolfer et al. (1998) statistically dissociated spatial learning in the watermaze from thigmotaxis and other species-specific swimming strategies. Emphasizing also the value of looking at LTP *in vivo* in association with behavioral studies, their work has played an important part in improving the analytical quality of modern studies.

Regionally specific mutants can now be made in which CRE recombinase is expressed downstream of specific promoters in one line of mice that, after crossing, target genes flanked with *loxP* sites in another. The resulting progeny enable the development of mutant strains in which a target gene is deleted (or mutated) in only one area of the brain. This approach was used to knock out the NR1 subunit of the NMDA receptor in area CA1 of the hippocampus only (Tsien et al., 1996; Mayford et al., 1997). The mice showed no LTP in area CA1, normal LTP in the dentate gyrus and neocortex, and learning impairment in the watermaze (Fig. 10–23B). Using multiple single-unit recording, McHugh et al. (1996) discovered that these mice had abnormal place fields and a reduction in the correlated firing of cells with overlapping place fields (see Chapter 11). Such regionally specific manipulations are beginning to allow the targeting of specific components of the hippocampal network. For example, Nakazawa et al. (2002) created a mouse in which the NR1 gene was deleted only in CA3, a manipulation that blocks NMDAR-dependent LTP at CA3 recurrent synapses but not NMDAR-independent potentiation in the mossy fiber input. These mice learned a watermaze reference memory task as well as the control animals. Retention was likewise unaffected when all extramaze cues were present, but performance deteriorated substantially when only partial cues were present (see Chapter 13, Fig. 13–21). These findings are consistent with a long-held view of CA3 as an autoassociative network capable of pattern completion—reconstruction of a complete output pattern from partial or degraded input (cf. Marr, 1971). According to this view, synaptic plasticity at recurrent synapses is necessary for the formation of a memory trace that can later be recalled in the presence of partial retrieval cues. In a follow-up study, the same mice were found to be impaired in one-trial place learn-

ing (see above), again supporting the notion of CA3 as a rapid autoassociative storage device (Nakazawa et al., 2003). Consistent with this finding, place cell recordings in area CA1 of these mice revealed a reduction in spatial tuning during early exploration of novel environments, implicating CA3 synaptic plasticity in the refinement of the spatial representation supported by the direct entorhinal input to CA1 (see Brun et al., 2002). The Cre-loxP system has now been used to target many components of the plasticity machinery in addition to the NMDA receptor (for reviews see Matynia et al., 2002; Lynch, 2004). For example, mice lacking the AMPA receptor GluRI (GluR-A) subunit show impairments in CA1 LTP and spatial working memory, although the acquisition of spatial reference memory is unaffected (Zamanillo et al., 1999; Reisel et al., 2002) (see Chapter 7). The impairments in LTP and memory can be rescued by adding a forebrain-specific GFP-tagged GluRI expression system to these mice, confirming the specificity of the impairment (Schmitt et al., 2005).

Region- and cell type-specific interventions are powerful, as they carry the potential to investigate gene function in specific cells, to manipulate pre- or postsynaptic sites of synapses independently, and to intervene in biochemical pathways for which there is no known ligand. The  $\alpha$ CaMKII promoter has been useful in such experiments because it is not activated until around day 20, obviating certain developmental problems. The approach, however, is expensive as numerous lines have to be developed of which only some show useful expression patterns. Moreover, although achieving precise regional and cell-type specificity is advantageous over pharmacological manipulations, it does not yet allow the same precise temporal control as drugs. In the previous section, experiments were described in which animals were “normal” in one phase of an experiment but “treated” in another. This enabled dissociations between encoding and retrieval processes of memory to be addressed using highly selective antagonists such as D-AP5. The corresponding way forward, using genetic interventions, is via conditional mutants in which inducible promoters are engineered to put gene activation (or inactivation) under experimental control. Use of the tetracycline transactivator systems, rtTA and tTA (see Box 7.1), provides one example of this approach (see Furth et al., 1994; Kistner et al., 1996). Inducible genetic interventions also finesse the complications of altered neuronal development that can occur with nonconditional knockouts (Lathe and Morris, 1994; Mayford et al., 1997) and can otherwise only be addressed using “rescue” experiments.

Using inducible techniques, Mayford et al. (1996) created a transgenic mouse in which overexpression of a constitutive CaMKII was under the control of tetracycline. This study built upon previous work using standard transgenic mice that overexpress the autophosphorylated form of CaMKII through a point mutation of Thr<sup>286</sup> (Mayford et al., 1995). These animals had exhibited normal CA1 LTP in response to high-frequency stimulation at 100 Hz, but stimulation in the 5- to 10-Hz range (encompassing theta) preferentially resulted in

LTD rather than LTP—a shift of  $\theta$  in the BCM function seen in Box Fig. 10–2A. Hippocampus-dependent learning was impaired: The mice showed impaired spatial learning using a Barnes maze (Bach et al., 1995). Mayford et al. (1996) replicated the learning impairments and deficits in LTP found by Bach et al. (1995) and Mayford et al. (1995), with suppression of the transgene by administration of doxycycline relieving the impairment of both learning and synaptic plasticity. Work by Giese et al. (1998) complemented these studies. Instead of using transgenic techniques, they introduced a point mutation (threonine to alanine) into the gene encoding  $\alpha$ CaMKII to block autophosphorylation at residue 286, thereby preventing the transition of this kinase into a CaM-independent state without disrupting its CaM-dependent activity. LTP could not be elicited in area CA1 in the mutant mice across a range of stimulation frequencies, a slightly different profile to that shown by Mayford’s transgenic mouse. Giese et al.’s mice also had profound deficits in spatial learning in the watermaze and showed altered dependence on extramaze versus intramaze cues in single-unit recording studies of place cells (Cho et al., 1998). Although this mutation is not inducible, temporal control can be achieved by combining pharmacological and molecular genetic techniques. Heterozygous Thr<sup>286</sup> mutant mice have no deficit in contextual fear conditioning or LTP, but injection of a low dose of CPP that in wild type mice has no effect results in impairment of both learning and plasticity, suggesting that the NMDAR-dependent activation of  $\alpha$ CaMKII is necessary for both processes (Ohno et al., 2001, 2002).

Other early studies to use the tTA technique were those of Mansuy et al. (1998a,b) and Winder et al. (1998). They reported that transgenic mice overexpressing a truncated form of the phosphatase calcineurin display normal early-LTP and short-term memory but defective late-LTP and long-term memory. However, evidence that the latter deficit was secondary to some other problem came from behavioral work showing that a change in training protocol could “rescue” the impaired long-term memory. This suggested that the deficit in these animals was more likely in the transition from short- to long-term memory than in the mechanisms underlying either on its own. Regulation of calcineurin overexpression using the rtTA technique was examined in animals tested in the watermaze (Mansuy et al., 1998b). In the latter study, animals completed training and were first tested with the transgene “off.” They learned the platform location as indexed by good performance in a posttraining probe test. When the transgene was then turned “on,” performance in a second probe test fell to chance; and when it was later turned “off” again, performance recovered. These results suggest that calcineurin constrains memory retrieval. The rtTA system has also been used to enhance the inhibition of calcineurin. Malleret et al. (2001) created a mouse with inducible overexpression of a C-terminal autoinhibitory domain that reduces calcineurin activity. Expression of the transgene facilitated LTP both *in vivo* and *in vitro* but did not affect LTD. Parallel enhancement of hip-

pocampus-dependent memory was observed. Following an analogous strategy, a regulatory subunit of calcineurin, CNB1, was deleted in a forebrain-specific manner, resulting in reduced calcineurin activity (Zeng et al., 2001). Although the mutation was not inducible, it did not become detectable until 5 weeks of age, obviating to some extent the possibility of developmental consequences. No enhancement of LTP was evident following a standard high-frequency tetanus, but an overall leftward shift in the function relating LTP/ LTD to tetanus frequency was observed together with impaired LTD. Perhaps for the latter reason, these mice did not show enhanced learning and memory. Performance in a watermaze reference memory task was normal, but acquisition of a task requiring the learning of multiple novel locations was impaired, as was performance in a radial-arm maze working memory task. These findings highlight the potential importance of decreases, as well as increases, in synaptic strength. Perhaps LTD-like mechanisms are particularly important in tasks that require flexible learning of new information in conjunction with rapid suppression of information that is no longer relevant (cf. Manahan-Vaughan and Brauneckell, 1999; Kemp and Manahan-Vaughan, 2004).

Despite its power, the tTA system still requires several days for complete induction and repression, and advances in temporal control are eagerly awaited. A novel inducible system has since been developed based on fusion of a target protein with the ligand-binding domain of the estrogen receptor modified to bind tamoxifen instead of estrogen (Kida et al., 2002). Using this system, expression can be turned on and off within hours, but the range of potential target proteins is limited compared to the tTA approach. Another development is the increasing use of viral vector-mediated gene transfer. This approach enables the targeted and temporally controlled overexpression of transgenes following local transfection within a specific brain region. For example, the virus-mediated expression of calcium-permeable AMPA receptors in CA1 resulted in enhanced CA1 LTP *in vitro* and facilitated place learning and memory (Okada et al., 2003). However, dentate transfection impaired watermaze performance despite similar enhancement of LTP, perhaps reflecting functional differences between these two subregions. The behavioral consequences of enhancing LTP are considered in more detail in the following section. In another study, intrahippocampal infusion of a viral vector conveying an inactive mutant form of CREB was found to block long-term, but not short-term, memory for socially transmitted food preference (Brightwell et al., 2005). Conversely, overexpression of CREB induced by intraamygdalar infusion of a viral vector results in enhancement of amygdala-dependent memory (Josselyn et al., 2001; Jasnow et al., 2005). Alternatively, the virus-mediated delivery of Cre can be used to trigger deletion of a target gene flanked by lox-P sites (e.g., Scammell et al., 2003). Using this technique, Rajji et al. (2006) were able to target deletion of the NR1 gene to area CA3 of the dorsal hippocampus, a manipulation that resulted in an impairment in the acqui-

sition, but not the expression, of odor-context paired associate memory.

Good temporal control can also be achieved using antisense techniques. These methods lie somewhere between the genetic and pharmacological approaches, having some of advantages and disadvantages of both. Examples of their use include studies in which the expression of mRNA for two different potassium channels was reduced by repeated intracerebroventricular injections of oligodeoxyribonucleotides to reveal a dissociation between learning and plasticity. Antisense disruption of the presynaptic A-type potassium channel, Kv 1.4, eliminated both early and late phases of CA1 LTP without affecting LTP in the dentate gyrus in rats (Meiri et al., 1998). However, this antisense “knockdown” of plasticity had no effect on spatial learning. Given that threshold changes in the intensity of the tetanus required to induce LTP have been seen with some genetic manipulations (Kiyama et al., 1998), the fact that Meiri et al. (1998) used different intensities to induce LTP significantly strengthens their conclusion that CA1 LTP was successfully blocked in the antisense group. However, this study did not include *in vivo* observations, a range of tetanization frequencies (Mayford et al., 1995; Migaud et al., 1998), or information about the regional spread of the antisense oligo. The latter point is important, as LTP may have been monitored in an area along the longitudinal axis of the hippocampus that was affected by the oligo, whereas learning may have utilized neurons along the full length of this axis. It should be recognized, however, that antisense disruption of Kv 1.1, a different potassium channel that is highly localized in dendrites of CA3 neurons, had no effect on LTP in either the CA1 subfield or the dentate gyrus but did cause profound deficits in spatial learning (Meiri et al., 1997). Clearly, the longitudinal axis objection cannot apply here, and the significance of both these studies should be recognized. The antisense approach has also generated discrepancies between LTP and memory in the opposite direction (i.e., enhanced LTP associated with impaired memory) (Pineda et al., 2004), although such findings are potentially less troublesome for the synaptic plasticity and memory hypothesis, as discussed below. Other studies have reported parallel effects on both LTP and memory (Guzowski et al., 2000; Hou et al., 2004). In the former study, for example, antisense inhibition of the expression of hippocampal Arc protein (see Section 10.9) resulted in a deficit in long-term spatial memory in a watermaze reference memory task and impairment in the late maintenance of dentate LTP *in vivo* (Guzowski et al., 2000), consistent with a role for Arc in the long-term synaptic modifications postulated to underlie memory storage.

The development of methods for gene silencing does not end with the antisense approach. A more effective alternative to antisense knockdown is the RNA interference technique (RNAi). In a refinement of this technique, small interfering RNA (siRNA) sequences are targeted to a specific brain region by local electroporation or by viral transfection, thereby offering excellent regional and temporal control (Akaneya et al.,

2005). Although highly promising, this approach has not yet been applied to studies of hippocampal synaptic plasticity and memory.

### Do Treatments That Enhance LTP Also Enhance Memory?

As we discussed earlier, the circuit-level consequences of enhancing synaptic plasticity may be far from straightforward. Synaptic plasticity might normally be optimally tuned for the efficient encoding of information, such that any disturbance—even enhancement—has disruptive effects on memory. Nonetheless, many pharmacological and molecular-genetic manipulations do enhance both LTP and memory. Perhaps the best-known example of the pharmacological approach involves treatment with “ampakines,” which decrease the rate of AMPA receptor desensitization and slow the deactivation of receptor currents after agonist application (Arai et al., 1994, 1996). Consequently, they facilitate the induction of hippocampal LTP (Staubli et al., 1994); and there is now a considerable body of evidence that they can enhance the encoding of memory in a variety of tasks (Lynch, 2006). A number of other compounds have also been reported to enhance both learning and hippocampal LTP (Cooke and Bliss, 2005).

Similarly, Manabe et al. (1998) reported that mice lacking the nociceptin/orphaninFQ receptor show enhanced LTP in area CA1 (possibly also due to a change in K<sup>+</sup> channel function) and both a modest but significant decrease in escape latency in the watermaze and enhanced memory consolidation in step-through avoidance learning. In a widely discussed study, Tang et al. (1999) showed that overexpression of the “juvenile” 2B subunit of the NMDA receptor both facilitated LTP across a range of induction frequencies and enhanced memory in novel object recognition, cue and context fear-conditioning, and the earliest stages of learning a watermaze. This pattern of results has since been observed following many other genetic interventions (e.g., Futatsugi et al., 1999; Madani et al., 1999; Routtenberg et al., 2000; Malleret et al., 2001; Nakamura et al., 2001; Jeon et al., 2003).

In contrast, Migaud et al. (1998) reported that a PSD-95 mutant that shows enhanced hippocampal LTP and decreased LTD across a range of induction frequencies displays profound impairment of watermaze performance. The finding of enhanced LTP and impaired spatial memory has since been reported in several other strains of mutant mice (Uetani et al., 2000; Zeng et al., 2001; Kaksonen et al., 2002; Cox et al., 2003; Vaillend et al., 2004), whereas other interventions result in normal (or near-normal) spatial memory despite enhancement of LTP (Jun et al., 1998; Gu et al., 2002; Cox et al., 2003; Pineda et al., 2004). However, impairment of other forms of memory were reported in some of these studies. In some cases, impaired behavioral performance might result from the dysfunction of extrahippocampal systems (Gerlai et al., 1998), but other factors may also be relevant. For instance, the PSD-95 mutant mice created by Migaud et al. (1998) exhibited a shift in θ<sub>M</sub> of the BCM function well to the left of its optimal

position for bidirectional plasticity. Perhaps it is this abnormality or simply a deficiency in LTD that underlies the learning problems evident in these animals.

### Parallels Between Different Phases of LTP Expression and Memory Consolidation

There is considerable evidence that both hippocampus-dependent memories and increases in synaptic strength each undergo a period of consolidation in the minutes to hours following their formation (McGaugh, 2000). A variety of interventions can interfere with both memory consolidation and stabilization of LTP, including (1) disrupting the activity of a range of protein kinases (Izquierdo and Medina, 1997; Micheau and Riedel, 1999) such as CaMKII (Lisman et al., 2002; Colbran and Brown, 2004), MAPK/ERK (Kelleher et al., 2004a; Sweatt, 2004; Thomas and Huganir, 2004), tyrosine kinases (Purcell and Carew, 2003), PKA (Nguyen and Woo, 2003), and PKC (Sun and Alkon, 2005); (2) disrupting the expression of immediate early genes such as *Zif268* (Jones et al., 2000) (Fig. 10–23C) or *arc* (Guzowski et al., 2000); (3) temporary neuronal inactivation (e.g., Ambrogi Lorenzini et al., 1999; Florian and Roullet, 2004; Daumas et al., 2005); and (4) inhibition of macromolecular synthesis (for review see Davis and Squire, 1984; Frey and Morris, 1998a; Dudai and Morris, 2000). Growing evidence also supports a role for cell adhesion molecules in consolidation processes (Murase and Schuman, 1999; Benson et al., 2000; Gall and Lynch, 2004). Studies such as these offer broad support for the idea that lasting changes in synaptic strength underlie the formation of long-term memory.

For instance, late-LTP (i.e., LTP lasting around 4 hours or more), like cellular consolidation, requires synthesis of new proteins (for review see Frey and Morris, 1998a). As discussed in Section 10.4.9, application of protein synthesis inhibitors such as anisomycin prevents late-LTP. Importantly, however, the events leading to protein synthesis do not have to occur at exactly the same time as the stimulation that induces synaptic potentiation. Tetanization in the presence of a protein synthesis inhibitor still results in late-LTP if a strong tetanus is applied to a separate pathway up to 2 hours previously (Frey and Morris, 1997). Together with other findings, this result has led to the notion that a high-frequency tetanus sets “synaptic tags” that can capture plasticity proteins as they become available (Frey and Morris, 1997, 1998b). The same may be true of memory formation. Activation of neuromodulatory systems by novelty, reward, or punishment (Frey et al., 2001; Richter-Levin and Akirav, 2003; Lisman and Grace, 2005) may cause widespread upregulation of gene expression and protein synthesis via activation of cAMP-, PKA-, and CREB-dependent pathways. This would enable capture of proteins by synapses that have recently been potentiated and “tagged” or are about to be potentiated as a result of normal experience (Frey and Morris, 1998a). However, MAPK-mediated upregulation of translation—perhaps in dendrites—

might also be critical under some circumstances (Martin et al., 2000a; Steward and Schuman, 2003; Kelleher et al., 2004b) (see Section 10.4 for a discussion of dendritic protein synthesis). The interaction of specific synaptic signals with widespread transcriptional or translational upregulation may provide an explanation for the facilitated retention of memory for episodes occurring shortly before or after events of motivational importance, episodes that would otherwise be rapidly forgotten (cf. Seidenbecher et al., 1995).

Consistent with this scenario, a number of studies have suggested that activation of CREB is necessary for both the induction of hippocampal late-LTP and the formation of long-term memory (i.e., cellular consolidation) in mice and rats (Bourtchuladze et al., 1994; Bernabeu et al., 1997; Guzowski and McGaugh, 1997; Kogan et al., 2000; Pittenger et al., 2002; Brightwell et al., 2005; Wood et al., 2005). Barco et al. (2002) recently created a mouse in which a constitutively active form of CREB, VP16-CREB, is expressed in a forebrain-restricted and temporally regulated manner. In these animals, the threshold for late-LTP induction in the Schaffer-commissural to CA1 pyramidal cell pathway was reduced, such that a weak tetanus capable of inducing only a decremental early-LTP in normal mice induced late-LTP in VP16-CREB animals. These findings suggest that elevated CREB-mediated transcription in these animals leads to synthesis of a pool of proteins or mRNAs that can subsequently be captured by synapses tagged during weak tetanization, without the need for new transcription. A follow-up study implicates the overexpression of BDNF in this phenomenon (Barco et al., 2002). However, it is not yet known whether VP16-CREB mice exhibit enhanced long-term memory for weakly encoded information, consistent with their LTP phenotype.

#### **Does Saturation of LTP or LTD Occlude the Encoding of New Memory Traces?**

In studies of expression mechanisms for LTP, occlusion was often deployed as a tool to identify that LTP had been engaged. The same approach can be deployed in behavioral studies. It is important, however, to distinguish between the cumulative induction of LTP (or LTD) and the saturation of either process. Successive episodes of LTP may have a cumulative effect on synaptic strength, at least at a population level (cf. Petersen et al., 1998), but not saturate the plasticity available on the pathway being stimulated (Jeffery, 1997). Cumulative LTP may *enhance* neural throughput and so improve learning. Berger (1984) obtained just such a result in a study of nictitating membrane conditioning in rabbits, the original species in which LTP was discovered. In contrast, true saturation of LTP prior to behavioral training should *prevent* new learning because no further LTP would then be possible. Similar considerations would apply to saturation of LTD, which can be achieved with three successive trains of stimulus pairs (Thiels et al., 1998).

Research on the behavioral effects of LTP saturation

reached an impasse in 1993 when a series of articles (Cain et al., 1993; Jeffery and Morris, 1993; Korol et al., 1993; Sutherland et al., 1993) reported an inability to replicate earlier findings indicating that saturation induced reversible occlusion of subsequent spatial learning (McNaughton et al., 1986; Castro et al., 1989). Jeffery and Morris (1993) and Korol et al. (1993) conducted exact replications of part of Castro et al.'s (1989) experiment. In neither study was any learning deficit observed. Reid and Stewart (1997) succeeded in replicating Castro et al.'s findings, including decay of the effect over time, but they used electroconvulsive seizures, which among other effects can cause indiscriminate induction of LTP rather than explicit saturation on a single pathway.

Bliss and Richter-Levin (1993) suggested several reasons the negative results might have been obtained: (1) cumulative LTP of perforant path terminals may not have reached a true state of saturation; (2) perforant path terminals may have been sufficiently saturated, but not those of other extrinsic or intrinsic hippocampal pathways that are also critical for learning (e.g., CA3-CA1 terminals); (3) appropriate saturation of the full septotemporal axis of the hippocampus may not have been achieved with stimulation at a single site in the angular bundle. Evidence for this third idea was presented by Barnes et al. (1994), who found upregulation of the immediate early gene *zif-268* restricted to the dorsal hippocampus after stimulation at one site in the angular bundle. They also noted differences in the sensitivity of various learning tasks to LTP saturation.

Moser et al. (1998) designed a study with these issues in mind. There were three key features: (1) use of an array of cross-bundle stimulation electrodes designed to maximally activate the perforant path, with the cathode switched frequently between active electrodes; (2) use of a separate "probe" stimulating electrode to test whether the asymptotic LTP induced by the electrode array was true saturation of LTP on that pathway; (3) use of animals given unilateral hippocampal lesions to reduce the amount of tissue to be potentiated. Subsequent to multiple high-frequency (HF) trains or control low-frequency (LF) stimulation, the rats were trained in a standard watermaze task. Controls learned normally. The HF group showed a bimodal distribution, with some animals learning where the platform was located and others failing to learn. When all animals were subsequently tested for induction of LTP from the probe site in the perforant path, the HF animals in which it was impossible to induce further LTP (i.e., the "saturated" subgroup) were the ones that had failed to learn the watermaze, whereas those in whom LTP could still be induced had learned a little about where the platform was located. Thus, true saturation of LTP in the perforant path does impair spatial learning. These findings vindicate the earlier claims of McNaughton et al. (1986) and Castro et al. (1989).

Despite these positive findings, there remains skepticism about the analytical potential of the occlusion approach. One concern is that repeated tetanization may result in acute pathological phenomena, such as seizure-like after-discharges,

that would cause learning deficits (McEachern and Shaw, 1996). However, Moser et al. (1998) found no after-discharges during tetanization. Also, learning was impaired only in the animals with saturated LTP, despite all rats having received the same course of tetanic stimulation. A second point concerns homeostatic compensatory changes, such as altered inhibitory transmission, synapse formation, and reduced postsynaptic sensitivity. These compensatory changes were considered in a review article by Moser and Moser (1999) but primarily as factors contributing to the difficulty often experienced in saturating LTP. Even when LTP saturation is successful, it might still be argued that such changes, rather than saturation itself, are responsible for the learning impairment. A third area of disquiet is that LTP saturation does, of course, increase synaptic weight; a global increase in the efficacy of synaptic transmission might, on its own, disrupt normal hippocampal information processing. However, the number of studies reporting normal learning despite the induction of substantial LTP suggests that a cumulative increase in synaptic weight does not in itself disrupt the encoding of new information. In fact, Moser et al. (1998) found no correlation between the magnitude of LTP induced by cross-bundle tetanization and subsequent learning.

Moser et al.'s (1998) study is unlikely to be the last word. First, saturation itself is not well understood physiologically. Doing so could offer new insights into the maximum amounts of potentiation the hippocampus could sustain. Second, saturation might be achieved in other ways. It might also be realized by bilateral stimulation of the ventral hippocampal commissure to potentiate the commissural/associational pathway in CA3 and CA1 (Bliss and Richter-Levin, 1993). Another study has suggested that as little as a single LTP-inducing tetanus delivered to the Schaffer-commissural pathway can impair trace eyeblink conditioning (Gruart et al., 2006). A pharmacological, rather than an electrophysiological, approach should also be considered using drugs such as BDNF (Bramham and Messaoudi, 2005) or agonists of adenylylate cyclase, protein kinase A, or mitogen-activated protein kinase (MAPK), to induce slow-onset but asymptotic synaptic potentiation. Multiple approaches are required to rigorously test this component of the SPM hypothesis.

#### 10.10.4 Retrograde Alteration: Does Further Induction or Reversal of LTP Cause Forgetting?

If memory traces related to a recent learning experience are temporarily stored in the hippocampus, procedures that induce further LTP in the same network, or successfully erase LTP, should cause forgetting. Erasure might be achieved (1) using trains of suitable depotentiating (e.g., low frequency) stimulation or (2) applying drugs or enzyme inhibitors that interrupt expression of LTP when given shortly after its induction (e.g., kinase inhibitors).

Depotentiation can be induced using continuous trains of single pulses at 1 to 5 Hz (Barrientos et al., 1980; Stäubli and

Lynch, 1990; Bashir and Collingridge, 1994). Stäubli and Chun (1996) found that a few minutes of 5-Hz stimulation can depotentiate recently induced LTP in area CA1 *in vitro*. The efficacy of depotentiation declines rapidly as the interval between the tetanus and 5 Hz is increased, with little effect being obtained 30 minutes after LTP induction. Dentate LTP *in vivo* can also be reversed by 5-Hz stimulation when delivered up to a few minutes after tetanization, but later stimulation is ineffective (Martin, 1998; Kulla, 1999). Unfortunately, none of the protocols for inducing depotentiation has yet been tested for its ability to cause forgetting in behaving animals.

Xu et al. (1998) reported that exposing freely moving animals to a novel but nonstressful recording chamber can reverse recently induced LTP without affecting a control pathway. They speculated that exposure to novelty has the effect of erasing hitherto unconsolidated information (see also Manahan-Vaughan and Brauneckell, 1999). Support for this interpretation is offered in a report (Izquierdo et al., 1999) in which exposure to novelty limited the ability of an animal to remember a one-trial inhibitory avoidance task carried out up to 1 hour previously. Exploration of novelty shortly before or long after the training trial was without effect. The effect appears to be NMDAR- and CaMKII-dependent.

Instead of erasing LTP, the induction of further LTP should alter the spatial distribution of synaptic weights in the distributed network of areas CA3 and CA1 and so prevent successful retrieval of information stored earlier. In an early study of this kind, McNaughton et al. (1986) trained rats to remember the location of an escape tunnel in a "Barnes arena" and then induced LTP in the dentate gyrus via chronically implanted electrodes in the angular bundle. Recently acquired reference memory was disrupted by LTP induction, whereas well established spatial memory was unaffected. Results consistent with these have been reported by Brun et al. (2001), who trained rats in a spatial reference memory task in the watermaze for 5 days, before also inducing LTP via stimulating electrodes straddling the angular bundle of the perforant path. In contrast to nonstimulated and low-frequency control groups, rats that had been subjected to high-frequency tetanization were completely unable to remember the platform location in a subsequent probe trial (Fig. 10–24B). Nevertheless, the same animals were able to learn a new platform location in a different watermaze environment as well as the controls, a result consistent with the finding reported by Otnaess et al. (1999) that pretraining eliminates the LTP saturation-induced deficit in new spatial reference learning (cf. Bannerman et al., 1995; Saucier and Cain, 1995).

In the study of Brun et al. (2001), a group of rats was tetanized in the presence of the NMDA receptor antagonist CPP. These animals remembered the platform location as well as the controls in a subsequent retention test (carried out in the absence of CPP). In conjunction with the intact ability of animals with asymptotic or near-asymptotic LTP to learn a new watermaze task, these results suggest that neither high-

frequency tetanization nor LTP induction per se causes significant hippocampal dysfunction, and they add further credence to the notion that memories are stored as patterns of changes in synaptic strength, and that these patterns can be disrupted by the addition of tetanus-induced LTP that constitutes meaningless noise. This notion is further supported by the finding that LTP induction at CA3–CA1 synapses prevents

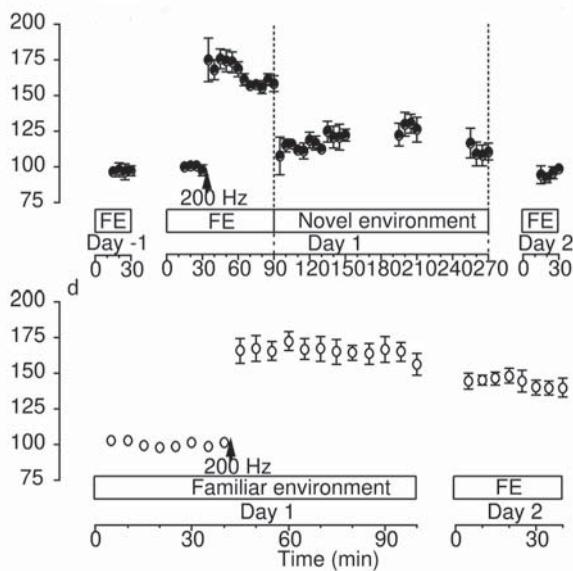

the recall of trace eyeblink conditioning (Gruart et al., 2006), although more widespread alteration of synaptic strengths is sometimes necessary to disrupt memory (Leung and Shen, 2006).

Finally, Pastalkova et al (2006) have shown that application of ZIP, a membrane permeable inhibitor of PKM $\zeta$  that is thought to mediate the persistence of hippocampal LTP over

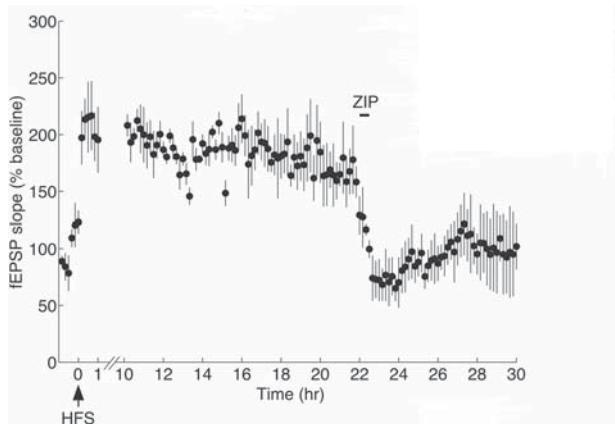

**Figure 10–24.** Retrograde alteration of LTP and memory. A. Depotentiation of LTP should erase memory. One way in this might be achieved is through experiences such as novelty exploration. Rats in which LTP had been recently induced showed persistent potentiation when placed in a familiar environment (top), but LTP was erased when they explored a novel room. The novelty acts in an analogous manner to “distraction.” (Source: After Xu et al., 1998.) B. Alternatively, if memory traces involve a particular spatial distribution of synaptic potentiation, artificial induction of further LTP (black symbols) should make it difficult to retrieve the appropriate memory (1,2,3) later. C. When rats, soon after learning a spatial watermaze task, were given high-frequency stimulation to multiple

afferents of the perforant path that ordinarily induces LTP in the dentate gyrus, they were later unable to remember the location of the hidden platform, as shown in post-training probe tests (see Fig. 13(23 for explanation of behavioural task). Giving such stimulation in the presence of an NMDA antagonist had no effect on memory. (Source: After Brun et al., 1998.) D. Application of ZIP (see text) reverses established LTP to baseline. E. Rats trained to avoid a zone on a rotating arena where they receive a footshock (place avoidance) take longer to enter this region as training progresses. Application of ZIP at the end of training abolishes this memory. (Source: Pastalkova et al., 2006).

### E ZIP induced loss of place avoidance memory

time (see Section 10.4.9), causes both a reversal of LTP established 22 hrs earlier and a loss of place-avoidance memory (Fig 10-24D,E). With this striking new result, it seems that predictions of the retrograde alteration criterion are being upheld.

### 10.10.5 Mimicry

A key test of any hypothesis concerning memory encoding and storage must be a mimicry experiment, in which apparent memory is generated artificially without the usual requirement for a learning experience. This would constitute a critical test that changes in synaptic efficacy are *sufficient* for memory, rather than merely necessary.

Pairing of electrical stimulation in specific CS and US pathways to the amygdala should result in potentiation of interconnecting pathways. Subsequent behavioral testing might reveal that this LTP constitutes the “engineering” of an emotional memory. Such an experiment may be difficult in practice, and no such reports have yet appeared; nor have any reports of the artificial engineering of hippocampal memory been reported. However, several “detectability” studies have employed a methodology that might be regarded as a halfway house between detectability and mimicry. Studies in which sensory stimulation is replaced with electrical stimulation of a particular neural pathway, as a discriminative cue (Mouly et al., 2001; Roman et al., 2004) or a conditioned stimulus (Matthies et al., 1986; Laroche et al., 1989; Doyere and Laroche, 1992) fall into this category. In such experiments, posttraining LTP-like changes in evoked potentials are often found in response to stimulation of the same pathway that was stimulated during learning. The difficulty lies in ensuring that the electrical stimulation adequately mimics natural sensory stimulation, such that any learning-related changes in synaptic strength might plausibly be expected to occur—albeit perhaps in a more diffuse and sparse fashion—during “normal” learning. In this respect, studies involving stimulation of sensory pathways are arguably easier to interpret than studies in which, for instance, perforant path tetanization is used as a CS (Laroche et al., 1989; Doyere and Laroche, 1992). A range of other relevant studies examining the artificial induction of receptive field plasticity in the neocortex has been reported, but they lie outside the scope of this book (e.g., Talwar and Gerstein, 2001; Weinberger, 2004). Nonetheless, we are unaware of any study to date that adequately meets the mimicry criterion.

### 10.10.6 Synaptic Plasticity, Learning, and Memory: The Story So Far

In this chapter we have covered the more important advances in the field of synaptic plasticity that have emerged from neuroscience laboratories around the world over the last three decades as a result of the enormous interest generated by the discovery of LTP. That interest is driven, at heart, by the belief

that in hippocampal LTP we have found a window into the synaptic basis of a central aspect of cognition—episodic memory. At the same time, the study of synaptic plasticity has led to a heightened appreciation of the richness and complexity of synaptic function. Synapses are simply more interesting when they are endowed with memory. The question remains, however, as to whether this avalanche of new knowledge about the physiology, pharmacology, and molecular and developmental biology of synapses has taught us anything fundamental about how the brain stores memories.

Many of the issues encountered in the last section are a product of the painful realization that although we now know a great deal about plasticity at the level of the individual neuron, and even the individual synapse, we know relatively little about how individual synapses integrate to influence the behavior of the single neuron. We know even less about how networks of neurons interact to encode and store information and about the processes of retrieval that allow memory to be expressed as changes in behavior. The problem of detectability discussed in Section 10.10.2 reflects our ignorance of hippocampal function at the network level. If LTP is so pervasive—estimates cited in Section 10.3.2 suggest that most synapses made by interconnected hippocampal pyramidal cells support LTP—why has it been so difficult to detect in the intact, learning animal? Does it reflect the sparseness of encoding, or is it that every instance of LTP is accompanied by LTD at other synapses, thus compromising the experimenter’s ability to detect changes in field potential responses? A striking increase in the number of CA1 neurons expressing mRNA transcripts activity related gene *arc/arg3.1* has been detected while animals explore a new environment, and it has been possible to show that different but overlapping networks of *arc*-expressing cells are engaged when different environments are explored (Guzowski et al., 1999) (see also discussion in Chapter 13). This is a promising approach, but it does not allow us to make the unequivocal claim that LTP has been detected, as *arc* and other potential markers such as *zif268* and *homer* are not exclusively activated by LTP. In this respect, phospho specific antibodies directed to protein kinases that are phosphorylated on different residues in LTP and LTD (see section 10.4.6) should offer a powerful tool in the analysis of plasticity at the network level.

Estimates of correlated activity between populations of neurons is another promising approach to the question: Does LTP happen in real life? A suggestive example was offered by Mehta et al. (2000), who examined changes in the statistical coupling of cells as animals repeatedly moved through their adjacent place fields in a toroidal running maze. Each time the animal traversed the circular maze, entering the CA3 place field just before the CA1 place field, the CA3 place cell repeatedly fired immediately before the CA1 cell. After several circuits, the place field of the CA3 cell moved toward that of the CA1 cell. This is the result that would be predicted if the two cells were coupled and the strength of the connection between them had become strengthened. Is it LTP? Does this change in

coupling reflect some gain in the animal's knowledge of the maze? Experiments on remapping of place cells when animals are put in a new environment suggest that NMDAR-mediated processes are required for the stability and fine tuning of the new mapping. These are promising but perhaps not compelling examples, an obvious difficulty being that changes in cell firing are an indirect measure of presumed changes in synaptic connectivity. Nevertheless, techniques for listening into the conversations between large ensembles of neurons offer one hope of establishing the role of synaptic potentiation in network behavior.

It is already possible to implant several multiunit recording assemblies into each of the hippocampal subfields and to record the activity of many tens of neurons in each subfield. Some of these neurons will be connected. Cross-correlational analysis of unit firing can pick out those that are and allow estimates to be made of the strength of the connection between them. The timing of monosynaptic connections between CA3 and CA1 neurons reduces the possibility that both cells are being driven by another cell. A protocol to detect LTP might be the following. Record simultaneously from many such pairs while the animal is learning a CA3/CA1-dependent task, and changes in the weights that connect at least some of the pairs should become apparent. Now depotentiate the potentiated pairs by stimulating the presynaptic neuron, via the appropriate electrode in the recording assembly, soon after the change is detected. Do that to enough pairs whose altered weights marks them as participating in the representation of the memory, and what has been learned, according to the SPM hypothesis, should be attenuated or lost. Now restore the synaptic weights to the pairs that have been depotentiated by tetanic stimulation, pair on pair, again using the presynaptic recording electrode as a stimulating electrode, and the memory should be recovered—a primitive form of mimicry. This is not, admittedly, the formation of a new memory but recovery of a lost memory by restoring synaptic strengths specifically to a subpopulation of the synapses that encoded the original representation of that memory. Achieving the stimulation specificity to achieve this project may be difficult, but thought experiments of this kind challenge us to consider what would be needed to test the SPM hypothesis with the appropriate rigor.

Although this and other experiments are for the future, they are within the bounds of what is technically feasible and make at least the point that the SPM hypothesis is potentially falsifiable. Before the role of the hippocampus in episodic memory was revealed in H.M. and before the Hebb synapse was made manifest in LTP, neuroscientists who thought about the neural basis of learning were faced with what must have seemed a series of unbridgeable chasms between the experience to be remembered and its representation and storage in the neural network, between the network and its constituent neurons, and between the neuron and its synapses, the ultimate units of information storage. The enormous advances in our knowledge of the mechanisms and functions of synaptic plasticity summarized in this chapter can give us some confi-

dence that we now have the conceptual and instrumental tools to tackle these obstacles. It is this sense of optimism that gives the field its vitality and excitement. If the field of consciousness has its easy and hard problems, so has LTP—with this difference: that its hard problem, the link between plasticity and memory, is solvable.

## ACKNOWLEDGMENTS

T.V.P.B. thanks those who over the years gave him refuge to write: Susan and Robert Alain at Lac Laroche, Quebec and on the north Norfolk coast Julia Peyton-Jones at Southrepps and Mike and Eithne Doy at Cley. Wai Han Yau skillfully turned sketches and scans into figures. G.L.C. is grateful to Andy Doherty for help with preparing figures. R.G.M.M. thanks Stephen Martin for assistance with the text and Simon Rempel for providing material for one of the figures. The work of T.V.P.B., G.L.C., and R.G.M.M. has been supported for many years in whole or in part by the MRC. We acknowledge support also from the Human Frontiers Science Program and the EU.

# Hippocampal Neurophysiology in the Behaving Animal

## 11.1 Overview

This chapter addresses a central question in the study of the hippocampus: What information is represented in hippocampal electrical activity? When asking this question, we are immediately confronted with one of the central problems in neuroscience, the nature of how information is coded in the nervous system. Historically, there have been two answers to this question: On the one hand is the view that the nervous system is composed of a large set of individual computing elements, the neurons, and that these neurons interact with each other by passing discrete bundles of information along their axons. An alternative view is that the system is organized on more holistic principles, with large numbers of cells acting in concert perhaps reflected in synchronous neuronal firing or in rhythmical electroencephalographic (EEG) activity.

The general position taken in this chapter is that the hippocampus uses both strategies. There is ample evidence that individual hippocampal pyramidal cells code for specific locations in an environment by a marked increase in firing rate; but, equally, that part of the code for location involves the timing of cell firing relative to a clock wave, represented by the EEG theta wave and associated interneurons, and that groups of pyramidal cells can act cooperatively in an ensemble fashion. On this view, each pyramidal cell acts as an oscillator, and a sophisticated set of mechanisms exists for producing these oscillations. Each cell has the biophysical machinery to oscillate in isolation from other cells or external inputs. These individual oscillators are stabilized and synchronized by a set of inhibitory feedback circuits primarily involving inhibitory interneurons. Neurons in the septum and brain stem provide the neuromodulatory inputs necessary for hippocampal pyramidal cells to enter the oscillatory state and may also provide a driving signal that sets the overall frequency of the oscillations.

One powerful approach to the study of the functions of a brain region is to correlate the electrical activity of its neurons with some aspect of observed behavior or inferred cognition. This approach reveals what information is available to that part of the brain and when it is available. Furthermore, it is sometimes possible to record both the inputs and the outputs of an area, and under these conditions it may be possible to compute what transfer function is being performed.

Several patterns of electrical activity have been recorded from the hippocampus, and they have been correlated with behavioral or psychological states. During the mid-1960s, Vanderwolf placed a relatively large electrode into the hippocampus of the freely moving rat and recorded the EEG activity during a wide range of behaviors (Vanderwolf, 1969). He identified three distinct states: the rhythmical theta state, the large irregular amplitude activity (LIA) state, and the small irregular amplitude activity (SIA) state. Theta, in turn, could be classified into two subtypes on the basis of behavioral correlate and pharmacological sensitivity. In this chapter, these two types are called a-theta (for arousal/attention theta), which is sensitive to anticholinergic drugs such as atropine, and t-theta (for translation movement theta), which may be serotonergic and glutamatergic.

The behavioral/psychological correlates of the two types of theta activity have been characterized best in rats: In this animal, the atropine-resistant component or t-theta occurs during a class of movements that may be loosely characterized as those that normally change the spatial relation between the animal's head and the environment. The correlates of the atropine-sensitive theta, or a-theta, are less well defined and are best summed up as psychological states such as arousal, attention, or intention to move. The behavioral correlates of LIA are those that do not change the animal's location in the environment: quiet sitting, eating, drinking, and grooming in the absence of postural shifts. The SIA state occurs during behavioral transitions, often when the animal awakens from

slow-wave or rapid-eye-movement (REM) sleep or when it abruptly stops running. It has not received much attention, and its behavioral correlates and physiological function are less well understood.

The rhythmical theta state reflects the synchronous membrane oscillations of large numbers of pyramidal cells in the CA1 field and dentate gyrus that are locked into synchrony by the inhibitory interneuronal network. One of its functions is to provide a clock signal against which the action potentials of the individual pyramidal cells can be timed. Another function might be to set up the optimal circumstances for the induction of long-term potentiation (LTP) (see Chapter 10). The nonrhythmical LIA state has a more random, broader spectrum especially in the lower-frequency range and may represent an inactive, relaxed state of the same network when it is not being driven. Alternatively, it may be an active state in its own right in which memories previously encoded in the hippocampus are strengthened and/or transferred to other regions of the brain. LIA is characterized by sharp waves of about 100 ms duration that occur randomly, with an average interval of 1 second. Associated with them are higher-frequency “ripple” oscillations of 100 to 200 Hz, which also may reflect the operation of the inhibitory network. In addition to oscillations in the theta and ripple bands, oscillations at intermediate frequencies (beta: 12–30 Hz; gamma: 30–100 Hz) have been recorded in association with various aspects of olfactory behavior.

Placing a microelectrode rather than a gross electrode into the CA1 hippocampal cell layer reveals a much richer and surprising set of behavioral correlates correlations between physiology and behavior. On the basis of the EEG recordings one might expect to see cell-firing patterns that are correlated with the animal’s movements, and indeed this is observed. However, it is not the whole story. Ranck (1973) placed microelectrodes into the pyramidal cell layers of CA3 and CA1 and found two classes of cellular response. One type, which he called the theta cell, fired at frequencies ranging from 10 Hz (when the animal sat quietly or engaged in other “LIA” behaviors) to as high as 100 Hz (as it ran around the environment or engaged in other “theta” behaviors). Furthermore, they burst at the same frequency and showed consistent correlations with different phases of the various EEG waves. Here, at the level of the single cell, was one clear correlate of the EEG patterns, banishing forever any lingering skepticism about their functional significance. The second class of cell, the complex spike cell, had a much lower baseline firing rate, and many were effectively “silent” for long periods of time. Their defining characteristic is the occasional short burst of action potentials with successively decreasing amplitudes. Their major behavioral correlate was first identified by O’Keefe and Dostrovsky (1971) as the animal’s location. They reported that these place cells were typically silent as the rat moved around the environment until it entered a small patch of the environment when the cell began to fire (the place field). It is now recognized that, within the place field, these cells also fire

in a rhythmical bursting pattern during the EEG theta state. Unlike the theta cells, however, the frequency of bursts is slightly higher than the gross EEG theta, causing each successive burst to precess to earlier phases of the theta cycle as the animal moves through the place field. This temporal code works together with the overall rate code to identify the animal’s location. In addition, variations in firing rate can signal aspects of behavior that occur in the place field or the presence (or absence) of objects encountered there. The same cells often fire in different environments, but the preferred locations are unrelated if the environments are sufficiently dissimilar to each other. One notable feature of these place cells is that in unconstrained open fields—environments in which the animal is free to move in all directions—the cells fire in the place field irrespective of the direction in which the animal is facing. In environments that constrain the animal’s behavior, the cells become directionally sensitive and may be said to represent the successive locations along a path. In addition to the animal’s location, some pyramidal cells signal the presence or absence of particular objects within the place field or the performance of particular behaviors there.

In addition to *representing* locations and features of the environment, the place cells have been shown to *learn* about new environments or changes in a familiar environment. For example, place cells initially treat similar environments as identical but can learn to differentiate between them with repeated exposure.

Place cells are typically recorded from the hippocampus proper but have also been recorded from other parts of the hippocampal formation, namely the subiculum, presubiculum, parasubiculum, and entorhinal cortex as well as the hippocampus. The properties of cells in these various regions vary, and it is still not clear how this diverse population of place cells is organized into a functional network or which functions are performed by each region.

Two other major classes of spatial cell have been found in the hippocampal formation: the head direction (HD) cell and the grid cell. The HD cell is sensitive to the orientation of the rat’s head with respect to the environmental frame, irrespective of the animal’s location in that environment. These cells have been found in several regions, most notably the anterior thalamus and dorsal presubiculum. Different cells have different preferred directional orientations. The animal’s orientation is given partly by environmental cues and partly by interoceptive cues derived from vestibular and/or proprioceptive inputs. In addition to directly controlling behavior based on environmental directions, these cells may provide directional information to the place cells. The third major class of spatial cell, the grid cell, provides a metric for marking off distances in the environment. These cells have been found in layers 2/3 of the medial entorhinal cortex, which sends a major projection to the hippocampus proper, and in the lower layers, which receive inputs from the hippocampus. Each of these cells lays a grid-like pattern of firing on top of every environment the animal encounters. The orientation and spacing of the grid varies in a

systematic fashion from cell to cell and appears to depend on information generated by the animal's self motion.

Place cells have also been described in primates including humans, as have a variety of other spatial cells: HD cells and spatial view cells, which respond when the animal looks at a particular location.

Nonspatial behavioral correlates of hippocampal complex spike cells have also been reported in rodents and primates. Simple sensory stimuli, such as tones or somatosensory stimuli, appear to be relatively ineffective in the untrained animal, although there are several reports that pyramidal cells respond to these stimuli following classic conditioning or discrimination learning tasks. Furthermore, increased firing in complex-spike cells has been reported to correlate with different aspects of behavior in approach tasks, such as whether the animal is approaching an area containing cues to be recognized or discriminated or containing a reward. Some authors have argued that these findings support the idea that the hippocampus is involved in many types of relational processing in addition to those in the spatial domain. As we shall see, it is sometimes difficult to decide whether the firing of a hippocampal cell in a particular task is spatial or nonspatial. Whether these non-spatial correlates can eventually be explained within a spatial framework or alternatively, signal the need for an extension of the functions attributed to the hippocampus into nonspatial domains is discussed.

## 11.2 Hippocampal Electroencephalogram Can Be Classified into Distinct Patterns, with Each Providing Information About an Aspect of Hippocampal Function

If an electrode is placed in the hippocampus and electrical activity in the frequency range 1 to 200 Hz is recorded as the animal goes about its daily business, distinct patterns of electrical activity are seen that vary as a function of state of alertness, sensory stimulation, behavior, and anatomical location. These patterns of electrical activity are known collectively as the "electroencephalogram," or EEG. The EEG reflects the activity of large numbers of neurons and probably includes contributions from action potentials in disparate cell types, excitatory and inhibitory synaptic potentials, and dendritic and glial slow potentials. As such, it can provide a measure of information about the overall function of a brain region but not at the same level of precision as the activity of single units. It is probably most useful for signaling when large numbers of neurons are acting together synchronously. Because this is an important mode of operation of cortical areas such as the hippocampus, it follows that different EEG patterns can serve as a bridge between behavior on the one hand and single or multiple unit activity on the other. As we shall see in this chapter, there are several types of hippocampal EEG pattern, and each type provides information about a different aspect of hip-

pocampal function, although none tells the whole story on its own. Theta and LIA have been studied most and so receive the most attention here.

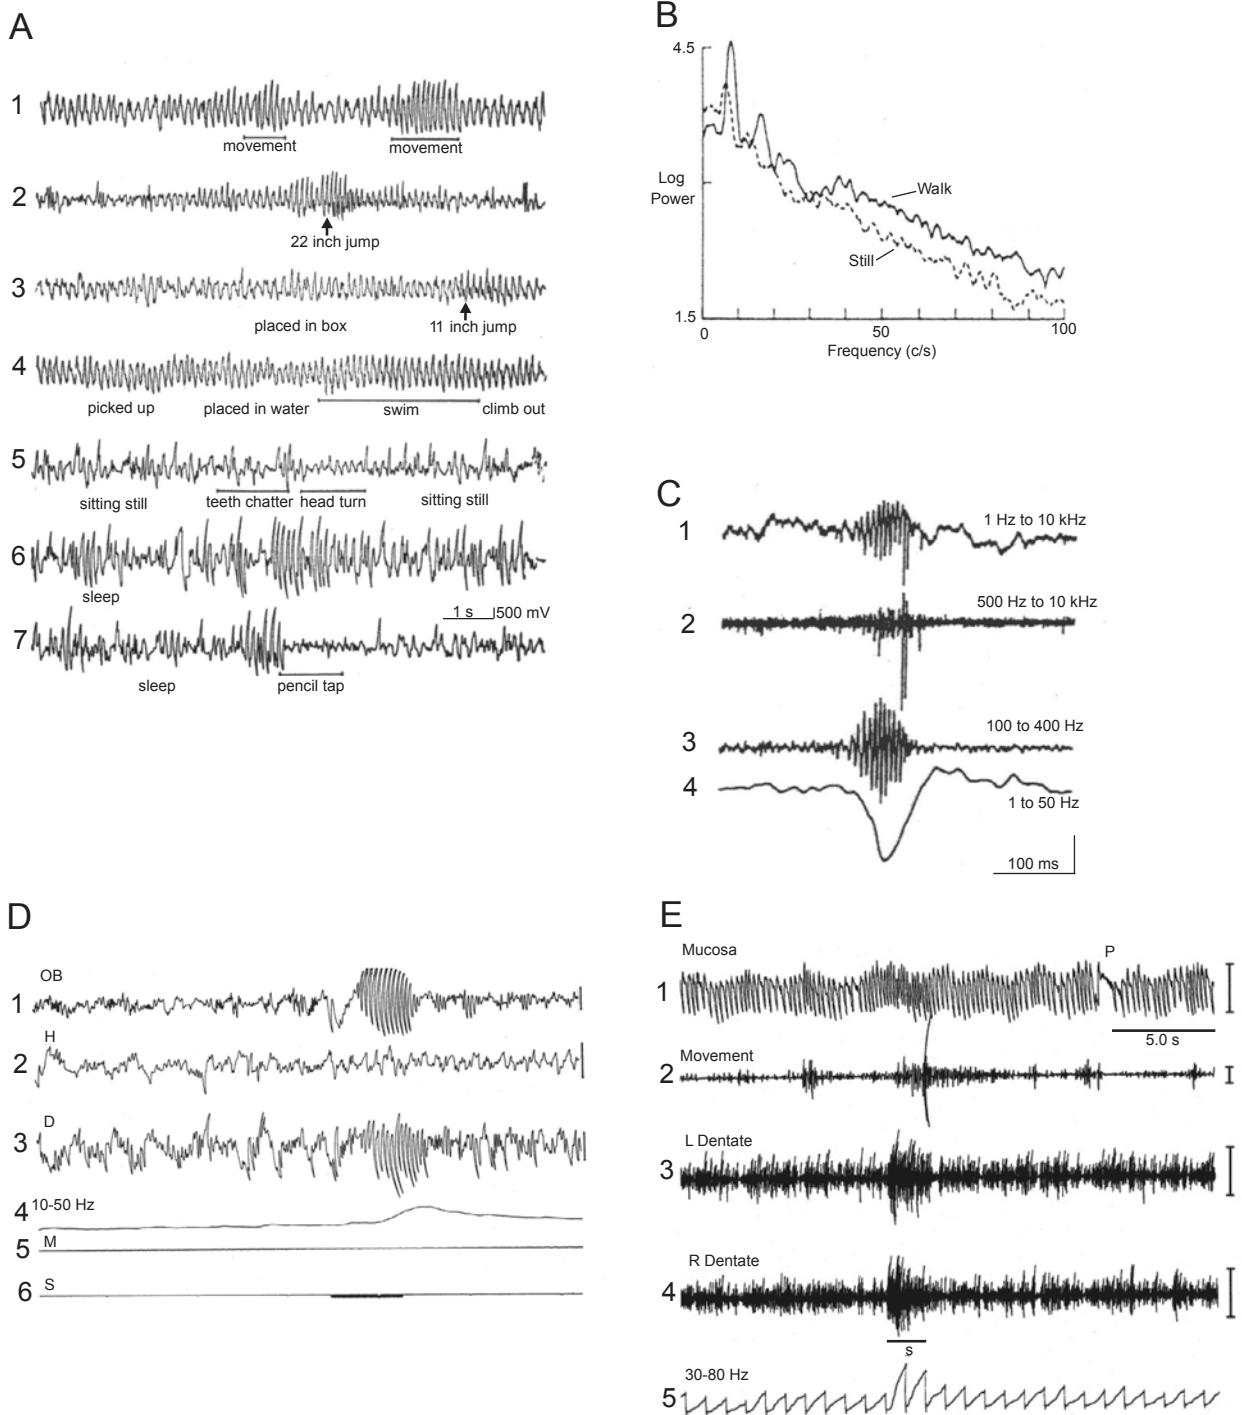

### 11.2.1 Hippocampal EEG Can Be Classified into Four Types of Rhythmic and Two Types of Nonrhythmic Activity

In the hippocampus of the freely moving rat, six prominent EEG patterns have been identified: four rhythmic and two nonrhythmic. Rhythmic patterns (and their frequency ranges) include theta (6–12 Hz), beta (12–30 Hz), gamma (30–100 Hz), and ripple (100–200 Hz) waves. Nonrhythmic patterns include LIA and SIA. Figure 11–1 shows examples of each. Some patterns can co-occur (e.g., LIA with ripples, theta with gamma), whereas others appear to be mutually exclusive (e.g., theta, LIA, and SIA). The latter three waveforms appear to correspond to mutually exclusive states of hippocampal functioning.

Theta consists of rhythmic, often sinusoidal oscillations that vary in frequency from 6 to 12 Hz in the rat but can be as low as 4 Hz in the rabbit and cat (Fig. 11–1A, traces 1–4). The frequency power spectrum is narrow (Fig. 11–1B, walking), with a sharp peak around 7 to 10 Hz and often associated with higher harmonics (second peak around 16 Hz in Fig. 11–1B, walking). The LIA pattern looks much more random and is often characterized by sharp waves that resemble the spike and wave of epileptiform tissue (see Fig. 11–1A, traces 6, 7). The LIA power spectrum is flatter, with fewer peaks than are seen in theta and more power in the lower (1–5 Hz) frequencies (Figs. 11–1B, still and 11–2G). High-frequency 200-Hz ripples occur on the LIA sharp waves (Fig. 11–1C). SIA is a low-amplitude pattern that contains a broad spectrum of high frequencies and occurs only occasionally (Figs. 11–1A, 7, pencil tap and 11–2C). Beta waves occupy the frequency range 12 to 20 Hz (Fig. 11–1D) and gamma waves the frequency range 20 to 100 Hz (Fig. 11–1E). Either can occur alone or in combination with theta, LIA, or SIA.

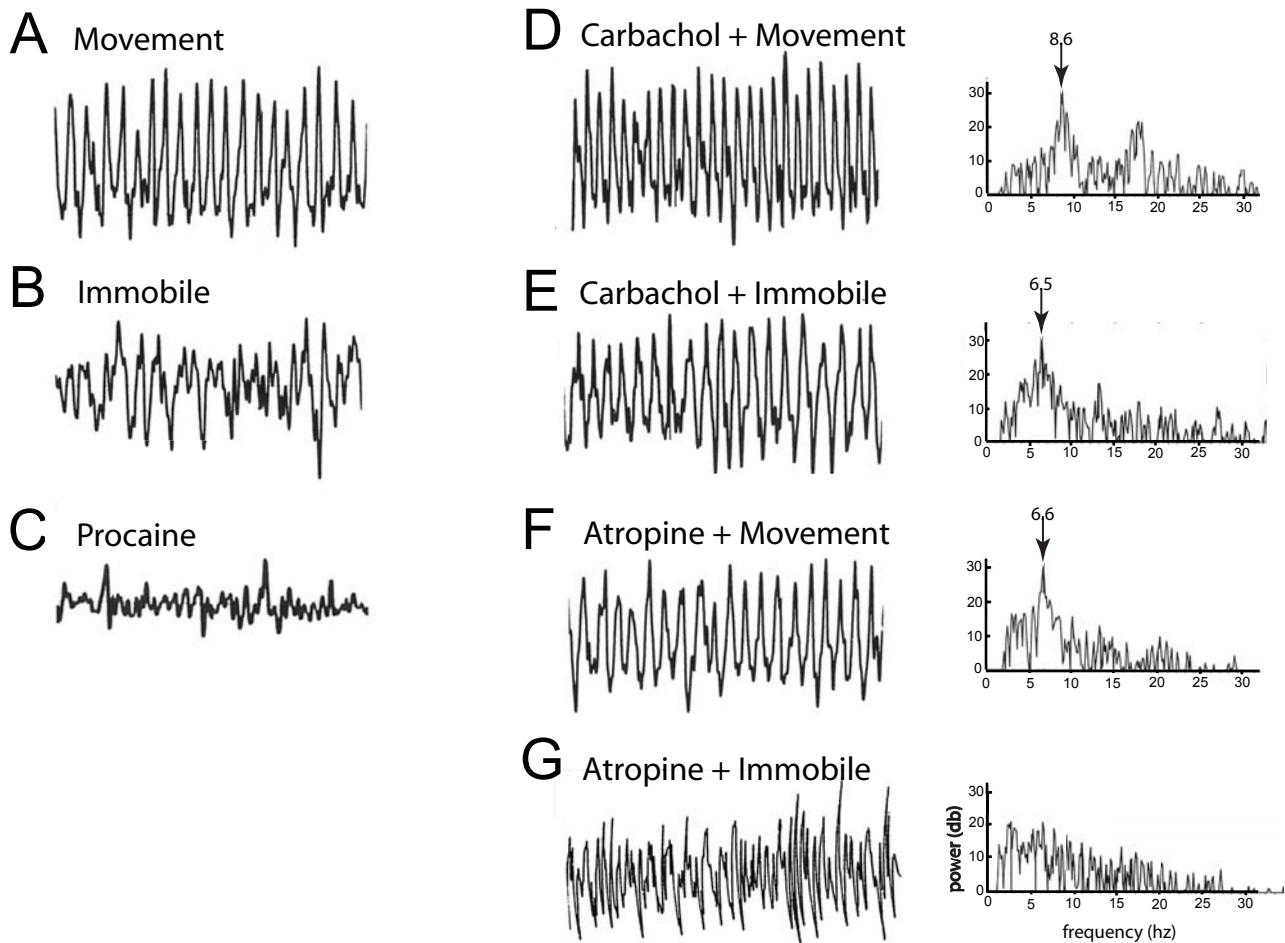

### 11.2.2 Each EEG Pattern Has Distinct Behavioral Correlates

The simplest behavioral correlates of the various EEG patterns occur in the rat, and here we follow Vanderwolf's general description (Whishaw and Vanderwolf, 1973; Vanderwolf, 2001). It should be noted, however, that theta, in particular, has slightly different behavioral correlates in different species. In the awake rat, theta occurs primarily during movements that can loosely be described as "translational"—those that change the location of the animal's head with respect to the environment: walking, running, swimming, jumping, exploratory head movements, struggling (see examples in Fig. 11–1A, 1–4). Theta also occurs during REM sleep and occasionally during immobile attention or arousal. In the rabbit and guinea pig, this immobile attention-related theta

**Figure 11-1.** Hippocampal electroencephalography (EEG) patterns. *A.* Theta during rapid-eye-movement (REM) sleep (trace 1), jumping (2, 3), and swimming (4). Large irregular amplitude activity (LIA) during quiet sitting (5) and slow-wave sleep (6, 7). Note the large amplitude sharp waves especially prominent during slow-wave sleep. Small irregular amplitude activity (SIA) during brief arousal from slow-wave sleep after a pencil tap (7). (*Source:* Whishaw and Vanderwolf, 1973.) *B.* Frequency power spectrum during walking and standing still. Note the peaks around 8 and 16 Hz and the generally higher amplitude in the beta and gamma bands during walking. (*Source:* Leung, 1992.) *C.* LIA ripples and sharp waves in

broad-band (trace 1) and filtered (2–4) recordings. Ripples (3) and sharp waves (4) are accompanied by bursts of action potentials (2) in hippocampal interneurons (small spikes) and principal cells (large spikes). (*Source:* Buzsaki et al., 1992.) *D.* Beta activity in the olfactory bulb (OB) and dentate gyrus (D) during sniffing toluene (thickening of s in trace 6). Note the absence of beta in the hippocampus (2, H) and the absence of gross movement (5, M). *E.* Gamma activity (3, 4) in the dentate during sniffing (s). Trace 5 shows the increase in breathing recorded during sniffing. (*Source:* Vanderwolf, 2001.)

**Figure 11-2.** EEG patterns and frequency power spectra during movement and immobility in the rat. *A*, Theta during spontaneous movement. *B*, LIA during quiet immobility. *C*, All theta is abolished by a procaine injection into the medial septum. *D*, Theta during movement following intraseptal injection of the cholinomimetic carbachol. *E*, a-Theta during immobility following intraseptal injection of the cholinomimetic carbachol has a lower frequency than

in *D*. *F*, t-Theta during movement is not blocked by an intraseptal injection of the anticholinergic atropine. *G*, LIA during immobility following intraseptal atropine. All EEG traces are 3 s long except *C*, which is 2 seconds. Arrows in *D*, *E*, and *F* indicate peak theta frequency in hertz. (Source: After Lawson and Bland, 1993, with permission.)

occurs more often. In the cat, it is related to active exploratory eye movements.

LIA occurs during behaviors that do not change the animal's location, such as sitting quietly, eating, drinking, grooming, and during slow wave sleep (SWS) (Fig. 11-1A, 5–7). SIA is seen infrequently: in the awake rat when ongoing movement is abruptly halted after a long train of theta, during sudden, motionless transitions from rest/sleep to alertness (Fig. 11-1A, 7, pencil tap), and during periods of SWS after REM episodes. Much less is known about the full range of behavioral correlates of beta and gamma, but they both have been shown to be associated with different types of olfactory input. Gamma occurs when the animal sniffs at a wide range of odors (Fig. 11-1E), whereas beta waves have been observed only during the sniffing of odors associated with predators (Fig. 11-1D).

### ■

## 11.3 Hippocampal Theta Activity

### 11.3.1 Hippocampal Theta Activity: Historical Overview

Theta activity and its behavioral correlates have been studied extensively ever since its discovery in the rabbit hippocampus by Jung and Kornmuller in 1938 (Jung and Kornmuller, 1938). The initial skepticism about the possibility that such regular large amplitude waves could be generated in the brain was overcome when Green and Arduini (1954) repeated the observations during the 1950s and showed that the theta pattern correlated inversely with neocortical desynchronization, suggesting that it represented the hippocampal arousal pattern. Later, attempts were made to correlate the theta rhy-

thm with aspects of learning: Adey et al. (1960) in the United States reported frequency shifts during simple discrimination learning, and Grastyán et al. (1959) in Hungary found high-frequency theta during orienting behavior early in auditory-reward conditioning but a desynchronized SIA pattern later, after the animal had learned to approach the reward. Studies by Gray (1971) in Britain suggested that particular frequencies of hippocampal theta activity (ca. 7.7 Hz) in the rat may also occur in association with reactions to nonreward.

These differences of opinion from different laboratories led to speculation that the behavioral correlate of theta varied from species to species and perhaps from task to task. Some measure of order was brought to the field by Vanderwolf's careful observations of the strictly behavioral correlates of hippocampal EEG patterns (Vanderwolf, 1969). He made the important point that changes of the kind seen by Adey and Grastyán that appeared to be correlated with different phases of learning were also correlated with specific changes in behavior at the same time. The changes in theta frequency seen by Adey, for example, tended to be correlated with changes in motor behavior during the course of learning. Vanderwolf argued that it was the strictly behavioral correlate of these EEG patterns that was primary. In various rodent species, he and his colleagues observed that theta activity was associated with what he termed "voluntary movements," whereas LIA occurred during stereotyped "fixed-action patterns." His subsequent observation that there were two types of theta, each with different behavioral correlates, clarified matters further (Kramis et al., 1975). One type is associated with arousal or attention, whether in association with movement or immobility, and the other with a class of movement alone. These two types are expressed to different degrees in different species and depend on different neuromodulatory inputs. The changes in hippocampal EEG during classic conditioning in the rabbit are examined in more detail in the section on nonspatial learning and memory (see Section 11.11).

### **11.3.2 Hippocampal Theta Activity Is Comprised of Two Components, a-Theta and t-Theta, Which Can Be Distinguished on the Basis of Behavioral Correlates and Pharmacology**

In addition to differences in their behavioral correlates, the two components of theta recorded in freely moving animals also differ in their pharmacology. One is affected by drugs that act at cholinergic synapses, such as the antagonists atropine and scopolamine, the agonist carbachol, and the anticholinesterase, eserine. Vanderwolf and colleagues (Kramis et al., 1975) called this component atropine-sensitive theta, but we refer to it here by the more psychological name, arousal- or attentional-theta (*a-theta* for short). The second component of theta is correlated with translational movements and is unaffected by cholinergic drugs. There is some evidence that it is dependent on the transmitters serotonin and glutamate. It is called translation-movement theta (*t-theta* for short).

Theta is not uniformly distributed in the hippocampal formation but varies in both phase and amplitude in different parts. Whereas synchronous, large-amplitude theta waves are prominent in the dentate gyrus and CA1 areas of the hippocampus, most mapping studies report the absence of theta in area CA3. Despite this, CA3 cells can show good phase correlates to the EEG recorded elsewhere (e.g., in CA1 or the dentate gyrus). The implication is that the presence or absence of theta waves in the EEG is not a simple function of the underlying single-cell activity. The presence of theta must depend, at least in part, on other factors, such as the anatomical arrangement of the cells and the phase relations of their activity (see Buzsaki, 2002 for a recent review of the cellular basis of theta).

### **11.3.3 Both Types of Theta Activity Are Dependent on the Medial Septal/DBB but Only t-Theta Is Dependent on the Entorhinal Cortex**

As discussed in Chapter 3, the major cholinergic input to the hippocampal formation arises from the medial septal nucleus and the nucleus of the diagonal band of Broca. The relative contributions of the medial septal nucleus and entorhinal cortex to the overall hippocampal theta pattern have been dissected using a combination of lesions and pharmacological manipulations (Bland and Oddie, 2001; Buzsaki, 2002). Lesions of the medial septal nucleus and associated diagonal band eliminate both types of theta activity. Injection of various drugs into the septum reveals differences in the pharmacological basis of *a*- and *t*-theta (Lawson and Bland, 1993). Inactivation by intraseptal injections of the local anesthetic procaine or the  $\gamma$ -aminobutyric acid (GABA)ergic drug muscimol eliminates all theta from the hippocampus (Fig. 11–2 C). Intraseptal injection of cholinergic antagonists (such as atropine) also block both thetas if the animal sits quietly (Fig. 11–2G) but leave movement-related *t*-theta intact (Fig. 11–2F). Conversely, injections of cholinergic agonists such as carbachol produce a state of continuous theta in the hippocampus regardless of whether the animal is moving (Fig. 11–2D) or sitting quietly (Fig. 11–2E). The frequency of the *a*-theta that occurs during immobility is about 2 Hz lower than when the animal is moving (compare power spectra in Fig. 11–2, D and E).

Lesions of the entorhinal cortex, in contrast, eliminate *t*-theta but leave *a*-theta intact (Kramis et al., 1975). Following such lesions, injections of atropine eliminate the remaining theta. Chronic injections of para-chlorophenylalanine (PCPA) or reserpine, both of which reduce the levels of serotonin in the brain, appear to eliminate *t*-theta. Because the *N*-methyl-D-aspartate (NMDA) receptor blocker ketamine also eliminates *t*-theta and results in a depth profile similar to urethane, it is likely that the glutamatergic afferents from the entorhinal cortex to the distal dendrites of CA1 and CA3 are responsible for this subcomponent of theta (Buzsaki, 2002).

The simplest explanation of these findings is that *t*-theta depends on fibers that pass through, or synapse in, the medial septum on their way to the entorhinal cortex with onward connection to the hippocampus. On the other hand, *a*-theta

requires the integrity of the direct cholinergic projection from the medial septal-diagonal band of Broca to the hippocampus perhaps through the activation of networks of inhibitory interneurons (see Chapter 8).

#### 11.3.4 t-Theta Occurs During Movement Through Space

Following Vanderwolf's observational studies, the tight coupling between t-theta and certain types of movement was strengthened by the results of "theta-conditioning" experiments by Black (1975). The idea was to reward animals for producing short trains of theta activity under two training conditions: In one they were allowed to move, but in the other they were forced to hold still. Training to produce theta with frequencies greater than 7 Hz (t- theta) was successful only when movement was allowed. Thus, movement is necessary for t-theta, but what aspect of such movement is being signaled by theta activity?

Vanderwolf's original suggestion that theta was correlated with some aspect of voluntary behavior is not operational enough because it is not clear whether, in the case of animals, a movement can ever be said to be truly volitional. Considering the movements during which theta occurs most readily—walking, running, swimming, jumping—the likely common factor is translation through space. The fact that small head movements during exploratory sniffing are also accompanied by theta suggests that the crucial factor is the translation of the *head* through space or, more specifically, the generation of motor outputs that would normally result in translation of the head through space. Changes in the frequency of theta activity are correlated with either the animal's speed of movement through the environment (Rivas et al., 1996; Slawinska and Kasicki, 1998) or the rapidity with which a movement is initiated. The latter has been shown in experiments in which rats have been trained to jump up onto a ledge or to initiate running in a runway (Whishaw and Vanderwolf, 1973).

The behavioral correlate of theta amplitude is less clear. Although Vanderwolf and colleagues failed to find a positive correlation between amplitude and speed, Rivas et al. (1996) reported a positive correlation between both the frequency and the amplitude of theta and the speed of movement in the guinea pig when movements are initiated in simple runways. On the other hand, there is no correlation in jumping experiments between amplitude and speed of movement. It seems that there are many factors contributing to the amplitude of theta, such that a consistent correlate of amplitude is not always seen.

#### 11.3.5 a-Theta Occurs During Arousal and/or Attention as well as Movement

a-Theta may correlate with psychological states such as arousal or attention. It rarely occurs in isolation in the rat but is much more common in rabbits, guinea pigs, and cats. In rats, it occurs naturally only when the animal freezes follow-

ing a noxious stimulus, in response to an aversive conditioned stimulus, or when the animal is immobile but preparing to move (such as just before a jump). It also co-occurs with t-theta during movement. In rabbits and guinea pigs, it is readily produced in immobile animals by innocuous visual, auditory, or tactile stimuli. Repeated stimulation, however, leads to habituation of this response. Sainsbury and colleagues (1987a,b) have shown that the ability of a stimulus to elicit hippocampal a-theta is dependent on the preexisting level of arousal. A relatively neutral stimulus such as a tone, which ordinarily has little effect, readily elicits a-theta if the animal has previously been "sensitized" with an arousing stimulus such as the sound of an owl or the sight of a predator. One possibility is that a-theta represents a subthreshold activation of the motor system. Experiments in support of this idea have been carried out by Sinnamon and his colleagues (Sinnamon, 2000; Sinnamon et al., 2000). They recorded theta activity in urethane-anesthetized rats before, during, and after hind-limb stepping movements elicited by electrical stimulation of the hypothalamus or pharmacological block of the midbrain raphe nucleus. Both manipulations elicited low-frequency premovement (presumptive a- type) theta activity as well as the higher-frequency (presumptive t- type) theta, which accompanied the hind-limb stepping movements. It might be that a- theta reflects the activation of movement programs in the absence of the movement itself. Alternatively or in addition, it might reflect the organization of sensory inputs as reflected in the correlation of single-unit activity in different sensory nuclei with hippocampal theta (see Section 11.3.7).

#### 11.3.6 Theta and Sleep

Theta occurs during the REM phase of sleep; LIA and SIA occur during slow-wave sleep; and SIA bursts frequently come at the termination of an REM episode. Pharmacological studies have shown that the theta recorded during the actual eye movements of the REM phase of sleep is unaffected by cholinergic drugs and therefore resembles t-theta, and that outside of these episodes is a-theta.

#### 11.3.7 Theta Activity in Nonhippocampal Areas

In the rat, the theta system is centred on the hippocampal formation, taken here to include the septum, subiculum area, and entorhinal cortex (Alonso and Garcia-Austi, 1987a,b; Brankack et al., 1993). However there are also reports of EEG and cellular activity phase-locked to theta in the cingulate cortex (Leung and Borst, 1987), prefrontal cortex (Hyman et al., 2005; Jones and Wilson, 2005; Siapas et al., 2005), perirhinal cortex (Muir and Bilkey, 1998), posterior hypothalamus including the mammillary bodies (Kirk and McNaughton, 1991; Bland et al., 1995; Slawinska and Kasicki, 1995; Kocsis and Vertes, 1997), brain stem reticular formation (Nunez et al., 1991), amygdala (Paré and Gaudreau, 1996; Seidenbecher et al., 2003), and superior (Natsume et al., 1999) and inferior (Pedemonte et al., 1996) colliculi. Some of these areas, such as the posterior hypothalamus and the brain stem reticular

formation, are involved in the circuitry that generates the hippocampal theta rhythm and might be expected to show activity synchronized with theta, whereas others are part of the sensory systems (the colliculi) or the limbic system (amygdala and cingulate cortex). These latter correlations must represent a fairly widespread function for theta, such as the synchronization or binding together of neurons in many sensory, motor, and emotional/motivational centers as well as those involved in spatial perception and memory.

### **11.3.8 Does the Hippocampal EEG in Monkeys and Humans Have a Theta Mode?**

Although theta patterns are readily observed in cats, dogs, and rodents, it has been difficult to establish whether a clear rhythmic theta pattern can be recorded from either monkey or human hippocampus. There have been hints over the years that it might exist. For example, Stewart and Fox (1991) reported a theta-like pattern (7–9 Hz) in the hippocampal EEG of urethane-anesthetized monkeys. In an earlier study, Watanabe and Niki (1985) reported the existence of the rhythmical theta-like firing patterns in monkey hippocampal cells. Similarly, rare experiments using depth electrodes in the human hippocampus have observed activity at theta frequencies, although their behavioral correlates were not clear (Halgren et al., 1978; Arnolds et al., 1980). This paucity of data has led some authors to suggest that theta may not exist in monkeys and primates or may not have the same behavioral correlates as in other mammals. Some reasons for the failure to record prominent theta patterns in the primate EEG are examined in the next section.

First, the existence of an oscillatory theta pattern in the EEG depends not only on the rhythmical firing of cells but also on the correct cytoarchitectonic orientation of pyramidal cells to create the appropriate electrical dipole. As was seen in the section on theta activity in field CA3, cells can burst with a theta pattern in the absence of pronounced theta waves in the EEG. Different neuroarchitecture could account for a theta system in primates in the absence of rodent-like theta patterns in the gross EEG.

A second problem is that most monkey and human recording is done while the subject is immobile, a condition that is not conducive to recording t-theta. Thirdly, most recordings in humans have been from the scalp, and it is possible that the skull and scalp are acting as filters, effectively screening out the theta patterns. Some evidence to support the last two possibilities comes from recent findings (Kahana et al., 1999) that theta patterns could be recorded from electrodes placed on the surface of the human neocortex while subjects navigated through a virtual reality maze. Theta activity was recorded from several cortical regions, but temporal lobe theta showed the best correlation with maze difficulty. More theta activity was seen during traverses through more difficult 12-choice mazes than through simpler 6-choice mazes. The same group has used depth as well as subdural electrodes in humans performing a virtual taxi driver task (Caplan et al., 2003) to show

that theta oscillations in humans are found during virtual movement, exploratory search, and goal-seeking. One difference from the rat is that human theta bursts tend to be of shorter duration. These kinds of studies confirm the suspicion that the difficulty recording primate theta has more to do with inappropriate behavioral paradigms and recording techniques than with the absence of a theta system per se.

There has also been recent interest in the related field of frequency analysis of EEGs recorded from scalp electrodes. For example, increases in the power present in the EEG at theta frequencies have been shown to be related to the successful encoding of new information (for a review see Klimesch, 1999). However, these studies typically do not demonstrate the peak in the power spectrum at theta frequencies or the long continuous records of trains of theta activity shown by Kahana and colleagues in their virtual reality study. Localizing the source of theta in scalp-recorded EEGs is even more problematical than with subdural electrodes; one experiment where it was attempted implicated the anterior cingulate rather than the hippocampus (in a task showing increased theta with increased working memory load) (Gevins et al., 1997). Spectral peaks at theta frequencies have been found in experiments using magnetoencephalography and have been interpreted as consistent with a generator near the hippocampus (Tesche and Karhu, 2000), although this technique also suffers from problems of accurate source localization. Nevertheless, these findings, and particularly the subdural recordings of Kahana et al., clearly show that theta activity exists in the human brain and tempt one to speculate that it might be related to the hippocampal system. There is a more extensive discussion of recording of the EEG and evoked potentials from the human brain in Chapter 12.

### **11.3.9 Functions of Theta**

Work on the rat hippocampus suggests three possible functions for theta. First, it acts as a global synchronizing mechanism, essentially locking the entire hippocampal formation into one global processing mode and organizing the activity in each hippocampal region with respect to the others. Simultaneous recordings of the EEG in different hippocampal locations have shown that theta activity at comparable locations (e.g., in the CA1 pyramidal layer) is in synchrony and coherent across large areas of the hippocampal formation (Mitchell and Ranck, 1980; Fox et al., 1986; Bullock et al., 1990). This means that if two cells have firing patterns that are systematically related to the local theta cycle, they have systematic temporal relations to each other, even if they are located far apart in the hippocampus. Although the theta rhythm is centered on the hippocampal formation, sensory and motivational areas are also brought under its sway. We begin to see here evidence for a widespread system of oscillations that organizes the activity of many disparate brain areas.

A second function of the theta oscillations is to provide a periodic clocking system for the timing of hippocampal spikes. As set out in greater detail in Section 11.7.9, the phase

relation of each pyramidal cell measured against the concurrent theta activity is not constant but can vary from one cycle to the next (O'Keefe and Recce, 1993; Skaggs et al., 1996). As a rat runs through the firing field of a spatially coded pyramidal cell (the place field), the cell fires bursts of spikes at an interburst frequency slightly higher than that of the concomitant EEG theta. This leads to a precession of the phase of firing to earlier points on each successive cycle. Over the course of the five to seven theta cycles that comprise the typical place field, the phase of the EEG at which the cell fires may precess through a full  $360^\circ$ , although smaller amounts of precession are also seen. Furthermore, the phase of firing is highly correlated with the animal's location within the place field (more so than with the duration spent in the field). Thus, temporal variation in spike firing conveys information about the animal's spatial location. An analysis of this phenomenon (Jensen and Lisman, 2000) shows that the temporal information provided by the phase precession can improve localization of the animal's position by more than 40% compared to that obtained by the use of firing rates alone.

A third function for theta is to provide temporal control over long-term potentiation (LTP) induction and, by inference, the storage and retrieval of information from the hippocampus. As noted in Chapter 10, theta-burst electrical stimulation of hippocampal afferents is an effective way to induce LTP. Furthermore, there is some evidence that volleys arriving at different phases of the ongoing theta are differentially effective (Pavlides et al., 1988; Huerta and Lisman, 1995; Holscher et al., 1997; Hyman et al., 2003). Inputs arriving at the positive phase of CA1 theta result in synaptic potentiation, whereas those arriving at the negative phase yield depotentiation or depression. On the basis of this and other evidence, Hasselmo (2005) proposed that the various phases of theta oscillation represent different modes of operation. Specifically, the peak of the CA1 theta is the period during which encoding of new information entering the hippocampus from the entorhinal cortex takes place, and the trough is the period during which retrieval of information from the hippocampus to the entorhinal cortex occurs.

## **11.4 Non-theta EEG Patterns in the Hippocampal EEG: LIA, SIA, Ripples, Beta, and Gamma**

### **11.4.1 Sharp Waves, Ripples, and Single Units During Large Irregular Activity**

During LIA, large sharp waves occur in the hippocampal EEG (Fig. 11–1A, traces 5–7 and Fig. 11–1C, trace 4). In CA1, the sharp waves occur most frequently during slow wave sleep and quiet sitting, less frequently during eating and drinking, and least frequently during grooming. They appear to occur during periods of low arousal and are often, but not always, inhibited by arousing stimuli. They may represent a resting state

of the hippocampus as a whole or the absence of some aspect of hippocampal function such as the theta state; functionally, it has been suggested that they represent a neural correlate of memory consolidation. Each sharp wave lasts 50 to 100 ms and has a maximum amplitude in the stratum radiatum that can be as large as 1 mV or more. Their resemblance to the interictal spike and wave complex of epileptogenic cortex may give some clues to the peculiar susceptibility of the hippocampus to seizure activity (Bragin, 1999; Draguhn et al., 2000; Buzsaki and Draguhn, 2004). They occur more or less synchronously over large areas of the CA1 field of the dorsal hippocampus: Recordings at different points along the septo-temporal axis of the hippocampus have shown that they are in phase over the entire extent (Buzsaki et al., 1992; Chrobak and Buzsaki, 1996). They reverse polarity in the pyramidal cell layer and reach their maximum amplitude several hundred microns into the stratum radiatum (O'Keefe and Nadel, 1978, pp. 150–153). Buzsaki and colleagues have suggested that sharp waves originate in the CA3 field and that the sharp waves recorded in CA1 are the summated extracellular excitatory postsynaptic potentials (EPSPs) of the Schaffer collaterals that result from synchronous firing of the CA3 pyramidal cells (Csicsvari et al., 2000). Direct stimulation of these fibres results in evoked potentials with similar shape and depth profiles.

Around the time of the negative peak of the sharp wave, there is a high-frequency oscillation of between 120 and 200 Hz whose peak amplitude occurs in the CA1 pyramidal cell layer (O'Keefe and Nadel, 1978, pp. 150–153; Buzsaki et al., 1992) (Fig. 11–1C). During these “ripples” there are synchronous bursts in almost all theta interneurons and in about 1 in 10 of the complex-spike pyramidal cells. Intracellular recordings from the soma of pyramidal cells during ripples reveals intracellular oscillations that mirror the extracellular pattern. Hyperpolarization results in a reduction of ripple amplitude at  $-70$  mV, with a reversal at more negative potentials. This sequence of events suggests that the sharp wave itself reflects the synchronous barrage of afferent activity from CA3 cells onto the apical dendrites of CA1 cells. The rapid activation of inhibitory interneurons causes synchronized hyperpolarizing inhibitory postsynaptic potentials (IPSPs) in the somata of pyramidal cells.

Are sharp waves and ripples confined to the hippocampus proper, or do they spread to other structures? Recordings in the subiculum and the deep layers of the entorhinal cortex show that sharp waves also occur in these structures at about the same time as those in hippocampus. The sharp wave in layers V and VI of the entorhinal cortex, which receive inputs from the hippocampus, followed those in the hippocampus by 5 to 30 ms (Chrobak and Buzsaki, 1996). In contrast, the presence of hippocampal sharp waves is not reflected in the activity of the upper layers (II and III) of the entorhinal cortex, which project to the dentate gyrus, hippocampus, and subiculum. Recordings from the dentate gyrus show that the granule cells are also influenced by the sharp-wave activity of CA3. The anatomical basis for this retrograde effect is not entirely clear.

There are projections from CA3 into the polymorph layer, and these fibers may be ending on mossy cells, which in turn project to the dentate granule cells. In the ventral tip of the hippocampus, there appear to be some CA3 pyramidal cells that project directly into the molecular layer of the dentate gyrus.

#### **11.4.2 Dentate EEG Spikes During LIA**

Sharp-wave activity during LIA also occurs in the granule cell layers of the dentate gyrus. It is also associated with a high-frequency ripple, although the frequency is not as high as that of the CA1 ripple. Most granule cells do not fire during dentate sharp waves, but intracellular recordings have shown that they are nevertheless depolarized at this time. Surprisingly, the overall effect of dentate spikes on CA3 cells is inhibitory. This presumably reflects the heavy innervation of interneurons by the mossy fibers (Acsady et al., 1998) (see Chapter 5, Section 5.7).

#### **11.4.3 Pharmacology of LIA**

Little is known about the pharmacology of LIA, the sharp waves, or the ripples. Ripples are eliminated under halothane anesthesia, and their frequency is reduced under urethane and ketamine to around 100 Hz (Ylinen et al., 1995). In the mouse, sharp waves and ripples can be elicited by application of KCl to the dendrites of pyramidal cells following pharmacological block of GABA<sub>A</sub> receptors, making it unlikely that they are due to activity in networks of the inhibitory interneurons (Nimmrich et al., 2005). Synchronization between ripples appears to depend on gap junctions. Consistent with the idea that the LIA state is a passive absence of theta, procaine or muscimol suppression of the medial septum, which inhibits theta activity, has only a small effect on the power of hippocampal LIA (Bland et al., 1996). Recordings of medial septal and diagonal band cells during LIA show that the firing rates of most of these cells are reduced relative to theta, strengthening this suggestion. On the other hand, cholinergic activation of the septum completely suppresses hippocampal LIA, replacing it with low-frequency theta even in the immobile animal (Fig. 11–2E). Theta appears to be the active state driven from the medial septum, and LIA is the passive state that occurs in its absence.

#### **11.4.4 Behavioral Correlates and Functions of LIA**

In their discussion of hippocampal sharp waves and ripples during LIA, O’Keefe and Nadel (1978, pp. 150–153) suggested that one way to think about this EEG state was as an absence of the theta state—it is the hippocampus in a non-theta idling mode. This suggestion was based partly on the observation that there was always a period of at least a few seconds between the onset of an LIA-associated pattern of behavior (such as immobility) and the onset of the sharp wave and ripples. They also argued that the nearly synchronous bursts in a

sizable percentage of the pyramidal cells, when compared with their highly differentiated patterns of activity during the theta state as the animal moved around an environment, would be unlikely to convey much information. Perhaps most tellingly, it was found that lesions of the fornix decreased neither the frequency nor the amplitude of ripples and sharp waves; if anything, they increased them—again suggesting release of the hippocampus from an activated theta state. In this view, the LIA state is the passive activity of a system with extensive positive and negative feedback loops and other oscillatory mechanisms.

An alternative hypothesis is that LIA is an active, rather than an idling, state of the hippocampus whose function is to strengthen synaptic modifications that have occurred during the immediately prior periods (Buzsaki, 1989). Pointing to the similarity between the synchronous volleys of afferent activity impinging on the dendrites of CA1 dendrites during LIA and the type of tetanic stimulation known to cause LTP, Buzsaki suggested that synaptic potentiation occurs naturally during LIA. He went on to propose that this potentiation acts as a boost to synapses that had been only weakly modified during the previous theta behaviors and perhaps plays a role in a memory consolidation process. Evidence in support of this idea comes from experiments by Skaggs and McNaughton (1996). They looked at pairs of CA1 pyramidal cells with overlapping place fields in freely moving rats that were running around a small triangular runway. When identified cells were recorded before and after the animal had run around for extended periods, they observed during LIA an increase in the cross-correlation between cells that had been simultaneously active during the previous period. That is, cells with firing fields that were close together in the environment were more likely to fire close together in time during an ensuing period of slow-wave sleep than cells with more distant fields. The small number of collateral fibers between CA1 pyramidal cells suggests that this effect might be due to an increase in the efficacy of the common input from CA3 or the entorhinal cortex onto these cells, rather than to the direct connections between them. In the consolidation view of LIA, the uncoupling of the hippocampus from the septum during LIA is merely a necessary condition for hippocampal consolidation to occur.

A related idea is that LIA is a period involving transfer of information from hippocampus to neocortex. Support for this view comes from experiments (Siapas and Wilson, 1998) that showed a correlation between hippocampal sharp waves and neocortical spindle waves during slow-wave sleep. The hypothesis that information might be transferred from the hippocampus to the neocortex as a result of LIA-associated sharp waves is consonant with evidence from behavioral experiments addressing the question of long-term storage of memory “traces” in or outside of the hippocampus. Chapter 12 presents evidence that lesions to the hippocampus in animals and humans can sometimes cause temporally graded amnesia. One interpretation of such a gradient is that memory traces are stored only in the hippocampus for a short period before being sent to the neocortex for permanent stor-

age (see Chapter 13, Section 13.3 for a more extensive discussion of consolidation). After this period, damage to the hippocampus would no longer result in memory loss. Although the sharp waves may be part of such a mechanism, there is some evidence against this general idea. For example, Leonard and colleagues (1987) have shown that LTP cannot be induced in the hippocampus during slow-wave sleep. If this finding can be generalized to other parts of the brain, it would greatly reduce the attractiveness of the hypothesis that sharp waves could serve as a basis for consolidation because no new LTP-based learning could take place. There is clearly much more to understand about ripple/sharp-wave states. A possible role in memory formation may not be restricted within the confines of the currently dominant theory of intrahippocampal consolidation or hippocampo-neocortical trace transfer during sleep. For example, ripple/sharp-wave events may have a purely intrahippocampal *housekeeping* function. To take just one possibility, synaptic renormalization or overall gain control processes might occur during LIA.

#### 11.4.5 Small Irregular Activity

Small irregular activity (SIA) is characterized by low-amplitude irregular activity in the hippocampus and desynchronization in the neocortical EEG. In 1967, Pickenhain and Klingberg reported low-amplitude irregular activity in the hippocampus of rats during transitions to alertness where no orienting movements were made, such as when a click awakened them from sleep. Vanderwolf and Whishaw (Whishaw and Vanderwolf, 1971) noted a similar pattern during transitions to alertness but added the observation that SIA, as they called it, occurred when rats abruptly halt voluntary movement.

Jarosiewicz and colleagues (2002) have extended the characterization of SIA to include periods during sleep. Sleep SIA bursts occur repeatedly during all periods of slow-wave sleep and after nearly every REM episode. Each burst typically lasts a few seconds, with a range from 200 ms to many seconds. A brief tone presented in sleep routinely elicited an increase in electromyographic (EMG) and neocortical arousal accompanied by hippocampal SIA, suggesting that it is a state intermediary between LIA and theta (Jarosiewicz and Skaggs, 2004b). Sleep SIA is characterized by the cessation of firing in most pyramidal cells. The 3% to 5% that continue to fire do so actively and repeatedly over successive bursts. These place cells are probably continuing to represent the location where the rat fell asleep because rotating the platform and the sleeping rat away from a given cell's place field location relative to the testing laboratory did not have an effect on SIA firing (Jarosiewicz and Skaggs, 2004a).

#### 11.4.6 Beta/Gamma Activity in the Hippocampus

In addition to the low-frequency EEG activity seen during theta and LIA, and the higher frequency ripple activity characteristic of sharp waves and dentate spikes, intermediate fre-

quency 10- to 100-Hz waves have also been described. This band is further divided into beta (10–20 Hz) (Leung, 1992) (Fig. 11-1D) and gamma (20–100 Hz) (Fig. 11-1E) activity. Gamma waves were first described in the cat amygdala by Lesse in 1955 and have since been reported in widespread brain regions of animals and humans (Singer and Gray, 1995). It has been suggested that gamma synchrony between various regions of the neocortex binds together the simple elements of a complex representation. In the hippocampal formation, they occur most clearly in the entorhinal cortex and dentate but have also been reported in the CA fields (Csicsvari et al., 2003). They may be related to 40-Hz oscillations that have been reported in the olfactory (Freeman, 1975) and visual (Singer and Gray, 1995) systems.

Gamma activity is slightly depressed in the rat by both septal lesions and cholinergic antagonists (Leung, 1985). In rabbits, drugs that stimulate a-theta during immobility (e.g., physostigmine) increase the amount of this intermediate frequency. However, this increase does not seem to occur in immobile rats. Seizures cause a dramatic increase in the amount of beta/gamma activity, an effect blocked by cholinergic antagonists and unaffected by the animal's ongoing behavior (Leung, 1992). The extent to which this beta/gamma activity is a reflection of the underlying behavior of neural elements (principal cells or interneurons) is unclear, although it may be a correlate of the activity of hilar theta cells.

#### 11.4.7 Olfactory Stimulation Can Elicit Hippocampal Gamma and Beta Waves

In the rat hippocampal formation, both beta and gamma waves occur preferentially during olfaction. The dentate gamma waves appear to occur during the sniffing of odors in general but do not occur during odorless sniffing or other sensory stimulation (Vanderwolf, 2001) (Fig. 11-1E). The behavioral correlates of the CA1/CA3 gamma have not been established. In general, gamma and theta occur independently, but under some (undefined) circumstances they become synchronized, with the gamma occurring preferentially at the positive peak of the dentate theta waves. The dentate, but not the CA1, gamma is dependent on the perforant path input from the entorhinal cortex, as lesions of the entorhinal cortex abolish the dentate gyrus gamma but enhance the CA1/CA3 gamma (Bragin et al., 1995). Dentate gamma waves may be part of the mechanism for synchronizing the olfactory inputs arriving via the entorhinal cortex with the hippocampal theta. Beta waves have a more restricted olfactory correlate than gamma waves. They occur in the dentate gyrus in response to olfactory inputs that signal, or mimic those that signal, the presence of predators (Fig. 11-1D) (Vanderwolf, 2001): compounds found in the anal scent gland secretions of weasels and foxes, most organic solvents including toluene and xylene, and phytochemicals derived from plants such as eucalyptol and salicylaldehyde. In general, these odors also elicit a fear response and behavioral avoidance. Other strong smells, such as ammonia, cadaverine, or

putrescine, which are either approached or not avoided, do not elicit dentate beta waves. Vanderwolf has argued that these olfactory correlates of gamma and beta waves in the hippocampus suggest a primary olfactory function for this structure, but it is more likely that, like the theta waves, they represent one aspect of a more complex overall function, such as cognitive mapping or associative memory formation.

## 11.5 Single-cell Recording in the Hippocampal Formation Reveals Two Major Classes of Units: Principal Cells and Theta Cells

Although EEG recordings provide some information about the circumstances under which large numbers of neurons in a brain region become synchronously active, it is generally accepted that a complete understanding of function can be gained only by looking at the behavioral correlates of single units. One reason for this is that although neighboring neurons often share common functional properties they may not always respond to the same specific stimulus or behavior. As we shall see, this is particularly true of the hippocampus, where neighboring pyramidal cells share the property of representing places in an environment. However, because different cells become active in different parts of an environment, this property is not revealed in the hippocampal EEG.

The recording of individual neuronal responses in the hippocampus of the awake freely moving rat began during the early 1970s with the work of Ranck (1973) and O'Keefe (O'Keefe and Dostrovsky, 1971). They both encouraged their animals to move around the environment, engaging in every-

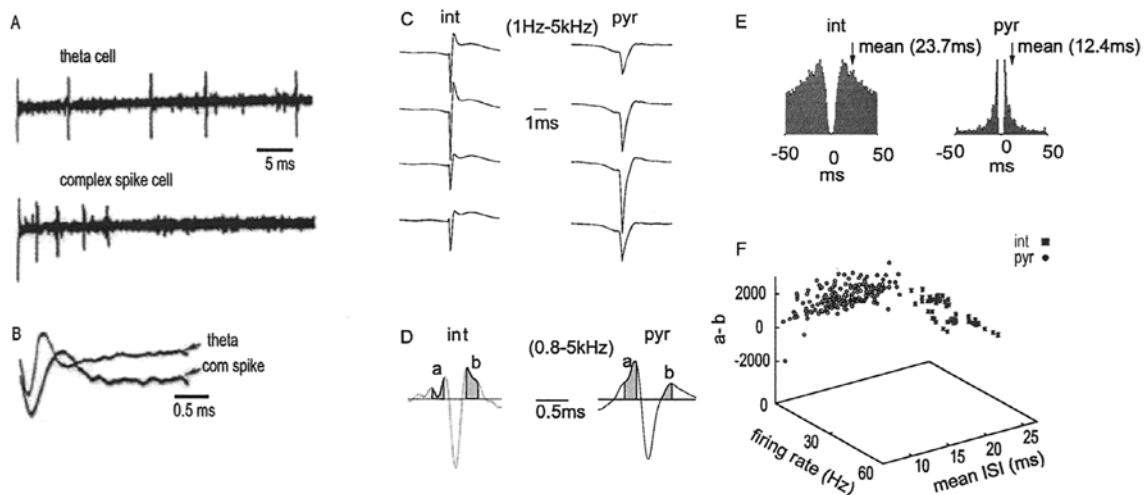

day tasks such as eating, drinking, sleeping, and searching for food and water. This emphasis on naturalistic behavioral correlates led to several important discoveries. The first was that they noticed that there were two major classes of cells that could be distinguished by differences in their anatomical and physiological properties (e.g., firing rates, action potential width, and relative locations in the hippocampus). Ranck termed these two classes complex-spike and theta cells, and these terms are still in general usage. We describe their properties in a subsequent section. Perhaps more importantly, they discovered that the firing patterns of the two cell types had repeatable behavioral correlates. Ranck had trained his animals to approach one location to obtain food and another to get water, and emphasized the relation of the complex-spike cell firing pattern to the behavioral approach to reward. O'Keefe was more impressed by the spatial correlate and named the cells *place cells*. It is now widely accepted that the location of the animal in a familiar environment is the major determinant of when such cells fire.

The second class of neurons, the *theta cells*, has less specific behavioral correlates. As the name implies, their behavioral correlates are closely related to those of the gross EEG waves and in particular theta. They tend to change rate during hippocampal EEG theta, and many display strong phase locking to the individual theta waves.

Extracellular recordings in the freely moving rat enable complex-spike and theta cells to be distinguished on the basis of differences in their wave shapes, firing rates, and other properties (Fig. 11–3). Complex-spike place cells have a much broader action potential than theta cells (Fig. 11–3B–D), often display a complex-spike burst pattern in which the later spikes in a burst are smaller in amplitude and of longer duration than the first (Fig. 11–3A), and have a lower spontaneous

**Figure 11–3.** Complex-spike cells and theta cells have different physiological properties. A. Theta cells have a steady firing rate and constant size amplitude spikes, whereas C-S cells sometimes emit a complex-spike burst in which the later action potentials in the burst are lower in amplitude and broader. B–D. Action potentials of C-S cells (pyr) are broader and have a larger initial hump than those of

theta cells (int). E. C-S cells have a narrower range of interspike intervals (ISI) F. Three-dimensional plot of firing rate against mean ISI and spike asymmetry (a-b in D) separates the overall population into two clusters. (Source: A,B. After Christian and Deadwyler, 1986; C–F. After Csicsvari et al., 1998 with permission.)

background firing rate (generally about 1 Hz) (Fig. 11–3F). In contrast, theta cells have a much higher firing rate (10–100 Hz) (Fig. 11–3F) with all action potentials being of the same amplitude (Fig. 11–3A) and of shorter duration (Fig. 11–3B–D). An important caveat is that in the rabbit this separation of spikes into two nonoverlapping classes is less clear as there appears to be a large subclass of complex-spike cells with spontaneous firing rates as high as 6 Hz.

It is highly likely that in the rat the complex spike cells are pyramidal cells and the theta cells are one or more types of interneuron. Intracellular staining of neurons that display complex spikes in brain slices reveals they have the morphology of pyramidal cells, whereas those without complex spikes are interneurons. Sometimes it is possible to activate complex spike cells antidromically from electrodes placed in hippocampal outflow pathways, but the theta cells can only be driven orthodromically (Berger and Thompson, 1978; Fox and Ranck, 1981; Christian and Deadwyler, 1986). Another strong piece of evidence in support of the idea that complex-spike cells are pyramidal cells and theta cells are interneurons comes from the temporal relation between their firing patterns. Most pyramidal cells innervate neighboring interneurons via an axon collateral, which should give rise to an increased probability of firing in the theta cell shortly after an action potential in the pyramidal cell. Just such a relation

has been reported. Some theta cells tend to fire a few milliseconds after a complex-spike cell recorded on the same tetrode (see Box 11–1), and this is reflected in a short latency cross-correlation between their spike trains (Csicsvari et al., 1998) (Fig. 11–4B–D and Box 11–2).

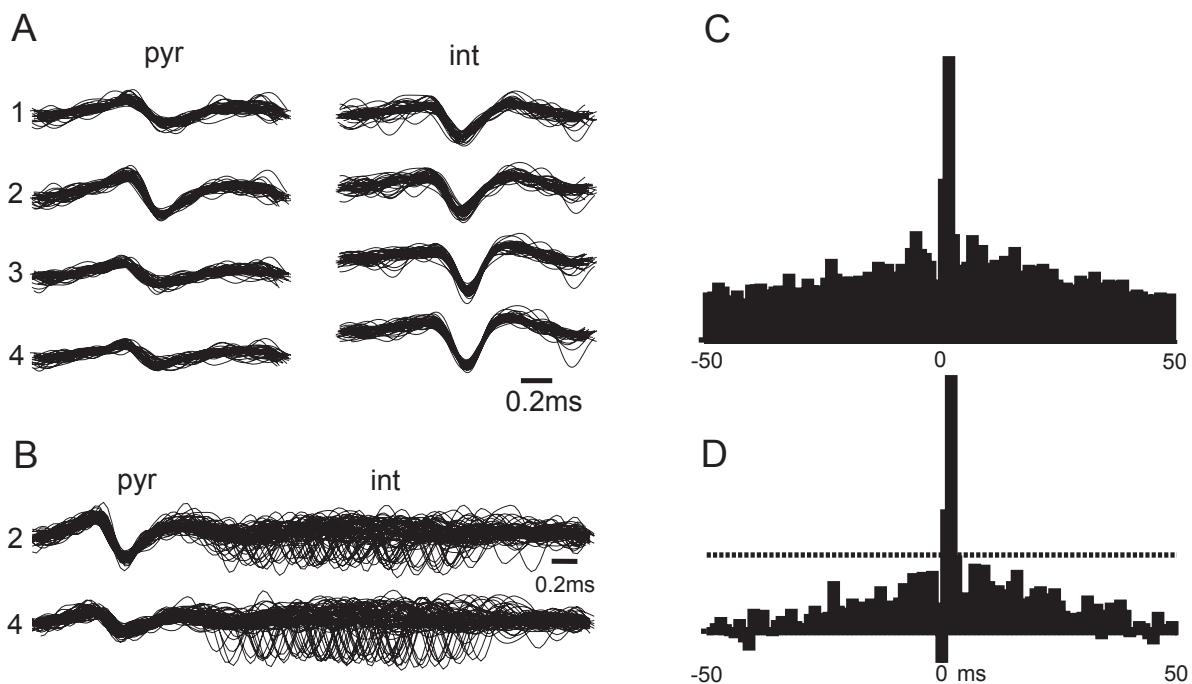

The same generalizations can be made for rabbits. However, there appears to be an additional group of intermediate cells that exhibit complex spikes and that can be antidromically activated by stimulation of projection pathways; but they have a resting firing rate that is intermediate between the theta and complex-spike cell firing rates shown in rats (Berger et al., 1983).

### 11.5.1 Distinctive Spatial Cells—Complex-spike Place Cells, Head-direction Cells, and Grid Cells—Are Found in Various Regions of the Hippocampal Formation

Discovery of the place cells led to the development of the *cognitive map theory* of hippocampal function by O'Keefe and Nadel (1978), which has guided much of the subsequent research and theorizing on hippocampal function (see Chapter 13, Section 13.4). Equally important for our understanding of the spatial functions of the hippocampal formation was the discovery of two other classes of spatial cell: In

#### Box 11-1 Microelectrode Recording Technique

Microelectrodes placed in the extracellular space in the vicinity of a neuron detect the current flow associated with action potentials. Experience has shown that relatively large electrodes with flat tips are preferable for recording in chronic animals because they do not puncture the cells and therefore do less damage during small movements of the electrode relative to the brain. One problem with the use of single electrodes in a structure such as the hippocampus is that it is difficult to isolate single units on the basis of action potential amplitude and shape. This is because of the close packing of the identically sized and shaped cells. Action potentials from all cells on a sphere with the electrode at the center are identical. There is a danger that all such spikes are considered to have come from one neuron. Template-matching algorithms, which are so useful when different cell types are in close proximity, offer no way out of this ambiguity and also have difficulty coping with the fact that a single pyramidal cell sometimes fires simple spikes and sometimes complex spike bursts in which the later action potentials in the burst have reduced amplitude and broader waveforms than the initial spike (Fig. 11–3A). One solution, introduced by McNaughton et al. (1983b), is to use multiple electrodes whose tips are close enough to sense the action potentials from a group of neurons but, being spaced a short distance apart, cannot both be at the center of a notional sphere. Each electrode tip is a slightly different distance from a given cell and, consequently, records its action potential with a slightly different amplitude and shape. These sometimes subtle differences can be used to distinguish a multiunit recording from several electrodes into spikes emanating from different cells. The principle is analogous to a “stereophonic” recording in which two or more microphones are used to capture the sound of an orchestra; hence, the earliest electrodes of this type used two wires and were called “stereotrodes.” In general,  $n + 1$  electrodes are necessary to identify uniquely the action potential from a neuron in n-space. In the hippocampus, “tritrodes” with three tips oriented in the plane of the quasi-two-dimensional pyramidal cell layer would probably suffice; but in practice, “tetrodes” are commonly used to ensure adequate isolation (O'Keefe and Recce, 1993; Wilson and McNaughton, 1993). Figure 11–4A shows the profile of action potentials of complex-spike and theta cells on the four electrodes of a tetrode.

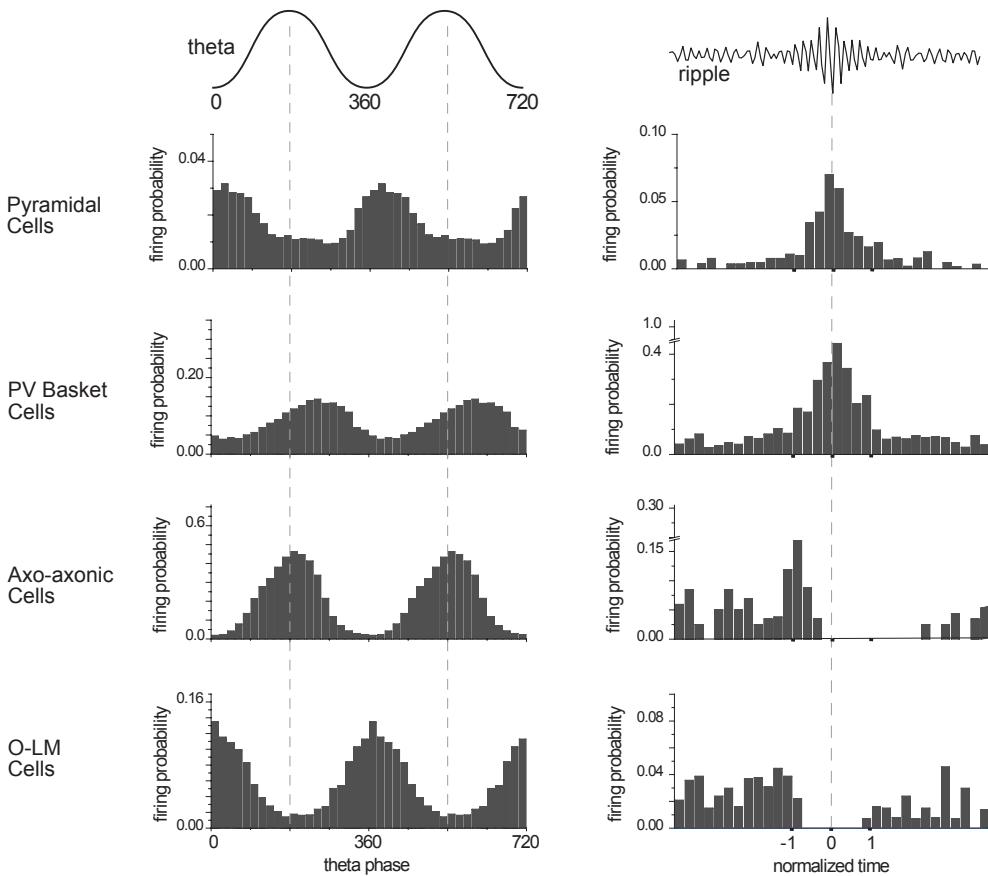

**Figure 11-4.** Hippocampal interneurons sometimes fire a few milliseconds after neighboring pyramidal cells. *A*. Waveforms of a pyramidal (pyr) and an interneuron (int) recorded on the same tetrode (traces 1–4). *B*. Multiple sweeps triggered on the pyramidal cell show that the interneuron often fired at a short but variable latency shortly after, suggesting a monosynaptic coupling between the two. *C*. Cross-correlogram between the firing trains of the two

cells in *B* shows the interneuron fires at a peak latency of 2 ms following the spike in the pyramidal cell. *D*. Controlling for the repetitive rhythmical pattern of firing within each of the spike trains does not eliminate the short-term causal relation between the two. Horizontal line in *D* indicates a significance level above which the correlation is highly significant. (Source: After Csicsvari et al., 1998, with permission.)

#### Box 11-2 Auto-correlation and Cross-correlation Functions

Correlation techniques are used to investigate the temporal relations of spike occurrences to themselves (auto-correlation) (Fig. 11-3 E), to the occurrence of spikes in other neurons (cross-correlation) (Fig. 11-4C,D), and to other brain events (e.g., theta waves) (Fig. 11-5) or to sensory and motor events in the environment (e.g., peristimulus event histogram) (see Fig. 11-17, later). The auto-correlation function is useful for revealing repetitive or rhythmical patterns of firing. A graph is constructed in which the x-axis represents time intervals before and after each spike event, and the y-axis represents the probability that the cell will fire during each interval before or after that spike event. A period of 50 ms is a useful period of time for looking at the complex spike properties of principal cells in which the cell fires repetitively within 10 ms (Fig. 11-3A,E); 500 ms is a useful length of time for demonstrating the rhythmical pattern of theta cell firing. The cross-correlation function reveals the tendency of two cells to fire with a particular temporal relation to each other. Here one cell is chosen as the target, and its spikes fix the zero point on the time axis. The probability of the other cell firing at times earlier and later is calculated and displayed as a histogram. This type of analysis is useful for identifying potential synaptic relations between cells or the existence of common inputs to the cells. The cross-correlogram between a complex-spike cell and a theta cell is shown in Figure 11-4C,D. The peak at 2 ms suggests that there is a short-latency excitatory synaptic connection from the pyramidal cell to the theta cell. The probability associated with this peak gives some indication of the strength of this connection. The correlation between hippocampal units and the phase of the global EEG theta signal is useful for showing the temporal relations of different types of unit to the EEG and to each other (Fig. 11-5). A final use of correlation techniques is to look for a relation of spike firing to a sensory event or motor action in the external world or to another brain event. Illustrated in Figures 11-17 to 11-19 are peristimulus histograms of hippocampal unit responses to auditory stimuli as a result of conditioning experiments and in Figure 11-20 (see later) the increase in activity during different aspects of the behavioral learning paradigm.

**Figure 11-5.** Phase relations of pyramidal cells and various classes of interneurons for theta (top left) and sharp-wave ripples (top right). Note that the various interneurons have phase relations different from those of theta activity. Note also that pyramidal cells and basket cells fire during the ripples, axo-axonic cells fire slightly before, and both they and the O-LM cells are silent during the ripples. (Source: After Klausberger et al., 2003.)

1984, Ranck described the *head direction* units, and in 2005 Hafting and colleagues discovered the *entorhinal grid* cells. The availability of directional and distance information to the mapping system was a prediction of the theory, and the discovery of these cell types in the hippocampal formation provides strong support for it.

Head direction cells were first discovered in the dorsal presubiculum (or postsubiculum) (Ranck, 1984; Taube et al., 1990a). The activity of these cells complements that of the place cells: They do not take into account the animal's location but signal the direction in which it is pointing relative to the environmental frame. They are rarely found in the hippocampus proper but mainly in another part of the hippocampal formation, the dorsal presubiculum, which has strong anatomical connections to the hippocampus via its projections to the entorhinal cortex, perhaps to the grid cells located there. The best estimate is that about 25% of the cells in this area are sensitive to head direction, whereas other cells there have angular head velocity, running speed, locational, and both directional and locational correlates (Sharp, 1996; Cacucci et al., 2004). They are discussed in Section 11.9.

The grid cells are found in the medial entorhinal cortex. Their firing maps lay down a regular pattern of locations across all environments the animal encounters. They are well suited to provide the self-motion or idiothetic information for the construction of place cells, as well as the distances and directions between them. They are considered in greater detail in Section 11.7.7.

Not everyone who has recorded from principal cells in the hippocampus agrees with this spatially conditioned way of looking at the data. For example, there have been reports of temporal correlates between pyramidal cell firing with eyelid responses during nictitating membrane conditioning and sensory, motor, and task-related correlates during olfactory learning and memory tasks. These reports have suggested a function for the hippocampus broader than spatial memory and navigation, perhaps as a storage device for nonspatial as well as spatial relations. Several authors, most notably Eichenbaum and Cohen (Cohen and Eichenbaum, 1993; Eichenbaum and Cohen, 2001), have returned to the original Ranck description of these cells as having behavioral approach as well as spatial and relational correlates. The next

sections focus on the extensive literature on place cells, theta cells, and on other spatially related cells in particular, head-direction cells, and grid cells. Work on nonspatial correlates is described in later sections (see Section 11.11).

## 11.6 Theta Cells

The second major class of cells in the rodent hippocampal formation is the theta cell. These cells are distinguishable from the complex-spike cells by having a briefer action potential, a higher firing rate, and a different anatomical location (Fig. 11–3). They also have a different relation to the hippocampal EEG. Given the predominance of theta EEG activity during certain behaviors, it is not surprising to find that many cells in the hippocampus have a rhythmical pattern of firing that is related to theta. Theta cells were originally defined by their strong, consistent phase correlation to the EEG theta pattern and by their increased firing rate during theta, irrespective of the animal's location. Subsequently, the class was broadened to include cells that decrease their firing rates during theta. In contrast, the timing of complex-spike action potentials relative to the theta waves is more complex and changes as the animal moves through the place field (see Section 11.7.9). In the rest of this section, the relation of theta cells to the EEG, their pharmacology, and their correlation with behavior are described.

### 11.6.1 Theta Cells Fire with a Consistent Phase Relation to EEG Theta

The defining feature of theta cells is their close relation to the hippocampal EEG. Bland and his colleagues (Colom and Bland, 1987) have identified four classes of theta cell, theta-on and theta-off cells, each of which is subdivided into phasic and tonic subtypes. Theta-on cells increase their firing rates during theta activity, whereas theta-off cells decrease their activity. Phasic cells have strong constant phase relations to theta; tonic ones do not. The theta-off cells are found much less frequently than theta-on cells and are particularly rare in the freely moving rat.

In the urethane-anesthetized rat, both CA1 and dentate theta cells fire close to the negative peak of the dentate theta. In contrast, in the awake animal, maximal firing is found much closer to the positive peak of the dentate theta (Fox et al., 1986). In addition, there is a broad range of preferred phases in the various cells pointing to a heterogeneous population of theta cells. It is likely that more than one class of interneuron is involved, corresponding to the different classes of hippocampal interneuron identified in Chapter 8. Different types of interneuron have different phase correlates to theta and the LIA sharp waves. For example, Klausberger (2003) reported that the basket cells, which have their cell body in the pyramidal cell layer and inhibit the perisomatic region of the pyramidal cells, preferentially fire on the positive/negative part of the theta wave and on each wave of the sharp-wave rip-

ple oscillation; oriens/lacunosum-moleculare cells, with their somata in the stratum oriens and their axons targeted on the distal dendrites of the pyramidal cells, fire on the negative phase of the theta wave and are silent during sharp waves; axo-axonic cells, which target the axon hillock of the pyramidal cells, fire on the positive theta wave and are also silent on the sharp waves (Fig. 11–5).

In the rabbit, the same cells take part in both a-theta and t-theta. Typically, the firing rate during a-theta is lower than during t-theta even for the same frequency of theta. Within each type of theta, the firing rates of the theta cells vary as a function of the frequency of theta. In Section 11.7.9, we discuss in greater detail the temporal relation between the complex-spike and theta cells and the EEG theta.

### 11.6.2 Pharmacology of Theta Cells

As we have seen in Chapters 3 and 8, interneurons in the hippocampus receive both GABAergic and cholinergic inputs from the septal nuclei, GABAergic and endorphin peptidergic inputs from other inhibitory interneurons, and glutamatergic inputs from the pyramidal cells. Finally, they receive catecholaminergic inputs from the brain stem and might be expected to respond to transmitters such as noradrenaline (norepinephrine). Firing rates of theta cells recorded in the urethane-anesthetized rat decreased by up to 75% following iontophoretic application of atropine or scopolamine (Stewart et al., 1992). There was, however, no change in the phase relation between the remaining spikes and the EEG theta. This is markedly different from the effect of the same drugs on complex-spike cells, which did not change their rate of firing but altered their patterns of firing from the usual complex-spike burst pattern to more continuous firing. This suggests that the cholinergic input to the hippocampus from the medial septal nucleus makes direct contact with the theta cells and increases their firing rate but has no influence on their theta burst mode of firing. It further suggests that the pattern of activity in complex spike cells, in contrast to the rate, has only a modest influence on the pattern of firing of the theta cell interneurons. Opiates have a different effect: They directly inhibit the interneurons and indirectly disinhibit the pyramidal cells, increasing their discharge rate firing (Pang and Rose, 1989). Finally norepinephrine has an effect that is broadly opposite to that of the opiates, exciting interneurons and inhibiting the principal cells in both the CA1 field (Pang and Rose, 1987) and the dentate gyrus (Rose and Pang, 1989).

### 11.6.3 Hippocampal Theta Cells Have Behavioral Correlates Similar to Those of the Hippocampal EEG

In the rat, theta-on cells increase their firing rates during the EEG theta and begin to fire in a bursting pattern in phase with the theta rhythm. This normally occurs during behaviors such as walking and swimming, which change the animal's location in an environment. During LIA behaviors (e.g., slow-wave

sleep, quiet sitting, eating, drinking, grooming), theta cell firing is lower in frequency and more random in pattern. Interestingly, low-frequency theta mode firing occurs during the postural shifts of grooming, such as changes from face-washing to flank-grooming.

Theta-off cells have the opposite behavioral correlates, increasing their firing rate during LIA and decreasing their rates during theta. There are differences between the behavioral correlates of theta in the rat and rabbit (see above), and similar differences are found in the correlates of theta cells in these two animals. For example, a-theta in the rabbit occurs much more readily in response to arousing stimuli in the absence of movement. It is no surprise, then, that the theta cells also fire during arousing stimuli as well as during movements such as walking and hopping. As we shall see in the section on conditioned responses in single hippocampal units (11.11.5), this a-theta related firing may help explain the involvement of the hippocampus in the timing of such responses to the (arousing) conditioned stimulus.

An important pointer to one function of the theta cells comes from an interesting observation by Nitz and McNaughton (2004). They found that a large number of CA1 theta cells turn off during the first exposure to a novel environment, whereas the dentate interneurons increased firing rates. Perhaps the CA1 interneurons are part of a mechanism for identifying familiar and novel environments and for controlling the processes of learning that occur in CA1 pyramidal cells when the animal is confronted with environmental novelty.

## 11.7 Complex-spike Cells and Spatial Processing

The primary correlate of hippocampal complex-spike cell firing is the animal's location in an environment. For this reason they have been called *place* cells (Fig. 11–21A, see color insert). This section begins with a description of the properties of place cells, followed by the factors that control the location, size, and shape of place fields. Both exteroceptive sensory cues and internal proprioceptive/vestibular cues play a role in determining place field structure and location. The frame of reference for the spatial coordinates of place fields can vary depending on the environment. It is known that the spatial code is conveyed by the temporal firing pattern of the complex-spike cells as well as by their absolute rate of firing. The animal's location in an environment is not given by the activity of a single place cell but by the pattern of firing across a large number of such cells. It follows, therefore, that it is important to look at the network properties of place cells. Place cells have been found in areas outside of the hippocampus, in particular in the subiculum and entorhinal cortex; and the properties of these cells and how they differ from those in hippocampus are discussed. The final section examines the data suggesting that place cell firing is controlled by activity in

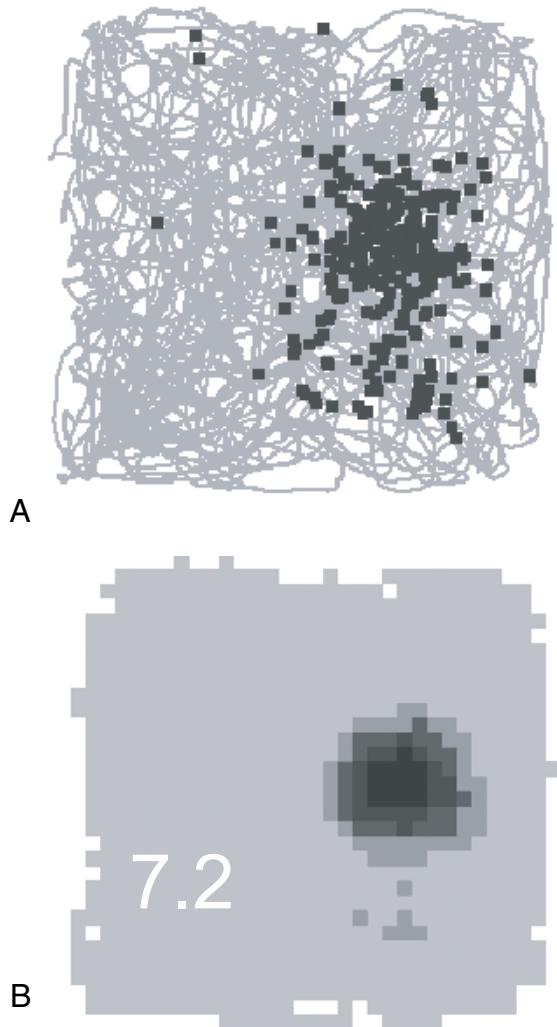

brain regions outside the hippocampal formation and in particular by cells in the septal region and in the thalamus.

### 11.7.1 Place Cells Signal the Animal's Location in an Environment

Place cells were discovered by O'Keefe and Dostrovsky in 1971 (O'Keefe and Dostrovsky, 1971). After recording from rat CA1 complex-spike cells during various behavioral tasks and in response to various types of sensory stimulation, they noticed that the activity of some cells was more closely related to the animal's location than to any aspect of the task in which it was engaged. O'Keefe (1976) confirmed and extended these observations by recording from rats as they ran between the arms of a three-arm maze to obtain different rewards. He christened these cells *place cells* and called the location where each cell fired its *place field*. There were several aspects of the firing patterns of these cells that suggested they were signaling the abstract concept of place rather than acting as simple sensory cells. First, it was not possible to identify any single sensory stimulus that reliably controlled the cell's activity. Second, after the rat had some experience with running on the maze in the dark as well as in the light, many of the complex-spike cells continued to fire in the appropriate location with the lights out. Third, on the broad-armed maze used by O'Keefe, many cells fired equally well as the animal faced in any direction. Finally, place field firing did not seem to depend on the animal's motivation or incentive for visiting a location. For example, interchanging the food and water rewards at the ends of the different arms of the maze had no effect on place cell firing. Thus, complex-spike cells did not appear to be tuned to specific sensory stimuli, they tolerated radical changes in lighting, and they were omnidirectional and uninfluenced by reward. The notion that something more abstract was being signaled—such as location—seemed an appropriate conclusion.

Some skepticism greeted the first qualitative reports of the properties of these cells. However, the introduction of photographic methods and, later, the development of computational methods of obtaining objective data gradually convinced the most ardent skeptics (Box 11–3 and Fig. 11–6). Over the years, improvements in single-cell isolation (see Box 11–2), coupled to ever more sophisticated behavioral procedures and unusual bits of apparatus (e.g., "morph" boxes with walls that can be reconfigured), have helped unravel many of the properties and determinants of place cells.

O'Keefe (1976) noted that although many complex-spike cells could be classified as simple place cells, others had more complex properties. For these cells, the firing rate was dependent on factors in addition to location. For example, some cells increased their firing rates if the animal experienced an object in their place field or engaged in a particular type of behavior there (e.g., running or sniffing). The clearest example of this type of cell was one that fired maximally when the animal went to a specific location on the maze and either failed to find something that had been there often before or found something new. These complex spatial cells were called *mis-*

**Figure 11-6.** Firing field of a CA1 place cell. *A*, Raw data from a rat foraging for food in a square box for 10 minutes. Gray line traces the animal's path through the environment; black boxes show firing of place cell. *B*, Place firing field as a grayscale map where darker colors represent higher firing rates. Inset number in white gives the peak firing rate. (Source: After Wills et al., 2005, with permission.)

place cells. Whether the firing of these misplace cells was due to the absence of the expected object or reward or to the myostatial (exploratory) sniffing elicited by the mismatch was not clear. Ranck (1973) noted similar behavioral correlates of hippocampal complex-spike cells but did not identify their spatial properties. He labeled one class “approach-consummate” cells because they fired as the animal ran toward the food or the water reward. Another class he called “approach-consummate mismatch” cells because they fired maximally when the animal sniffed around the reward location when the reward was withheld. It now seems likely that many and perhaps all of Ranck's first class of cells are synonymous with O'Keefe's category of place cells and his second class synonymous with the misplace cells. Eichenbaum and his colleagues have recorded cells during odor discrimination tasks with properties similar to those described by Ranck and

### Box 11-3 Quantitative Recording of Place Fields

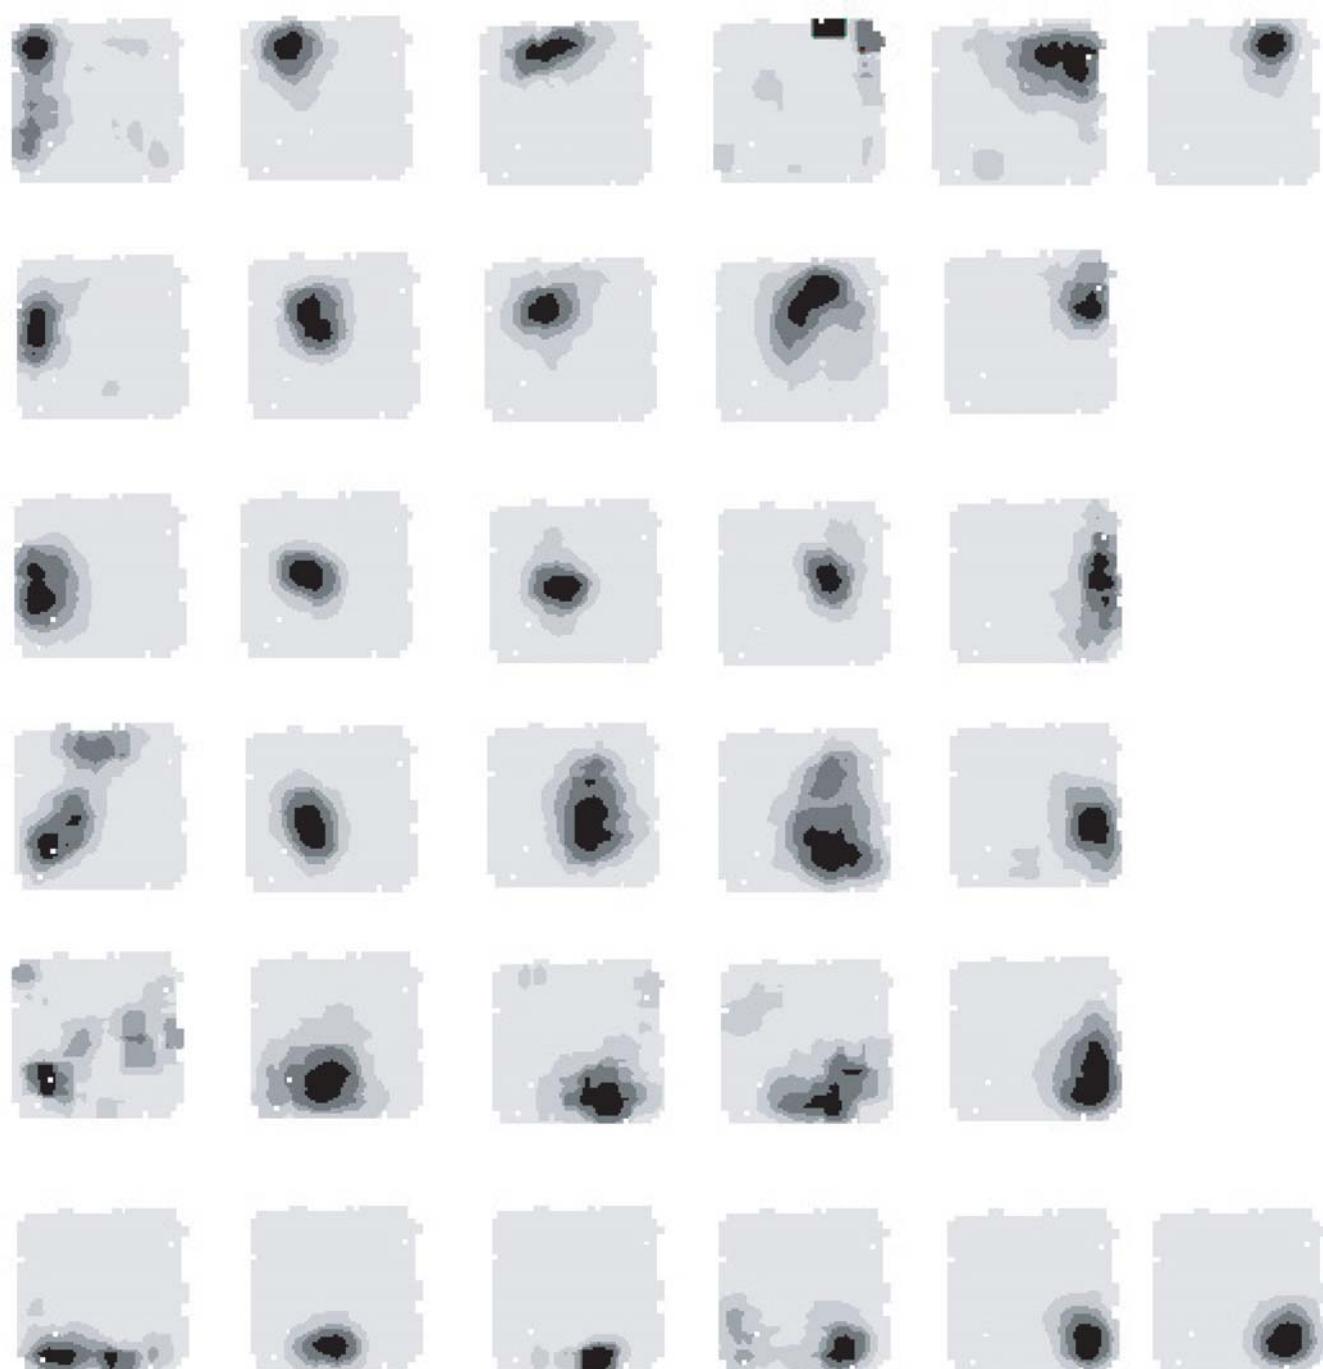

An objective description of the firing field of a place cell is achieved by constructing a map of firing frequencies across the surface of an environment (see Fig. 11-6). The location of a small light fixed to the animal's head is monitored by an overhead television camera, and the animal's position is recorded throughout the trial. The environment is broken up into a set of squares, and two independent measures are computed for each square: the amount of time the animal spent there and the number of times the cell fired while the animal occupied that square. A firing rate per square can be calculated by dividing the number of spikes in each square by the amount of time the animal spent there. Spatial firing rates are often portrayed as false color or grayscale maps in which different colors or shades of gray represent different firing rates. In some laboratories, the data are spatially averaged and smoothed before this step. The colors or grayscales allocated to the different firing rates are usually adjusted relative to each cell's peak firing rate (auto-scaling) to give comparable field pictures from high- and low-firing cells. When fields are created for the same cell across different conditions, it is often useful to fix all of the color map levels to the first one to facilitate comparisons. In some experiments, two differently colored lights or infrared lights of different intensities are fixed at different positions on the animal's head so the computer monitoring the animal's movements can compute the instantaneous heading direction as well as location. The best estimates of spatial firing are achieved during tasks in which the animal visits each section of the environment for an equal amount of time.

questioned whether all of these cells are best described as having spatial fields. This work is described in more detail later (see Section 11.11).

#### 11.7.2 Basic Properties of Place Fields

The size and shape of place fields vary with the shape and perhaps also the size of the testing enclosure as well as with the part of the hippocampus from which the recordings are taken. In the dorsal hippocampus, fields on small, open platforms have a tendency to be located along the edges or just off them (seen when the animal peers over the edge), whereas those in closed cylinders or rectangular boxes tend to be equally distributed around the environment (Muller et al., 1987) (Fig. 11-7). On mazes, fields may be located anywhere, with no tendency for them to cluster in particular arms or in particular parts of the maze such as at choice points (O'Keefe, 1976; Olton et al., 1978; McNaughton et al., 1983a; O'Keefe and Speakman, 1987). There are, however, occasional reports that provide exceptions to this generalization: Hetherington and Shapiro (1997) reported that fields tended to cluster closer to walls than in the center of rectangular boxes, and Hollup et al. (2001) found a greater representation of fields in the region of the goal in an annular-shaped swimming pool.

## Place fields of 32 simultaneously recorded complex-spike cells

**Figure 11-7.** Firing fields of 32 place cells simultaneously recorded while a rat foraged for food in a 62-cm<sup>2</sup> box. The place field maps are arranged topographically so fields in the northwest of the box are located at the upper left, fields in the southwest are located at

the lower left, and so on. In reality there is no topographical relation between the location of cells in the hippocampus and the location of their fields in an environment. (Source: After Lever et al., 2002, with permission.)

One distinctive feature of the representation of any particular environment by the hippocampal place cells is the absence of topographical mapping of function onto anatomy, such as is seen in the neocortex. That is, place cells located next to each other in the hippocampus are no more likely to have fields located next to each other than those far away (O'Keefe et al., 1998). In contrast, there have been some reports that neighboring cells have fields closer than expected by chance (Eichenbaum et al., 1989) or that cells in the hippocampus are functionally organized in bands separated by 300 to 400  $\mu\text{m}$  along the long axis (Hampson et al., 1999). A definitive resolution of the question seems to have been given by Redish and colleagues (2001). Using tetrodes to ensure adequate spike isolation, they collected a large number of recordings of pairs of complex-spike cells during tasks in which the animals ran along circular or linear tracks. They compared the place fields of cells recorded from the same tetrode (see Box 11–2) and therefore anatomically neighboring each other, with those of cells from different tetrodes and therefore more distant from each other. They found no tendency for the place fields of neighboring cells to be closer to each other than would be expected for cells located at any two points in the hippocampus. They also recorded the activation of the immediate early gene *Arc*, which identifies active cells, as the animal explored two different environments. In neither case did they find any evidence for clustering of cells with similar spatial or temporal correlates. One is tempted to speculate that there must exist some mechanism for preventing neighboring cells with their overlapping inputs from adopting similar place fields in any environment. Perhaps one function of the inhibitory interneuronal networks is to allow some pyramidal cells to capture a territory in an environment and to exclude their neighbors from firing in that region.

Place cells rarely have more than one field in a single environment (typical testing environments are less than 1  $\text{m}^2$ ). The best current estimate is that cells with double fields comprise no more than about 5% to 10% of the total. The sizes of place fields in the dorsal hippocampus vary considerably. To some extent, field size is a function of the threshold used for separating signal from noise and the location of the recording site along the dorsal septo-temporal axis of the hippocampus. Using a 1-Hz threshold as the minimum rate within a place field, field sizes in a cylinder of 76 cm radius ranged from a minimum of 4% of the surface area to a maximum of 62%, with a median size of 18% (Muller et al., 1987). (These data were obtained with single-electrode recording techniques; it is likely that the actual place field sizes are even smaller.) As can be seen from Figure 11–7, there appears to be a slight tendency for the fields in the center of the environment to be larger than those toward the periphery, but this has not been quantified.

The average size of the place field varies with location along the long axis of the hippocampus. As the recording electrode is moved to more ventral portions of the hippocampus, the size of place fields expands. Fields in the middle region of the hippocampus are almost twice as large as those in the septal hippocampus (Jung et al., 1994). The most ventral regions

of the hippocampus were not extensively explored in these studies, but a small number of cells recorded there (Maurer et al., 2005) appear to have fields twice the size of those in the middle region. It seems reasonable to assume, therefore, that field sizes increase as one goes from the dorsal to the ventral hippocampus; and some fields in the most ventral hippocampus might be very large, covering areas the size of the usual laboratory testing enclosures or even larger. This wide range of field sizes has important implications for analysis of the sensory correlates of hippocampal cells and for analysis of the differences in behavioral functions of the dorsal versus ventral hippocampus. Some authors have claimed that hippocampal complex-spike cells respond to specific sensory inputs (e.g., an odor) in the absence of a spatial correlate because the cells did not fire at higher rates in one part of the testing apparatus than in any other (e.g., Wood et al., 1999). Clearly, however, if some spatial firing fields can be as large as or even larger than the size of the apparatus, this conclusion is not warranted. At the very least, it is necessary to test sensory responses in two enclosures located in different laboratories. Similarly, when trying to discern the differences in function between the dorsal and ventral hippocampi, it is important to take this average field size difference into account. Fields that cover an entire testing enclosure might be described as spatial context neurons and in conditioning paradigms, for example, might have the primary function of distinguishing between two testing boxes rather than identifying different locations within the same testing box.

How quickly are place fields formed, and how do they develop? The answers to these questions can provide some indication of whether some or all of the representation of an environment is prefigured and what rules govern the plasticity involved in the initial development of the spatial representation. Several studies have provided reasonably good answers. On a small sample of 15 place cells, Hill (1978) found that 11 had fully fledged fields on the first entry into the relevant part of the environment. On a larger sample of cells and using tetrode recordings, Wilson and McNaughton (1993) allowed their rats to explore one-half of an open field box until it was familiar; they then removed a partition wall of the box, giving access to the whole. They reported that all place fields had stabilized within 10 to 15 minutes of entry into this new part of the enclosure. Frank et al. (2004) looked at the development of fields on a three-arm maze when one of the usual arms was closed and a new one with a different angular orientation was opened. They found that about one-quarter of the new fields on the novel arm developed rapidly within the first 2 minutes and that most fields had stabilized after 5 to 6 minutes of experience with this arm. Interestingly, cells that had less than 4 minutes of novel experience on the first day showed considerable plasticity on the second day, whereas those with more than 4 minutes' experience were much more stable. The firing in some fields strengthened in the initial location, that of others weakened, and some shifted to a new location altogether. Still others were initially silent on the arm, but after several minutes of exposure to the new arm turned on from this zero baseline and began to fire. The authors

pointed out that the latter phenomenon is incompatible with a role for postsynaptic spike timing-dependent plasticity in the recorded cells as the mechanism underlying place field development. This mechanism suggests that presynaptic activity coincident with postsynaptic spiking strengthens the active synapses, and the absence of postsynaptic cell firing prior to the development of the full-blown place field rules it out. Of course, it could be that the changes are taking place in an earlier part of the circuit with postsynaptic cells that are initially active. Our own studies (Lever, Cacucci, Burton, O'Keefe, unpublished) have examined CA1 place field dynamics during the first exposure to an entirely novel environment: a 60-cm sided square box located in a curtained environment of which the animal had no prior experience. In agreement with Frank and colleagues, we found that place field establishment was rapid and could occur within 2 to 3 minutes. Most of the CA1 cells that developed fields during the first exposure to an environment maintained these fields, but some stopped firing or changed field location. This is reminiscent of the process of place field development upon exposure to a new part of a familiar environment, described above. Setting up a representation of a new environment or part of an otherwise familiar environment seems to involve a competitive competition among a group of neighboring cells perhaps mediated by the inhibitory interneuronal networks. Initially, a small number of seed cells have place fields from the moment the animal enters the environment, although the field firing rate may increase or decrease with continued experience. These cells prevent neighbors from firing in their territories through activation of inhibitory interneurons. Other cells gradually fill in the unclaimed territory until the entire space is represented, at which point no other cells are allowed to develop place fields in that environment and the representation stabilizes. Both Wilson and McNaughton (1993) and Frank and colleagues (2004) noted that some theta cells showed a marked

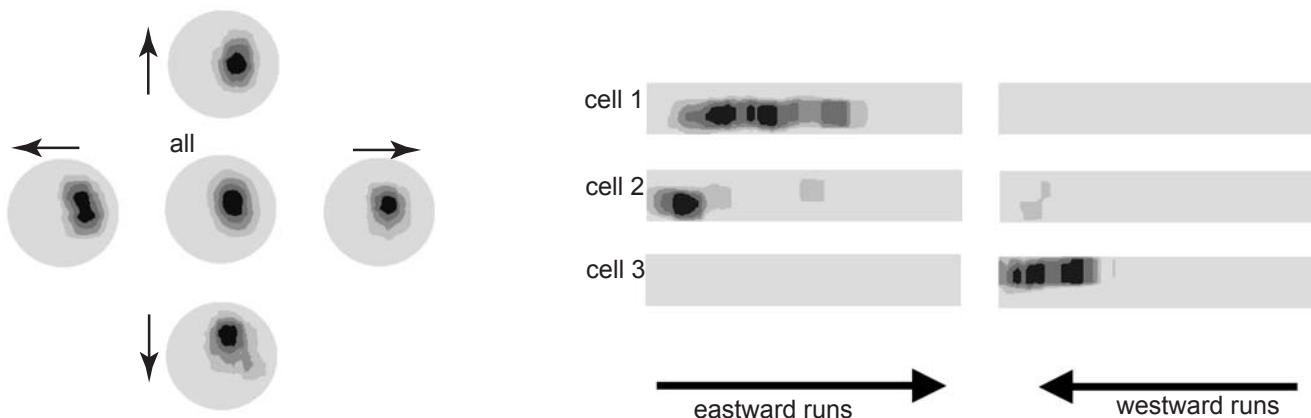

reduction in firing rate during the first entry into the novel environment, although according to Frank et al. this lasted only for the first minute of exploration. In a subsequent section, evidence is presented in support of O'Keefe's (O'Keefe, 1976) original idea that place cells could be activated in the place field by sensory cues experienced there or by path integration signals that compute the distance and direction from other locations. McNaughton et al. (1996) has speculated that when an animal first enters a novel environment the firing of place cells is driven by the path integration inputs and that only subsequently are the environmental stimuli experienced in each location associated with these place fields. A plausible alternative is that the small number of seed cells are driven by the appropriate combination of environmental cues from the first exposure (perhaps including the animal's own urine), and the rest of the cells are subsequently co-opted by the path integration system as the animal moves around the environment relative to these known locations. Further experimentation is needed to distinguish between these alternatives.

### 11.7.3 Place Fields are Nondirectional in Unrestricted Open-field Environments but Directional When Behavior Is Restricted to Routes

Place field firing sometimes depends on the direction in which the animal faces and sometimes it does not. In open-field environments, the place fields are nondirectional (Muller et al., 1994) (Figs. 11–8A; see Fig. 11–21A, color insert); on radial arm mazes (McNaughton et al., 1983a; Muller et al., 1994; Markus et al., 1995) and narrow linear tracks (O'Keefe and Recce, 1993; Gothard et al., 1996a), they are highly directional (Fig. 11–8B). Whereas in the first situation each cell may be said to represent a location, in the second it might more properly be described as representing a serial position along a path.

**Figure 11–8.** Place fields are nondirectional in open-field environments but directional on linear tracks. *A*. Central panel shows the firing field of a place cell in a 78 cm diameter cylinder regardless of the direction in which the rat is facing. The four outer panels show the field when the animal is facing in the four cardinal directions: northward at the top, eastward to the right, and so on. (Peak rates are shown in black: 12 center, 10 north, 12 east, 9 south, 9 west.) *B*.

Firing fields of three cells recorded simultaneously as the rat runs back and forth on a 1.5-m linear track for food reward at each end. Cells 1 and 2 fired as the animal ran from left to right but not in the opposite direction; cell 3 fired during right to left runs. (Peak rates shown in black: 9 top, 10 middle, 7 bottom.) (Source: Courtesy of O'Keefe.)

The difference between the two situations appears to be due, in part, to the constraints that the shape of the testing apparatus places on the animal's behavior. It is not a matter of sampling from two cell populations because the same cells can have directional or nondirectional fields in different testing apparatuses or under different behavioral constraints (Muller et al., 1994; Markus et al., 1995). The most important variables appear to be whether the animal can turn around in any given location and if it approaches the same location from many directions. If it can, cells are relatively nondirectional. However, if the animal always runs through the same location along the same one or two paths, place cells tend to be directional. Note that one can induce narrow and stereotypical pathtaking in open fields by reward shaping. Markus et al. (1995) originally trained rats to perform random foraging in an open cylinder and then retrained them to take direct paths in the same cylinder among four reward locations in either clockwise or anticlockwise sequences. The proportion of place fields defined as directional doubled from about 20% in the random foraging condition to 40% in the direct path condition. An important study has reexamined directionality in CA1 cells (Battaglia et al., 2004). These authors trained rats to run on narrow linear and circular tracks of the kind that would normally induce a high proportion of unidirectional place fields. Their finding across experiments was that placing various proximal multimodal cues along the tracks significantly increased the proportion of bidirectional place fields. This is puzzling because there are usually no distinctive local cues in open fields where the cells are typically nondirectional. The dynamics of (non)directionality need further study; there are no published reports examining directionality on first exposures in linear tracks. Does omnidirectionality appear as soon as a place field develops, or do the fields start out with a directional bias and only lose this directionality with further experience of the environment (Kali and Dayan, 2000)?

The existence of both directional and nondirectional modes of spatial representation raises the question of whether the hippocampus is providing fundamentally different types of information in these two situations. Specifically, does the spatial localization system, of which the place cells are a part, "know" that the rat is in the same location when, say, traveling east as when traveling west? Perhaps it is only acting to its fullest capacity when the cells are omnidirectional and is showing limited functionality when they are unidirectional. Against this is the recent demonstration (Rosenzweig et al., 2003) of a good correlation between the degree to which place cells recorded on a linear track used a particular reference frame and the animal's ability to localize an unmarked location defined within that framework. Place cells were recording on a linear track where locations could be identified in one of two conflicting frameworks: in the framework of (1) a goal box that changed location along the track from trial to trial or (2) stable room cues. The target location remained fixed relative to the stable room cues but moved from trial to trial relative to the moving goal box. The authors showed that the higher the percentage of place cells that related to the frame-

work of the stable room cues in each rat's hippocampus, the more likely the animal was to be successful at the task. The relation of place fields to different environmental reference frames is considered at greater length in a subsequent section.

One major difference between directional and nondirectional field firing is the influence on the firing rate within the field of the overall trajectory of the path in the former but not, so far as is known, in the latter. During behavioral tasks that promote directional firing and require the rat to traverse the same part of the apparatus as part of two different paths, place cells fire differently in the place field on the two paths (Frank et al., 2000; Wood et al., 2000; Ferbinteanu and Shapiro, 2003). For example, Wood and colleagues (2000) trained animals on a continuous alternation task in a T maze that had been fitted with return tracks from each goal to the start of the stem so the animal could run in a continuous figure-of-eight path by turning left or right alternatively at the choice point of the T junction. Activity in two-thirds of the place fields in the stem of the T varied markedly depending on whether the animal entered the stem following a return from the left-hand or right-hand goal. In the Wood et al. study, it was not possible to distinguish between firing owing to the previous part of the path (retrospective coding) and the future part of the path (prospective coding). Two of the three studies (Frank et al., 2000; Ferbinteanu and Shapiro, 2003), however, did allow for this distinction and reported that, in addition to the retrospective effect of the previous path on place cell firing, the subsequent path (i.e., the upcoming turn to be made at the T junction) also had an effect on firing in the stem (a prospective effect), although the effect was seen in only a few hippocampal cells in the Frank et al. study and was much more prominent in cells in the entorhinal cortex.

These effects appear to be due to the animal repeatedly running in a continuous trajectory in the same direction through the entire path and thus activating a fixed sequence of place cells. These prospective and retrospective effects have not been reported in nondirectional fields in open-field environments, suggesting they have something to do with the stereotyped ballistic nature of the paths taken on linear tracks. In the one study in which the effect was not seen, the animals were trained to alternate on a Y maze with broad arms (Lenck-Santini et al., 2001a). They had to return to the start arm following each visit to a goal arm, resulting in a start arm → left goal → start arm → right goal → start arm, etc. alternation pattern. This behavioral pattern would activate the same cells in a different order on successive runs, and the wide arms would allow the rat to take slightly differing paths on each run. Interestingly, one observation in the Ferbinteanu and Shapiro study suggests that the effect is not due solely to the activation of the immediately prior place cell in the sequence or the execution of the immediately preceding turn. On error trials in which the animal first visited an incorrect arm before entering the correct goal arm for that trial, about one-half of the cells with place fields in the goal arm continued to fire correctly. This shows that small deviations from the standard path through the environment do not disrupt the effect. The authors suggested that it is the overall journey from one place

to another that is important, not the actual sequence of locations traversed. Buzsaki (2005) has speculated that the firing of any given place cell may be influenced by place cells from early stages in the path and not just by the immediately preceding cell in the sequence. At this stage, it is not clear how much these effects are due to the beginning and end points of the path and how much to particular motor behaviors, such as body turns made during the path. One possibility is that the firing of many cells on these tracks is driven by the path integration system (see Section 11.7.7), and activation of the motor, proprioceptive, and vestibular systems at the turn into the stem of the T maze marks an important location on the path and is carried over to the rest of the path. This would explain some of the retrospective effects but would not explain the prospective effects unless there is activation of the turning machinery some period of time prior to reaching the turn itself.

These studies have been interpreted by their authors as pointing to a place cell basis for the episodic functions of the hippocampus (see Chapter 13, Section 13.4). O'Keefe and Nadel (1978, 1979) originally suggested that the spatial functions of the rat hippocampus could be elaborated into a spatiotemporal episodic memory in humans by adding a temporal time-stamp signal, which would allow each set of events occurring in the same location to be distinguished from each other on the basis of their time of occurrence. The present results, however, do not provide evidence for this unique time-stamp signal, which would enable different runs to be identified as independent episodes. Rather, it seems to be more appropriately interpreted as evidence of the organization of place cells into integrated, ordered sequences, as might be expected for the representation of paths.

To conclude this section, it is clear that the place cells can be directional or nondirectional depending on the specific circumstances in which they are recorded. It is important to emphasize that the nondirectional mode of place cell activity rules out the possibility that they are simply responding to a particular configuration of distal sensory cues. They cannot be responsive just to a particular view or scene in front of the animal (sometimes called the "local view"), as this would change radically as a function of the heading direction. Moreover, as these experiments routinely control for local sensory inputs such as intramaze smells and textures, nondirectionality is evidence in favor of the idea that these cells can signal something quite abstract.

#### 11.7.4 What Proportion of Complex-spike Cells Are Place Cells?

To estimate the proportion of complex-spike cells that are place cells, it is necessary to record from the same cells in several environments. This is because most place cells do not have a place field in every environment. For example, early studies (O'Keefe and Conway, 1978; Kubie and Ranck, 1983) reported that whereas some complex-spike cells had fields in two or more recording environments others had fields in one but not the other. A second problem is that many complex-spike cells

are silent most of the time, making it difficult to estimate the population number. Thompson and Best (1989) tried to get an accurate estimate of the population by recording during slow-wave sleep or while the rat was under light barbiturate anesthesia. Both procedures are known to enhance the spontaneous firing rates of complex-spike cells and may therefore provide a better estimate of the total population under the recording electrode than can be obtained during the active, awake state. They also recorded complex spikes in three environments: an elevated eight-arm radial maze, an enclosed cylinder, and an enclosed rectangular environment. They concluded that slightly more than a third of the cells that could be identified under barbiturate anesthesia had place fields in at least one of the three environments. Almost all of the other cells recorded had very low spontaneous rates in all environments (and were thus termed "silent cells"), with many firing no spikes for the entire period of testing. Only 14% of cells had fields in two environments, and only 1% had fields in all three environments. That is, many cells with fields in one environment acted like silent cells in the other environments. On the basis of the physiological similarities between the place cells and the silent cells, and the distribution of fields across the three boxes, Thompson and Best suggested that if enough environments were tested every complex-spike cell would have a field in at least one of them. In several studies, McNaughton and his colleagues (Wilson and McNaughton, 1993a; Gothard et al., 1996a) have sampled large groups of complex-spike cells and find that 30% to 70% have place fields in a given environment. Their group (Guzowski et al., 1999) has used the immediate early gene *Arc* to label all of the CA1 cells active in two groups of animals, each exploring a different environment. In one group 44% of CA1 cells were active and in the other group 45%—in broad agreement with the results from single-unit recordings. In animals that were allowed to explore both boxes and in which double staining was carried out, 22% of the cells were active in one environment, 23% in the other, and 16% in both. These studies make it clear that a large proportion of complex-spike cells have a place field in some environments, consistent with the view that spatial representation is one of the primary functions of the hippocampus.

Is there any relation between the size or shape of the place fields that a cell displays in one environment and those obtained in another? The answer depends on the similarity between the environments and the amount of experience the animal has had with them. When the environments are sufficiently different, such as the eight-arm radial maze without walls and a small enclosed rectangular box used in the study of Thompson and Best (1989), and the animal has had considerable experience in both, the fields are very different. In contrast, when both environments have walls and the animal is inexperienced, most fields are initially similar in shape and location despite differences of shape or color between boxes. With experience, the place cells begin to differentiate between the two environments, and after a period of time most cells fire differently in the two boxes (Bostock et al., 1991; Lever et al., 2002; Wills et al., 2005). This phenomenon is called remapping and is a good example of a type of learn-

ing that is reflected in hippocampal cell firing. Most of the remapping that occurred between square and circular environments involves the cessation of firing in one of the two environments; more rarely, there is a shift in field location between the two (Lever et al., 2002). One important factor influencing whether a complex-spike cell has a place field in any given environment might be the overall level of inhibition experienced by that cell in that environment. Thompson and Best found higher background rates in environments in which the cell had a place field than in environments in which it did not. A reasonable speculation, therefore, is that silent cells are potential place cells whose level of inhibition is high in the “silent” environment perhaps due to enhanced excitatory inputs to its inhibitory interneurons from place cells with maintained fields in that environment.

### 11.7.5 Frame of Reference of Place Fields

If place cells identify an animal’s location, they must do so ultimately on the basis of sensory information. In this section, this issue is addressed from the perspective of frames of reference. In the next, the role of specific sensory modalities is examined. The framework to which place fields are referenced might be egocentric or allocentric. An egocentric framework is one that is anchored to the animal’s body (or some part of it, such as the trunk, head, or eye) and that travels with the animal as it moves through the environment. An allocentric framework, on the other hand, is one that is fixed to some part of the environment. It is therefore a framework in which the animal’s position changes as it traverses the environment. The fact that complex-spike cells recorded in an open field environment fire in their place field irrespective of the direction in which the animal is facing appears to rule out a purely egocentric reference framework. On the other hand, the fact that complex-spike cells can sometimes be directional (e.g., on linear tracks) shows that under some circumstances they can be egocentric or that the inputs to these cells may be coded in egocentric frameworks.

In open fields, where place cells appear to be anchored within an allocentric reference frame, it has been shown that this frame can be a reference to the room, the testing box, or the maze in which the animal has been placed. When recording takes place on symmetrical elevated mazes or open fields with low side-walls, the room generally provides the overall framework. This is readily revealed by rotating the testing apparatus. The usual result is that place fields follow cues located outside the apparatus (O’Keefe, 1976; Olton et al., 1978) (see Fig. 11–12B, later). This is not to say that the intra-apparatus, or what are commonly referred to as “intramaze,” cues are without influence. They ordinarily may contribute to place field size or location but be overshadowed in importance by more distal, or “extramaze,” cues when the two types are put in opposition. Maze rotation, however, sometimes gives rise to locational ambiguity. A cell may develop two place fields immediately after the rotation, but they quickly resolve into one field with repeated experience of the new configuration (O’Keefe, 1976; Thompson and Best, 1989).

In boxes with high walls and limited views of the room, place cells often use the box itself as the frame of reference. Rotation of the box or rotation of a “cue-card” suspended prominently on the interior wall of the box, generally causes equal rotation of the place fields (Kubie and Ranck, 1983; Muller and Kubie, 1987). On multi-arm mazes with high walls, the fields sometimes take their reference from specific arms and not from the entire maze. Under these circumstances, interchanging arms can result in the fields following a specific arm of the maze irrespective of its allocentric location (Shapiro et al., 1997). In this situation, the cells do not fire all over the surface of the arm but maintain a localized firing field relative to the “frame of the arm” and can thus still be said to be spatially coded. It should not be thought, however, that there is a sharp distinction between extramaze and intramaze cues and frameworks or that any given cell is forced to choose between them. In an experiment described in more detail later, O’Keefe and Burgess (1996) found that although most place fields were controlled by either the animal’s location relative to the walls of the testing box or relative to the laboratory frame, some were responsive to combinations of one wall of the testing box and an extramaze cue, such as the wall of the testing room. Bures and colleagues (Rossier et al., 2000) developed an elegant behavioral paradigm for dissociating intramaze from extramaze frames of reference. Rats are trained to avoid a prohibited area of a static circular platform with a good view of the surrounding laboratory. Under these circumstances, the prohibited area can be defined with reference to the extramaze laboratory reference frame or the intramaze frame of the platform itself. Recording from place cells with the platform rotating slowly showed that the firing fields of some are fixed to the extramaze room cues, whereas those of others remain with the rotating intramaze cues. Turning off the lights increased the number of intramaze fields. A large proportion of place fields disintegrated when the two frames of reference were dissociated, suggesting that information from both was required.

In a subsequent experiment, Zinyuk et al. (2000) demonstrated that the proportion of cells related to the extramaze frame, the intramaze frame, or both depended on whether the animal was trained to navigate within the environment. The animals in the navigation group were trained to use the extramaze environmental cues to go to an unmarked location in the static open-field box to receive food pellets. Each entry into this target zone triggered the release of a food reward into a random location for which the rats had to forage. When the intra- and extramaze frames of reference were dissociated by rotating the box at 1 rpm, 38% of the place fields stayed with the extramaze framework, 9% with the rotating intramaze framework, and 31% with the conjunction of both. Cells in this last category fired only at that point of the cycle when the two frameworks coincided. The firing fields of only one-fifth of the cells were disrupted during rotation. In contrast, when another group of animals carried out a random foraging task in the same environment without the navigational component, almost three-fifths of the cells were disrupted by rotating the platform. Of the small number of intact fields, 21%

stayed with the extramaze environment framework, 14% with the rotating intramaze framework, and 7% with both. This study makes several important points. First, it confirms that place cells can be anchored by the extramaze environmental cues, the intramaze box cues, or both, in agreement with previous findings. Second, it shows that training the animals to pay attention to the extramaze cues increases the proportion of place cells that use these cues, alone or in combination, from less than one-third to more than two-thirds. Third, somewhat surprisingly, training to attend to the extramaze cues markedly increases the proportion of cells responsive to the conjunction of the relevant extramaze cues and the irrelevant intramaze framework. It appears that in the absence of explicit training to attend to the spatial aspects of the environment many place cells take their inputs from combinations of a small number of weak distal and local intra-maze cues which are easily disrupted by the rotation. In animals trained to attend to the distal cues the cells incorporate much more robust information especially about the extra-maze cues and are less easily disrupted when these cues are placed into conflict. Support for this interpretation comes from experiments in the same testing paradigm using blockade of one hippocampus by injection of tetrodotoxin. This has no effect on the ability of rats to avoid a place successfully on the basis of either extramaze or intramaze cues alone but blocks their ability to avoid a place on the basis of extramaze cues *in the face of conflicting intramaze cues* (Wesierska et al., 2005). The effects of unilateral blockade are probably due to the disruptive effect of the procedure on the other intact hippocampus (Olypher et al., 2006). These results should serve as a warning that some of the conclusions drawn from studies on animals foraging in the open fields in the absence of an explicit requirement to encode the spatial aspects of the environment might not be providing an accurate picture of the full range of the spatial capacities of the hippocampus.

Interestingly, this group has also shown that training rats to use room-based but not arena-based cues to navigate increases the amount of total variance in place cell firing that is accounted for by position (Olypher et al., 2002). Accordingly, they speculated that some of the variance in place cell firing not accounted for by position (Fenton and Muller, 1998) is attributable to attentional switches between alternative spatial reference frames. Their analysis may provide an interesting window into ostensibly unstable coding of place by hippocampal cells in some experiments.

### 11.7.6 Place Fields Can Be Controlled by Exteroceptive Sensory Cues

What sensory information does a place cell use to determine where it fires? O'Keefe (1976) suggested that two sources of information were available.

Each place cell receives two different inputs, one conveying information about the large number of environmental stimuli or events, and the other from a

navigational system which calculates where an animal is in an environment independently of the stimuli impinging on it at that moment. The input from the navigational system gates the environmental input, allowing only those stimuli occurring when the animal is in a particular place to excite a particular cell. One possible basis for the navigational system relies on the fact that information about changes in position and direction in space could be calculated from the animal's movement. When the animal had located itself in an environment (using environmental stimuli), the hippocampus could calculate subsequent positions in that environment on the basis of how far, and in what direction the animal had moved in the interim. . . . In addition to information about distance traversed, a navigational system would need to know about changes in direction of movement either relative to some environmental landmark or within the animal's own egocentric space. . . . (O'Keefe, 1976, pp. 107–108)

Both hypotheses have received experimental support: Place fields can be controlled by exteroceptive information from the environment or by movement-generated proprioceptive and vestibular stimuli. This section looks at the external sensory information arising from the environment and asks: Are some sensory modalities privileged over others? Which cues determine the angular orientation of a field in a symmetrically shaped environment, and do these differ from those that control its distance from the borders of the environment? The following section examines the role of internal cues generated by the animal's own behavior in providing estimates of distance and direction traveled.

We begin by asking: Are some sensory modalities privileged over others? There are two ways to identify the role of sensory inputs in controlling place fields. The first follows the pioneering methods of Honzik (1936) in his study of the sensory control of maze learning. Here, a specific sensory modality is eliminated by lesion or occlusion and the consequences examined. The second approach is to construct artificial environments in which there are a few controlled cues that can be experimentally manipulated. Various manipulations have been explored: Cues have been rotated; the distance between them changed; the geometry of the environment altered; associative value or cue meaning taken into account. The results show that many place cells receive information from more than one sensory input; they can use subsets of this total input to identify correctly the preferred place; and geometrical information about distance to features of the environment is particularly important.

A simple manipulation to test the role of vision is to turn out the room lights (O'Keefe, 1976; Quirk et al., 1990; Markus et al., 1994). Some cells are unaffected, but others show a more interesting response. For example, the field may disappear on the first visit to the preferred area but return on the second or third visit. In a cylindrical open-field apparatus, place fields tend to remain intact if the animal is in the environment when

the lights are extinguished. However, if the animal is removed from the environment and then put back into it in the dark, about half of the fields change (Quirk et al., 1990). New fields may appear, and they are maintained even if the lights are now turned on. In contrast, there are many fewer cells that retain similar fields in the light and the dark on the radial arm maze. Furthermore, of the cells firing in both light and dark, the firing in the light was more reliable. Such observations offer yet another indication that place cells act in distinct ways in differing environments. It appears that, in a cylindrical arena or rectangle, once a pattern of place fields is set up for a particular environment it is relatively stable to alterations of exteroceptive cues—unless the animal is removed from the environment. In contrast, place cells are more sensory-bound on radial arm mazes and in other situations that restrict an animal's movements to a linear path.

Eliminating sensory modalities by occlusion or using lesions indicates that there are still place cells after the elimination of olfactory, visual, or both visual and auditory inputs. Save and colleagues (1998) found that rats blind from birth have completely normal place fields when tested as adults. The only discernible difference was a decreased firing rate of place cells compared to controls. Hill and Best's study (1981) of animals deprived of both vision and audition during adulthood revealed they also had apparently normal place fields. However, rotating the arms of the maze showed that, on average, these animals were much more "bound" to the local cues of an arm. Further experiments on the small group of cells that had fields anchored to the allocentric room frame of reference showed that rapid rotation of the animal for 20 to 30 seconds prior to running on the maze caused their fields also to come under the control of the intramaze cues. On the assumption that the rotation primarily affected the vestibular system, these results suggest that, in the absence of distal visual and auditory cues, the angular orientation of place cells can be controlled by olfactory/tactile cues on the maze and by vestibular cues. The latter may be mediated by inputs from the head direction system (see Sections 11.9 and 11.10).

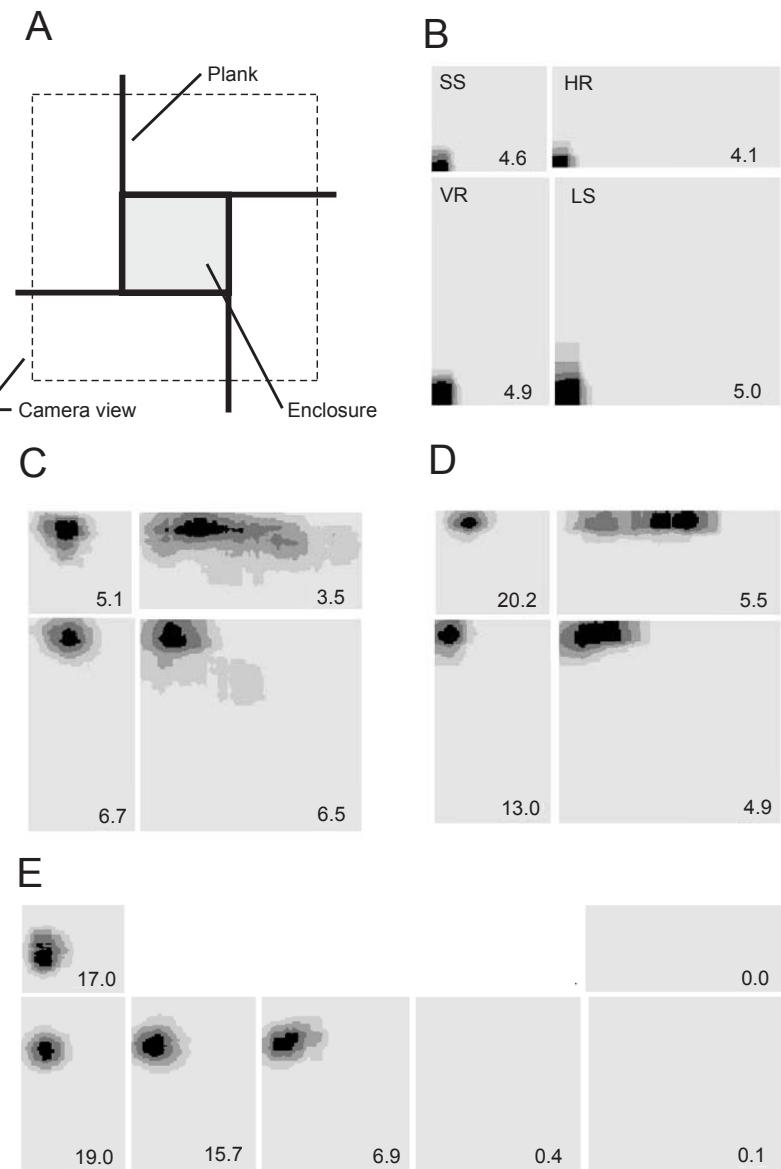

Several studies have attacked the problem of cue control by constructing environments in which the distal stimuli were explicitly identified and controlled. O'Keefe and Conway (1978) trained animals on a T maze located within a set of curtains that excluded visual cues from the rest of the laboratory. Four objects were hung around the periphery of a T maze inside the curtains, and the animal was taught to choose an arm of the maze. The four cues were rotated from trial to trial. Place fields always rotated with the cues (see Fig. 11–12B, later, for a similar result). Removal of one or more cues on each trial showed that a few fields depended on one specific cue, but most were maintained so long as any two of the four cues were present. Muller and colleagues (Muller and Kubie, 1987) showed similar cue dependence of place fields recorded from rats foraging for food in cylinders or rectangular boxes. A single white cue-card fixed to the wall exerted control over the angular location of the field but not its distance from the wall. Rotation of the card rotated the fields by the same

amount. Neither the shape of the field nor its distance from the walls of the box was affected, but there was a slight loss of place specificity.

The location of the controlling cues within the environment can be important. Cressant et al. (1997) found that three objects placed in a triangular configuration in the center of a cylinder did not control the orientation of place fields, but they did do so when these same objects were moved to the periphery. This result was interpreted as suggesting that distal peripheral landmarks are more important for fixing the orientation of the place fields, perhaps because the animal's movement relative to centrally placed local cues causes constant reordering of their positions relative to each other within the egocentric frameworks of the distal sensory modalities, whereas movements relative to distal cues do not. Central object A is sometimes seen to the left of central object B and sometimes to its right.

If the angular orientation of a place field in a symmetrical environment is controlled by distal cues, what determines its shape and size and its radial distance from the walls of the environment? The first clue came from an experiment (Muller and Kubie, 1987) that showed that doubling the dimensions of a cylinder or a rectangular box had two effects: In many cells, the fields remapped to unpredictable shapes and locations; in about one-third of the place cells, however, field size increased to about twice the original size without significant effect on field shape. This is less than the fourfold increase that would have represented an exact proportion to the increased area of the recording chamber. Factors other than simple scaling seemed to be at work. A related experiment (Wilson and McNaughton, 1993b) looked at field changes after a partition was removed, converting a square box to a rectangular box whose long dimension was twice that of its short one. Here cells with fields in the square were maintained, whereas other cells began to fire in the new section of the box. It appears, then, that under some circumstances the field sizes are influenced by the size of the testing environment, but under others they are not. The factors controlling this difference are still unclear, but they may relate to whether the animal is, or is not, in the box when the change is made. If in it, the animal is better placed to see the change happening in front of him, which triggers exploration. Under these circumstances the existing fields are maintained intact and new ones created to represent the new part of the environment. However, when the animal is removed from a recording chamber with which it is familiar and placed in a dilated version of it, the system may be tricked into treating this as the "same" environment with the resulting alteration of existing fields.

O'Keefe and Burgess (1996) employed the second procedure to look at the effect of changing box size and shape on established place fields. Combining features of the preceding studies, the same cell was studied while the rat foraged for food in four differently shaped boxes: two squares, one with double the dimensions of the others; and two rectangles, each with its small side taken from the dimensions of the small square and its large side from the large square (Fig. 11–9). One

**Figure 11-9.** Place fields in four rectilinear enclosures reveal that each field is comprised of several subcomponents. *A*, Layout of the testing area shows how the small square ( $61 \text{ cm}^2$ ) is constructed from four wooden planks set on their edges. The same set of planks can be joined in different configurations to make rectangular ( $61 \times 122 \text{ cm}$ ) and large square ( $122 \times 122 \text{ cm}$ ) enclosures. *B*, Place field with strong inputs from the left and bottom walls does not change its relative location in the various boxes. *C*, A different place field with strong inputs from the top, left, and right walls is elongated in the horizontal rectangle. *D*, A field similar to that shown in *C* breaks into two components in the horizontal rectangle. *E*, A cell with fields in the small square and vertical rectangle (two left-hand panels) shows steadily diminishing firing rates in the boxes intermediate to the vertical rectangle and the large square. Numbers in each panel represent the peak field firing rate (shown in black). (Source: After O'Keefe and Burgess, 1996, with permission.)

rectangle was oriented with its long side parallel to the long dimension of the testing laboratory and the other with its long side perpendicular to this dimension. The same construction materials were used, and the floor covering was interchanged frequently, eliminating local olfactory and tactile cues as determinants of field shape and location. The important finding was that for most cells the field location and shape was determined by the distance to two or more walls usually of the box but, more rarely, of the room itself. Some cells were controlled by the distance to two box walls in orthogonal directions (e.g., the south and west walls) (Fig. 11-9B); others were sensitive to the distance to three or four walls (e.g., Fig. 11-9C,D). The expansion of field width along one dimension sometimes resulted in double peaks or even the apparent splitting of a field into two (Fig. 11-9D). Some cells (e.g., Fig. 11-9E) that had a field in one box (vertical rectangle) but were silent in an adjacent box (big square) could be shown to

reduce their rates in an incremental way in boxes intermediate to these two. A small number of cells had one of their field dimensions determined by the distance to the room walls and the other by a wall of the box. One important observation was that no cells used the framework of the shape of the box itself. If this had been the case, one would expect to see cells with fields that rotated by  $90^\circ$  in the two rectangular configurations or that fired only in the small and large squares. These patterns were never observed. The experiment shows that in environments in which the animal has sufficient distal information to fix its directional orientation it is not the geometry of the testing box that is being captured by the place field but the intersection of distances to two or more elongated features of the environment (see Chapter 13 for a further discussion of the geometry of the spatial representation and Chapter 14 for a discussion of a computational model that accounts for these findings).

Gothard and her colleagues obtained similar results (Gothard et al., 1996b). Place cells were recorded while the rat attempted to find a reward hidden at a fixed distance and direction from two large objects. Each trial began with the rat leaving a small box and ended when it returned to it where it was also rewarded. The location of the box, like that of the objects, was moved around the room from trial to trial. Cells were found that fired as the rat entered or exited the start/goal box; others fired relative to one or other of the goal objects; and a third group maintained their field location relative to the framework of the room, regardless of the location of the goal or start box. This study complemented that of Burgess and O'Keefe in showing that relative location to objects or walls is important. It also reinforced the notion that different place cells recorded at the same time may use two or more frames of reference in a single environment.

In another study, Gothard et al. (1996a) examined the "frame of reference" issue further by recording cells in rats trained to run back and forth on a linear track for food reward at each end. The goal at one end of the track remained fixed relative to the room, whereas that at the other end was a box that could be moved between one of five locations along the track from trial to trial. Recall that on linear tracks or narrow-armed radial mazes many place cells tend to have directional fields. In the present experiment just over 42% fired in one of the two directions, another 45% in the opposite direction, and just over 12% in both directions and these usually did not bear a close spatial relation to each other. Place fields closer to the goal box were tied to it and moved with it, whereas those closer to the other end of the track tended to stay fixed with respect to the room and the fixed goal location. A number of cells were influenced by both the moving box and the fixed goal. In these cases, as the box was moved farther away from the other end of the track there was evidence for the stretching and splitting of the fields described by O'Keefe and Burgess in their expanding two-dimensional world.

Two interpretations of these results are possible. Gothard and her colleagues suggest that there are two representations or charts of the space on the track: one related to the framework of the box and the other to the room. As the animal runs along the track, it switches from one map or chart of the environment to the other. The animal was, in some sense, treating this single runway as two separate environments: a world in which it was located relative to the goal box while it was in its vicinity and a world in which it was located in the room frame as it got farther from the moving box. These authors further interpreted the constant distance of the box-related fields from the box as evidence for a path integration mechanism.

O'Keefe and Burgess favor the alternative view: that under the conditions of these experiments, the normal map-like omnidirectionality and connectedness between place cells has been lost, and they are essentially acting as isolated individuals. Each individual cell is influenced by the box and the fixed goal in proportion to the distance of its field from each. Cells close to the box are almost entirely controlled by a box, whereas those far from it are controlled by the fixed room

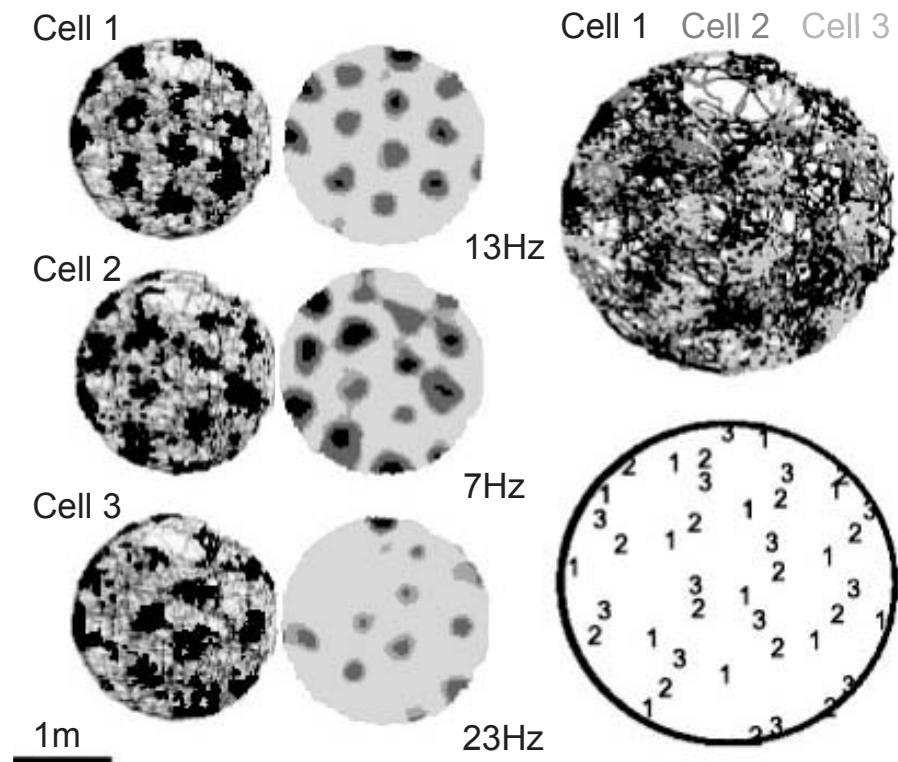

cues. The distance from each set of cues could be computed on the basis of sensory inputs from that cue or from path integration signals (see Chapter 14, Section 14.3 for a more detailed discussion of this model).

Fenton et al. (2000a,b) investigated the problem of cue-control of place fields in a different experimental paradigm. They recorded while rats foraged for food pellets in cylinders with two distinct cue cards on the wall and varied the angle between the cards by small amounts. Removal of either card had no effect on place fields, and rotation of the remaining card caused equal rotation of the place fields, demonstrating independent control over the fields by each card. In contrast, changing the angle between the cards from 135° to either 160° or 110° caused subtle changes in the location and shape of the fields. In general, fields shifted and transformed in the direction of card movement. Fields closer to the cards were more influenced than those farther away. An interesting finding was that the peak firing rate was highest for the original card configuration and decreased as the cards were brought closer together or placed farther apart. Although carried out under different experimental circumstances and interpreted somewhat differently by the authors, these results are broadly in line with those of O'Keefe and Burgess and of Gothard et al. in showing that place fields are determined by distances from specific environmental features.

An overview of all the experiments reviewed in this section suggests that there are at least two independent exteroceptive determinants of place fields. The directional orientation of a place field in a symmetrical enclosure is controlled by polarizing distal cues in the room or at the periphery of the testing box. On the other hand, the location and shape of the field is determined by the distance of the animal from two or more walls or by other features of the environment. In addition, it is clear that interoceptive cues can influence place field shape and location, which we discuss in the next section.

### 11.7.7 Idiothetic Cues Can Control Place Fields

Place fields can also be located on the basis of idiothetic cues generated by an animal's own movements, which consist of interoceptive stimuli such as head, neck and limb proprioceptors, vestibular signals, and motor reafference signals from intended movements together with exteroceptive stimuli derived from optic flow and whisker-detected airflow. We noted earlier that rats blind from birth have completely normal place fields when tested as adults (Save et al., 1998). Detailed analysis of the behavior of these animals suggested that they used olfactory and tactile information to recognize objects in the recording environment and then "updated" the locations of place fields on the basis of interoceptive cues associated with their own movements. Whereas some 80% of place cells in the sighted control rats in this study fired in the appropriate location before the animal had made contact with any of the objects, none of the place cells in the blind rats did so. However, after contact with one of the objects, 60% of cells fired appropriately in a single place, and 75% did so after

**Figure 11-10.** Entorhinal cortex grid cells. Raw data (left) and firing fields (right) for three grid cells. Note the regularity of the firing, which forms a triangular grid pattern in each cell. Numbers indicate the peak rate. Peaks of the three cells (top in grayscale, bottom as numbers 1–3) are slightly offset from each other so when superimposed they tend to tessellate the space. (Source: After Hafting et al., 2005, by permission.)

exploring two objects. Completely normal firing patterns were seen after contact with all three objects.

Maintaining spatial specificity in this way represents a form of “memory.” It is presumably an “active” or “working” memory that is maintained by some form of inertial navigation or path-integration mechanism. Once an animal had identified its location in an environment on the basis of exteroceptive cues, a path integration mechanism could continuously update its position by calculating the changes in distance and direction from the original position resulting from the animal’s movements. This type of mechanism might explain the short-term memory properties of place cells, which are discussed in greater detail in Section 11.8.

Further evidence for idiothetic influences on place fields comes from experiments in which animals have been passively rotated. As we saw in the experiment of Hill and Best, rotating animals deprived of vision and audition before placing them on a radial arm maze results in the rotation of place fields. Several groups (Sharp et al., 1995; Wiener et al., 1995; Bures et al., 1997; Jeffery et al., 1997) have studied the effect of rotating the testing enclosure, or parts of it, with the animal inside it. Sharp et al. (1995) rotated the cylinder walls or floor separately at a fast or slow speed and in the light or dark. It was assumed that the slow rotations were below the speed detectable by the vestibular system and would not be compensated for: The fields rotated with the rotating enclosure relative to the laboratory frame. Both visual and vestibular signals influenced the angular location of place fields to about the same extent. Slow rotation of the rat in a separate chamber outside of the testing enclosure also led to rotated place

fields when the rat was replaced into the enclosure (Jeffery et al., 1997). In both experiments the rotations were brief, and their effects were subsequently assessed in a stationary environment. Similar findings with head direction cells (Blair and Sharp, 1996) raise the possibility of a coupling between the spatial localization and head direction system. The interactions between the two are discussed in Section 11.10.

A movement-generated estimate of distance and direction would explain the instances of place cell stability in the shift from light to dark in memory tasks and following lesions that limit access to exteroceptive cues. The source of this “path-integration” signal is either input from interoceptive cues or “collateral discharges” arising from motor structures actively generating movements. This information arrives at the hippocampus via several routes. Information about the animal’s heading direction is carried by the head direction cells and enters the hippocampal system through the presubiculum projection to the medial entorhinal cortex. We discuss the properties of the head direction cells in greater detail in Section 11.9 and their interaction with the place cells in Section 11.10. When it arrives to the medial entorhinal cortex, head direction information is combined with distance information in a set of grid cells (Hafting et al., 2005). One of the functions of the grid cells is to convey information about distances in specific environmental directions. Each grid cell fires in several locations in an environment, with the locations forming a regular pattern as though they were nodes on a triangular grid (Fig. 11-10; see also Fig. 11-21D, color centerfold). Different cells recorded at the same location have the same grid spacing and orientation relative to the environment. They differ, however, in the loca-

tion of the nodes such that the firing peaks of one cell are slightly shifted from those of its neighbor. The multiple interdigitated fields of several such cells together cover the environment (Fig. 11–10, right). For each cell, the size of the grid appears to be independent of the size or shape of the environment. The orientation of the grid relative to the environment, however, is dependent on the location of a polarizing visual cue on the wall of the enclosure in much same way as are the postsubiculum head direction (Taube et al., 1990b) and the hippocampal place cells (Muller and Kubie, 1987). It seems likely, then, that the orientation of each grid is controlled by the head direction cells of the presubiculum. Cells located at increasing depths from the postirhinal border form grids whose nodes have fields of increasing size and spacing. In summary, the grid cells probably do not form a map of a given environment by themselves but provide the Euclidean distance and direction metric postulated by the cognitive map theory of hippocampal function (O'Keefe and Nadel, 1978). This idiothetic information is combined with sensory information about each environment to create the specific map of that environment in the hippocampus.

To maintain the appropriate distance between grid points as the animal moves around the environment, the grid cells must take its speed into account. Information about speed may arise in posterior hypothalamic areas that are known to provide theta-related inputs to the hippocampus and where electrical stimulation produces running or jumping, with the speed of the movement increasing as a function of the stimulation intensity (Bland and Vanderwolf, 1972). Integration of a speed signal over time as the animal ran in a constant direction would give a measure of distance traveled during that time. There is direct evidence that information about an animal's speed of movement is available to the hippocampus. A small number of nonprincipal "speed" cells have been recorded in the hippocampus. The firing rates of these cells directly correlates with the animal's speed of running regardless of direction or location (O'Keefe et al., 1998). Second, higher running speeds tend to increase place cell firing rates (McNaughton et al., 1983a; Wiener et al., 1989; Zhang et al., 1998). Furthermore, the firing frequencies of many place cells from a stationary animal running in a wheel located in the place field were positively correlated with the speed of running (Czurko et al., 1999; Hirase et al., 1999). Some cells asymptoted within the range of speeds reached in the wheel. Cells that wholly or partially code for speed have also been found in the presubiculum (Sharp, 1996), which projects to the hippocampus via the medial entorhinal cortex. In all, we can conclude that information about both an animal's heading direction and its speed of movement through the environment is available to the hippocampal formation, and this information most likely is combined in the medial entorhinal grid cells.

The path integration system suffers from the fact that errors accumulate rapidly as the animal's heading direction and distance from the original location are continuously updated. On the basis of data from several studies in which attempts were made to remove exteroceptive information after initial localization or make it irrelevant, it has been esti-

mated that place fields can be maintained for only 1 to 2 minutes on the basis of path integration information alone (Save et al., 2000).

### **11.7.8 Are Place Cells Influenced by Goals, Rewards, or Punishments?**

If place cells are part of a navigational system that can guide an animal to locations containing desirable objects such as food and water or to avoid dangerous places, one might expect to find goal cells whose activity was sensitive to goal location or navigation to a goal or, more generally, a change in place cell firing following a shift in the valence of parts or all of an environment. These "goal" or "valence" cells might exhibit any of several characteristics: The location of their place fields might alter when the valence of the environment changes, and it might happen in a way that reflects the goal location in an environment; there might be a disproportionate number of place cells with fields located at reward sites; or there might be nonlocational cells whose firing rate depended on which goal was being sought or navigated toward. Several experiments have searched for the first type by shifting goal locations: Some reported no effect (O'Keefe, 1976; Speakman and O'Keefe, 1990; Zinyuk et al., 2000), while others found concomitant place field shifts (Breese et al., 1989; Kobayashi et al., 1997; Hollup et al., 2001). Here we need to bear in mind that rewards have both sensory and incentive properties, and field shifts might be due to the former rather than the latter. Three recent studies employed experimental paradigms in which the goal was not marked by any physical stimulus. The rats in the Hollup et al (Hollup et al., 2001) experiment searched for a hidden platform in a modified annular watermaze and the fields of some cells shifted when the goal location was changed. Kobayashi used rewarding brain stimulation of the hypothalamus in order to designate particular locations as goals and reported that six of 31 place cells either developed additional new fields in the rewarded location or shifted their place field to that location {Kobayashi et al., 1997}. Finally, Zinyuk et al. (2000) used a paradigm similar to that of Kobayashi et al. but rewarded the animals with random food pellets rather than electrical brain stimulation; they found no changes in place fields when the reward location was moved. Because there was no physical reward at the goal locations in these experiments, the explanation of the discrepancies cannot rely solely on the perceptibility of the goal or its role as a sensory cue. We note that many of the cells that shifted fields in the Kobayashi et al. experiment had very low (< 1 Hz) place field rates, below those normally accepted in these types of experiment. These considerations, however, do not apply to the Hollup findings (Hollup et al., 2001).

Moita et al. (2004) used aversive electrical stimulation of the orbit of the eye to condition rats to an auditory conditioned stimulus (CS) or to the background context. They found that as a result of training some place fields were altered. More place cells changed their firing fields in the context than in the cue-conditioned group and more in the conditioning box than in a different control box. Furthermore,

they found that following cue conditioning the place cells began to fire with a short latency response to the auditory cue but only if the animal was in the place field of that cell when the CS was delivered (Moita et al., 2003). This result is discussed further in Section 11.11.3.

Evidence for the second type of goal representation comes from Hollup et al. (2001), who found twice as many cells representing the unmarked goal in their annular watermaze than would be expected by chance. The third type of active goal cell was reported in a study of temporal and frontal cells recorded in human epileptic patients while they played a taxicab game in which they searched for passengers in a small virtual reality town and took them to their destinations in the form of specific storefronts (Ekstrom et al., 2003). About one-fifth of the cells recorded were sensitive to the goal being sought, almost three-fourths of which responded while searching for a specific location. An additional 7% were involved as the subject searched for more than one store and 22% while searching for passengers. A small number of cells showed a place by goal interaction, firing in a particular location if the subject crossed it en route to a particular goal. These goal cells were located throughout the temporal and frontal lobes and not concentrated in the hippocampus or parahippocampal gyrus as were the place and spatial-view cells (see below) recorded in the same study.

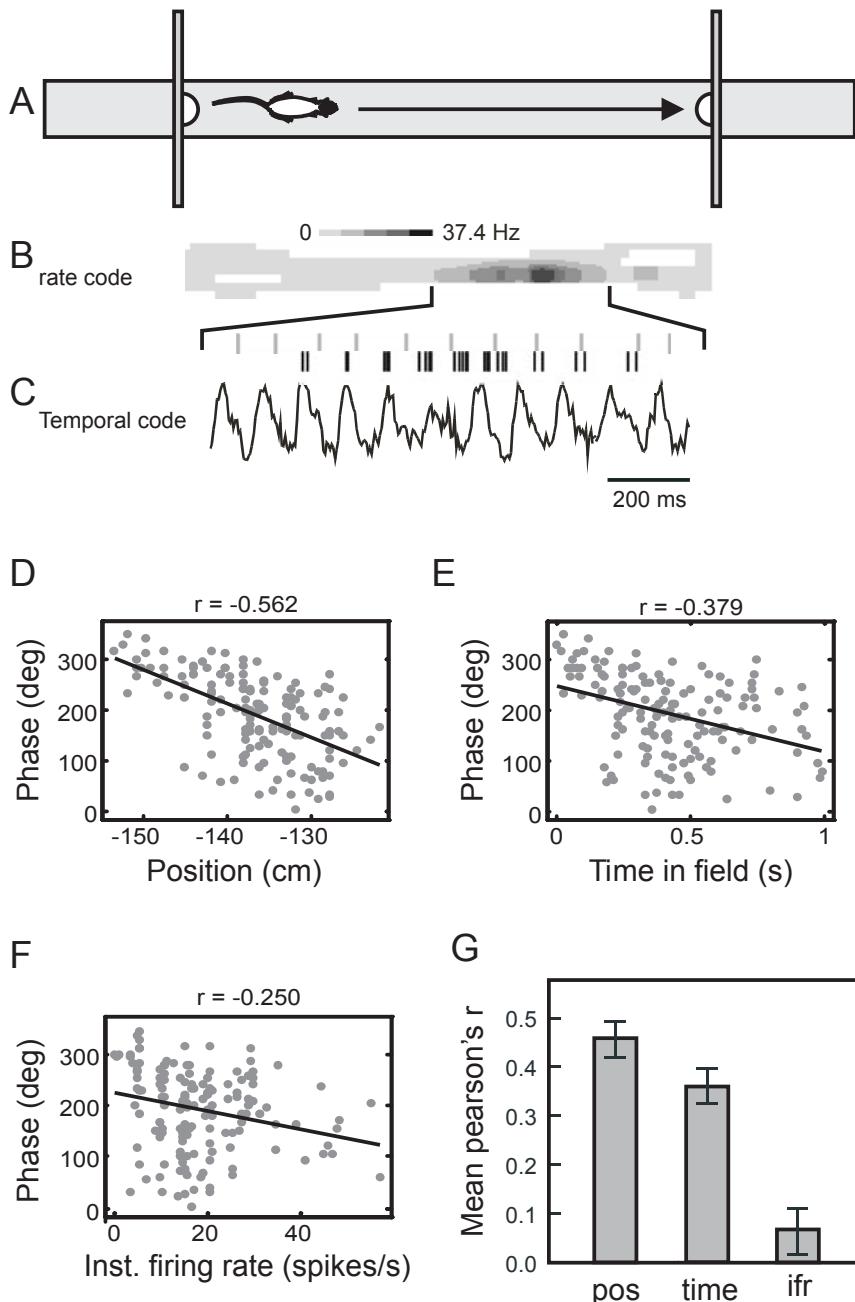

It seems clear, then, that changing the valence of an environment or regions within that environment can cause the firing fields of some place cells to shift. The functional significance of this is not clear, unless it turns out that the cells that changed had fields where the animal was located during the occurrence of the rewarding or punishing event. At present, it is not clear exactly how goals are represented or whether goal location is stored in the hippocampus or outside of it. When no distal sensory information is available, the sensory qualities of rewards may be used to locate place fields. In a “richer” environment, food and water may be “categorized” as objects that are potentially unstable over time. Food sources become depleted and new ones become available, and this happens over a time scale quite different from that of other cues such as trees or bushes. Nonetheless, the locations of reward have to be stored somewhere. However, on balance, the experimental results, although not conclusive, suggest that the information about goal location is probably not stored in any simple fashion in the CA3 or CA1 areas of the hippocampus itself. Regions such as the lateral septum subiculum, nucleus accumbens, or prefrontal cortex, which receive inputs from the hippocampal formation, might be the site of such place-reward cells. In support of this hypothesis is a recent study strongly suggesting that one type of goal cell can be found in the prelimbic/infralimbic areas situated in the rat’s medial prefrontal cortex (Hok et al., 2005). Rats were trained in a cylinder to spend a short period of time in a localized but unmarked region to receive a pellet of food elsewhere. The pellets dropped from an overhead dispenser into a localized zone but then bounced elsewhere, ending up all over the enclosure. There were thus two localized but unmarked zones, a goal zone, which upon entry triggered the reward, and a

landing zone, where the pellets initially dropped. Most pellets, however, were retrieved and eaten elsewhere. One-fourth of the cells in the prelimbic/infralimbic areas had place fields and these were about three to four times larger than those found in the hippocampus. The centers of a large percentage of these fields were concentrated in the trigger (36%) and landing (42%) zones. Rotating the cue card on the wall of the enclosure rotated the animal’s representation of the trigger zone location, as judged by its behavior, but had no effect on the landing zone place fields. Conversely, changing the location of the pellet dispenser and thus the location of the landing zone caused a shift in the landing zone fields to the new area but had no effect on the behavioral approach to the trigger zone. The large size of the prefrontal place fields and the concentration of their centers at goal regions to which the animal navigated make them much better potential candidates for goal cells than hippocampal neurons. They bear some resemblance to the goal cells postulated in the models of spatial navigation of Burgess and colleagues (Burgess et al., 1994; Burgess and O’Keefe, 1996) (see Chapter 14, Section 14.4).

### 11.7.9 Temporal Patterns of Place Cell Firing

Complex-spike cells do not fire in a continuous pattern when the rat runs through a place field but burst with a frequency close to that of the EEG theta rhythm. In several studies (Fox and Ranck, 1975; Buzsaki et al., 1983) recordings were made while the rats were running on a treadmill. Unfortunately, pyramidal cells do not fire at their maximal rate in such a situation unless the animal is in that part of the environment that the cell represents (its place field). On a treadmill, CA1 complex-spike cells often fire at a low rate and display a preference for the positive peak of the dentate gyrus theta. Phase correlates have also been studied on narrow tracks as the rat runs through a cell’s place field (O’Keefe and Recce, 1993; Skaggs et al., 1996; Harris et al., 2002; Mehta et al., 2002; Yamaguchi et al., 2002; Huxter et al., 2003), and a different, more interesting pattern has emerged. O’Keefe and Recce first noted that instead of remaining correlated to a constant phase of the EEG theta cycle, as on treadmills, the phase of firing changed in a systematic way. When the rat entered the cell’s place field, the cell began firing at a particular phase of theta. However, as the animal progressed through the field, the bursts of unit firing occurred on an earlier phase of each successive theta cycle (Fig. 11–11C). The phase of firing correlates with the animal’s location in the place field (Fig. 11–11B,D), and this correlation is higher than for time after entry into the field (Fig. 11–11E) or instantaneous firing rate (Fig. 11–11F). This *phase precession* phenomenon is partly explained by cells firing rhythmically at a frequency higher than that of theta. Dentate granule cells also phase shift but by a lesser amount, and the onset of firing is at an earlier phase of the theta cycle than that seen in the CA1 cells (Skaggs et al., 1996).

Is there information in the phase correlate of place cell firing beyond that contained in the firing rate? If there is, does it add greater precision to the locational information contained in the rate, or are the two coding for independent variables

**Figure 11-11.** Temporal coding of location in hippocampal pyramidal cells. *A*. Rat shuttled from left to right and then back again to receive a food reward at each end wall of a linear track. *B*. Firing rate field map of the cell based on multiple runs. *C*. Spikes on a single run through the field show phase precession, moving to earlier phases of the EEG theta cycle with each successive wave. Spikes are shown in black; lighter tick marks above identify the zero crossing point of the EEG. *D*. Plot of theta phase versus the position for multiple runs through the field of an example cell. The correlation between phase and position (*D*) is higher than the correlation with the time in field (*E*) or the instantaneous firing rate (*F*) for an average cell. *G*. Correlation of phase with position, time, and instantaneous firing rate across a population of 94 place fields. Best correlation is with position. (Source: After Huxter et al., 2003, by permission.)

(O'Keefe, 1991)? Jensen and Lisman (2000) have used data collected by Skaggs et al. (1996) and shown that, with certain assumptions, the accuracy of locating an animal's position on a narrow track can be increased by more than 40% when phase is taken into account in addition to rate. In this view, phase acts like a vernier, permitting finer-grain location of the animal within the place field. Evidence for the dual coding hypothesis comes from a linear track study showing that phase and rate could vary independently (Huxter et al., 2003). The rate within the field varied as a function of the animal's running speed, and phase coded for the proportion of the place field the animal had traversed. Changing the size of the field by changing the distance between the walls at the ends of the track increased the rate of phase precession to maintain

the correlation between phase and a fixed proportion of the total field size. Whether phase and rate can represent variables other than location and speed is an open question. It has been known for some time that the firing rate in the place field can vary considerably from one traverse to the next (see above), and there is some evidence that different odors located in a place can be coded by different rates (Wiebe and Staubli, 1999; Wood et al., 1999a). Some evidence in support of the idea that phase can represent a nonspatial as well as a spatial variable comes from the running wheel experiments of Hirase et al. (1999) and Harris et al. (2002). They found that whereas the rate of firing of the place cells was a function of the animal's speed of running, the phase with respect to theta was relatively constant at low firing rates but occasionally changed at higher

rates in the absence of changed location. One variable that caused a change in phase in some cells was the directional orientation of the wheel, and thus the animal, to the room.

One important consequence of the phase precession effect is that the spatial overlap between the firing fields of two place cells is represented within each theta cycle by the amount of time the bursting pattern in the cell of the first field entered precedes that of the second field. This temporal difference can be demonstrated in the cross correlation between the firing patterns of the two cells (Skaggs et al., 1996). The farther apart the field borders, the larger is the temporal gap between firing peaks within each theta cycle.

Part of the phase precession effect might be explained by a coupling between the amount of cellular depolarization and the time of firing of the cell (Harris et al., 2002; Mehta et al., 2002). As the animal advances farther toward the center of the field, the cell would be more depolarized, fire more spikes on each cycle, and begin firing at an earlier phase of the cycle. This cannot be the whole story, however, as the phase continues to precess in the latter part of the field when the firing rate (and presumably the level of depolarization) is falling. An alternative explanation for phase precession invokes a mechanism based on the interaction of two theta-like waves (O'Keefe and Recce, 1993; Lengyel et al., 2003). These waves would normally be of the same frequency but 180° phase-reversed so that, when added together, they cancel each other. A slight increase in the frequency of one of these oscillators relative to the other would result in an interference pattern when the two waves are added together. If it is assumed that the extracellular EEG represents the lower frequency of the two oscillators, and that place cells fire on the peaks of the interference pattern, the precession phenomenon would be seen. The dual oscillator model predicts that the size of the place field is dependent on the difference between the frequencies of the two oscillators. The closer the two frequencies are together, the larger is the field. An article by Maurer et al. (2005) provides experimental evidence in support of this predicted relation between field size and the oscillatory frequency of the pyramidal cell. They showed that the average sizes of place fields are not uniform along the long (septo-temporal) axis of the hippocampus but increase in the temporal direction. In parallel with this field expansion, place cells in the dorsal hippocampus have a higher (intrinsic) frequency of oscillation than those located more ventrally despite no differences in the frequency of the EEG theta or the theta cells in the two regions. The dual oscillator interference model suggests there is a causal link between these two phenomena, with the dorsoventral gradient in intrinsic frequency (higher in the dorsal hippocampus) leading to the gradient in the spatial extent of the firing fields (smaller fields in the dorsal hippocampus).

The origin of the two separate but interacting theta rhythms and the site of their interaction are unknown. The latter may be in the hippocampus proper. One may be internal to CA3 and CA1 pyramidal cells, which can oscillate under the cholinergic influence of the septal nuclei. The other theta rhythm might arise from the direct projection from the entorhinal cortex to the CA3 and CA1 areas. Kamondi et al.

(1998) studied the oscillations inside the dendrites of CA1 cells during theta and showed that they are 180° phase-shifted with respect to those in the soma, as predicted by the wave interference hypothesis. They also found that depolarization of the dendrites causes an increase in the frequency of these oscillations. This and other models of the phase shift are considered in greater detail in Chapter 14.

Alternatively, the site of phase shift generation may ultimately be found in areas outside of the hippocampus but projecting to it, such as the entorhinal cortex. A study by Zugaro and colleagues (2005) lends strong support to the idea of an extrahippocampal origin. They trained rats to shuttle between two ends of a linear track and recorded the phase precession in hippocampal place cells. During some runs through the place field, a single 0.1 ms duration electric shock was delivered to the fibers of the ventral hippocampal commissure. This had the effect of resetting the phase of the hippocampal theta and inhibiting all recorded cells for approximately 200 to 250 ms. They found that when the cells recovered and began firing again they did so at the correct phase of the (reset) theta to code correctly for the animal's location at that point. This finding appears to argue against a primary role for the hippocampus itself in the phase precession and points in the direction of structures afferent to the hippocampus that might not have been affected by the brief intervention. The most likely source of this preserved positional information is the entorhinal cortex, which has direct projections to the CA3 and CA1 pyramidal cells as well as to the dentate granule cells and which was probably not affected by the electrical shock to the ventral hippocampal commissure. Evidence that it escaped comes from an observation by Zugaro et al. They looked for but did not see a rebound evoked potential in the hippocampus in response to the shock, suggesting that the entorhinal-hippocampal pathways were not greatly affected via the CA1-to-entorhinal return pathway. As we have seen, the medial entorhinal cortex contains grid cells that are theta-modulated and might be able to identify changes in the animal's location in the environment independent of the hippocampus.

### 11.7.10 Place Fields in Young and Aged Animals

In altricial animals, which depend on their mother after birth (such as the rat), the brain and in particular the hippocampus continues to develop for considerable periods of time after birth. For example, the dentate gyrus continues to generate large numbers of new granule cells for several weeks after birth and at a lesser rate throughout life (see Chapter 9), and inhibitory processes do not reach their full adult level of functioning until postnatal age 28 days (P28). Tests of spatial memory and navigation suggest that the hippocampus is not fully functioning until P40. Schenk (1985) trained rats of different ages on two versions of the Morris watermaze: the standard version in which the platform was hidden and the animal had to use distant spatial cues throughout learning and a version in which the platform was hidden but its location was marked by a visible proximal cue. This meant the task

could be learned by a hippocampal or a nonhippocampal strategy. Which of these methods was used was probed by trials in which the proximal cue was removed. Schenk found that animals aged P28 took longer to learn a new platform task than did adults and reached adult levels of performance only at ages greater than 40 days. Animals at age P35 could perform the version of the task with the proximal visual cue; but when the cue was removed, they failed to show transfer to the distal cues. This finding suggests that they had developed all of the abilities necessary to solve the watermaze task except formation of the distal cue-based spatial representation needed to navigate to the goal in the absence of the visible proximal cue. A longitudinal study in which rats were originally trained on the hidden platform version of the watermaze at age 21 and then given daily trials for 69 days put the development of spatial navigation ability somewhat earlier (Clark et al., 2005). They found that the performance of the animals rose above chance level after the second day of training and steadily increased over the next 10 days to asymptote at adult levels at approximately P35. It is reasonable to conclude that the ability to form allocentric spatial memories and to perform spatial navigation does not fully develop until around 35 to 40 days of age in rats.

In the only study of the development of place cells in young animals, Martin and Berthoz (2002) recorded complex-spike cells from animals at ages P27, P29, P34, P40, and P52 and above while they were searching for random food pellets on an open field platform. They found that the place fields of younger animals were larger and more diffuse than those of adults and became more compact with age, finally reaching adult values at about P52. Furthermore, the place fields recorded on successive 10-minute trials were unstable in younger animals, shifting location from one trial to the next, and reached adult levels of stability only at age P52. In contrast, a small number of head direction cells, which signal the orientation of the animal's head relative to environmental cues (see Section 11.9), were recorded from the cingulum at P30 and appeared to be indistinguishable from those reported in the adult. Previous work on the development of hippocampal theta had suggested that theta waves could be recorded on the hippocampal EEG as early as P10, developing to adult levels over the next 2 weeks (Leblanc and Bland, 1979). It seems reasonable to conclude from both the behavioral and the electrophysiological data that the rat hippocampus continues to develop over the first month of life and reaches the mature adult level of functioning only at ages 40 to 50 days after birth. The head direction and the theta systems, on the other hand, appeared to be functioning at earlier ages, reaching maturity by P30.

At the other end of the life cycle, when animals get older, their spatial learning abilities decrease (for a review see Rosenzweig and Barnes, 2003) and their hippocampal place cells appear to undergo changes. There seems to be little overall agreement as to whether place fields get larger or become less reliable as animals age. In the first study that compared the sizes of place fields in adult and aged animals, it was reported

that the older animals had larger firing fields (Barnes et al., 1983). Subsequent studies, however, have not been able to replicate this change but have found that the field sizes of the aged animals were normal or, under some circumstances, even more compact than those of the adult controls (Mizumori et al., 1996; Tanila et al., 1997a). There is also disagreement as to whether the place fields in aged animals are more or less reliable than in younger animals. Whereas Barnes and colleagues (1983, 1997) found that the CA1 place fields in aged animals are less reliable, Tanila et al. (1997a) found that, if anything, they were more reliable. Mizumori et al. (1996) found that they were more reliable in the CA1 pyramidal cells but less reliable in the hilar cells. Barnes et al. (1997) has suggested a reconciliation of these apparently conflicting results. They also found no difference in field size between groups but found that older animals spontaneously remapped between trials in the absence of any environmental changes. In the earlier Barnes et al. study, data were averaged across trials. If spontaneous remapping occurred between trials, it might lead to the impression that the firing fields were more dispersed and less reliable. The cause of the spontaneous remapping is not clear but may signal weakening of control of the head direction system over the hippocampal place fields with age. Spatial behavior in the watermaze also appears to reflect a decrease in the consistency of the spatial representation in older animals in that they sometimes head directly for the hidden platform and on some trials take much longer to get there, resulting in a bimodal distribution of scores (Barnes et al., 1997).

Tanila and colleagues (1997a) looked at whether cue control over place fields changed with aging. Aged animals were divided into spatial memory-impaired and spatial memory-unimpaired groups following testing in the Morris watermaze. They were then trained on the four-arm radial maze, with both distal visual cues and local visual, tactile, and olfactory cues available on the arms of the maze. Their place cells were then recorded. Probe trials in which either set of cues was rotated or scrambled were also conducted to determine which set of cues was controlling the fields. About two-fifths of the fields of young animals remapped when the distal and local cues were rotated by 90° in opposite directions, and approximately another third followed the distal cues. A smaller percentage (about one-fifth) followed the local cues. In contrast, more than three-fourths of the place fields in the aged animals with memory deficits followed the distal cues with fewer than one-fifth remapping. Scrambling the distal cues caused the latter group of place cells to become responsive to the local cues, showing that the predominant influence of the distal cues in the double rotation probes was not due to a sensory deficit. It appears as though the cells of the younger animals were relying on all of the cue information, whereas those of the memory-impaired aged animals were selectively attending to the distal visual cues. It is not clear why this shift should occur with age or how to explain it. It is especially puzzling because the aged animals were selected on the basis of their deficits in the Morris watermaze, which requires attention to

distal cues for its solution. The authors noted that all of the animals had adopted a strategy of entering adjacent arms of the maze to solve the task and therefore may not have been using a spatial strategy. Whether forcing them to use a spatial strategy would have made a difference is not clear.

Rosenzweig and colleagues (2003) looked at environmental control of place fields in a different way and compared it with the animal's performance in a spatial task. They trained animals in a task where they (and their place fields) could locate themselves within one of two frameworks (Gothard et al., 1996a). The goal at one end of a linear track was fixed relative to the room cues, whereas the goal at the other end was located inside a box that moved along the track from one run to the next. Place fields located close to the moving box tended to move with the box, whereas those distant from it stayed fixed relative to the room framework. As the animal ran from the box to the fixed end of the track, the population of cells could be said to switch frameworks. Rosenzweig et al. trained the rats to slow down at an unmarked location on the track to receive positively rewarding electrical brain stimulation. This goal location stayed fixed relative to the room cues and thus would be better located after the population response of the cells had switched into the room frame of reference. They found that the adult animals learned the task better than the aged animals and that as a group the adult animals switched from the box framework to the room framework earlier on the track than the aged animals. Furthermore, on an animal-by-animal basis there was a good correlation between the point at which the ensemble of place cells recorded switched and the ability of the animal to distinguish between the goal location and a control location. Although it was not formally tested, it seems reasonable to conclude that the ability to switch into the fixed room framework was at least in part dependent on the ability of room cues to influence the place fields and that this was deficient in the aged animals.

### 11.7.11 Hippocampal Place Cell Firing Is Influenced by Other Areas of the Brain

Lesions of the septal or entorhinal projections to the hippocampus have been reported to cause a decrease in the number of place cells that are found and, in the case of entorhinal lesions, to a shift in the stimulus control of place field firing (Miller and Best, 1980). Following entorhinal cortex lesions, the fields rotated with the maze, unlike the fields of normal animals, which remain anchored to extramaze cues. These findings are consistent with the idea that CA1 and CA3 cells have access to distal sensory input via the entorhinal cortex. The importance of direct entorhinal–CA1 connections has been highlighted by Brun et al. (2002), who removed the input from CA3 (and thus the dentate gyrus as well) onto CA1 cells and showed that CA1 place cells could still form well defined, stable place fields in repeated exposures to a familiar environment.

The influence of the medial septal nucleus is somewhat different from that of the entorhinal cortex. Recall that it

provides powerful cholinergic and GABAergic inputs to the hippocampal formation and has a major influence on hippocampal theta activity. As we shall see in Section 11.12.6, many medial septal cells are theta cells that have a good phase relation with the hippocampal theta. Its role in the control of place field firing has been studied by Mizumori et al., 1989). They trained rats in an eight-arm radial maze and recorded from place cells in CA1 and CA3 during performance of the task. Surprisingly, blocking the medial septum with the anesthetic procaine left place fields intact despite disrupting maze performance. Subsequent experiments have suggested that firing in the subiculum is disrupted and that this area of the hippocampal formation thus contributes to the control of behavior in this task. Leutgeb and Mizumori (1999) replicated this observation but found a difference between the place cells in the lesioned animals and controls when the animals were placed in a new environment or faced with altered spatial cues. Interestingly the place fields of the lesioned animals showed less transfer from light to dark and slightly greater transfer between rooms.

Lesions or temporary inactivation of other regions have been shown to affect place fields in different ways. Lesions of the perirhinal cortex, which projects to the entorhinal cortex and therefore might be providing sensory information to the hippocampal place cells, have no effect on basic field parameters but reduce the consistency of locational firing (Muir and Bilkey, 2001): In contrast to the stability of field locations in the control animals, field centers in the lesioned rats frequently moved from one exposure to the testing box to the next. A similar effect on the stability of hippocampal place fields was found after lesions of the prefrontal cortex (Kyd and Bilkey, 2005), and this may have been mediated by frontal projections to the entorhinal/perirhinal cortex.

Temporary inactivation of the retrosplenial cortex (Cooper and Mizumori, 2001) disrupt an animal's performance on the radial arm maze in the dark and during the initial learning phase in the light. During inactivation, the location of place fields shift on the maze. There are head direction (HD) cells and more complex HD, location, and movement cells in retrosplenial cortex (Chen et al., 1994; Cho and Sharp, 2001). This suggests that the retrosplenial cortex is more involved in nonvisual (perhaps path integration) control of place cells and spatial behavior. On the other hand, the role of objects placed at the periphery of the environment in controlling the orientation of place fields in a symmetrical environment seems to be mediated, at least in part, by the visual and the parietal cortices. After lesions of the visual cortex, 70% of place fields did not rotate in step with the rotation of the landmarks. In comparison, 100% of place fields in the controls did so (Paz-Villagran et al., 2002) (see Section 11.7.6 regarding how place fields can be controlled by exteroceptive sensory cues). When the objects were removed, the fields in both lesioned and control animals remained in the standard position fixed relative to the room. The parietal cortex also seems to be involved in the control of place cell orientation relative to the landmark objects but in a different way (Save et al., 2005). Following

lesions to the parietal cortex, most cells (78%) still rotated with the objects but, unlike in control animals, did not maintain this rotated location when the objects were subsequently removed. This type of short-term memory for the visual location of landmarks is discussed in greater detail in Section 11.8 and appears to be dependent on the integrity of the parietal cortex.

### **11.7.12 Primate Hippocampal Units also Exhibit Spatial Responses**

The spatial properties of single units in the hippocampus of primates including humans have been studied. This is important because it establishes the generality of the spatial nature of the hippocampus and shows that the findings in rodents are not unique. However, if there is broadening of the function of the human hippocampus to include episodic memory as well as spatial memory, it might be expected that the cells in humans and, more generally, primates might have a broader spectrum of response properties than those found in rodents. Furthermore, the standard approach to recording single units in primates is markedly different from that found in the freely moving rat. Primates are usually restrained with their heads fixed, and stimuli are often presented in ways that make it difficult to identify a spatial correlate or to dissociate the different frames of reference that might be used for the localization. It is also known that restraining rats severely depresses the locational correlate of the hippocampal complex-spike cells (Foster et al., 1989). These constraints have been partially overcome in a few studies by giving the animals increased mobility either in movable chairs or carts or by allowing them to move freely around a large cage. We should not be surprised, then, if there are differences between the unit/behavioral correlates found in primates and those in rodents. The spatial responses are described in this section; the nonspatial responses are described separately in Sections 11.11. 1 and 8.

Several types of spatial response have been found in primate hippocampal units. Responses to the location of the stimulus on a VDU screen, spatial-view cells that respond to the location at which the animal is looking, and place cells similar to those in the rodent have all been described. When the response of hippocampal units to the identity of a stimulus is compared to its spatial location, considerably higher percentages of units are found to the latter variable. Rolls and his colleagues (1993) tested monkeys on object recognition tasks and compared unit responses to object familiarity with those to object location. They reported that about 9% of cells in the hippocampal region responded differentially to the location of the stimulus on a display screen. In contrast, only a small percentage (2%) of cells responded to familiar objects (see Section 11.11.8). Colombo et al. (1998) recorded units in the primate hippocampus during a similar delayed matching to sample task in which either the spatial location or the object identity of the sample stimulus had to be remembered. They found 41 neurons that responded during the delay period, and of these 15(37%) were related exclusively to spatial position

and 5 (12%) to object identity. The remaining 21 responded to both. Most of the responses were inhibitory. Interestingly, the spatial neurons were more heavily concentrated in the posterior hippocampus, which is the analogue of the dorsal hippocampus in rodents. Ringo and colleagues (Ringo et al., 1994; Sobotka et al., 1997; Nowicka and Ringo, 2000) investigated the role of eye movements in hippocampal single unit responses. Monkeys were trained to look to one of five locations in the light or in the dark to receive rewards. In an early study, about one-third of the units changed their rate during saccades; in a subsequent study, 13% of the cells were shown to be sensitive to position and another 17% were shown to be sensitive to direction. Because the animal's head was fixed in these experiments, it is not possible to say whether the effective saccades were to locations in the laboratory or in a head-centered framework. Remembering the location of a stimulus on a computer screen might not be the same type of spatial task as locating oneself in an environment and might more easily be solved using egocentric spatial strategies dependent on parietal than hippocampal cortex (Burgess et al., 1999). Wirth et al. (2003) studied the responses of hippocampal neurons during a task that required the monkeys to learn the association between specific scenes and specific locations. Novel pictures of scenes were presented on a VDU screen, and the animal's task was to learn to move its eyes to one of four locations on the screen at the end of the presentation to obtain a reward. Each scene was presented for 0.5 second followed by a 700-ms delay during which the screen was blank before the animal was allowed to move its eyes to the required location. In all, 61% of the hippocampal cells recorded had firing rates that were significantly altered during the presentation of one of the scenes, during the delay that followed it, or both. Furthermore, there was a good correlation between the altered firing during the trial and the learning of the behavioral response. Changes in firing rate preceded the behavioral learning by a small number of trials for 14 cells, occurred at the same time in 4 cells, and followed learning in 19 cells. This suggests that although the firing rate of some cells may have been related to the learning of the scene-location association it may have been involved in learning other aspects of the scene in others. Control trials involved the presentation of familiar scenes that required the same eye movement as the novel scene. This rules out the possibility that the hippocampal firing was related to a particular eye movement or to a specific location on the screen. Although it is possible to describe this task as learning an arbitrary association between a scene and an eye movement to a location defined relative to the VDU screen, it is also possible that the animals were learning to attend to a particular location in each new scene, to remember the scene and the location during the delay, and to look at the location when allowed to do so after the delay. On this view, these cells would be closely related to the spatial-view cells, which respond when an animal looks at a location rather than goes there (Rolls et al., 1997) (see next paragraph).

Several groups have also looked for spatially coded cells in the hippocampus of monkeys free to move around the envi-

ronment. Rolls and colleagues (1997) have found a type of spatial cell not described in the rodent: the spatial-view cell. Spatial-view cells respond selectively when the animal looks at particular locations in the testing room irrespective of where the animal is situated in the room when it looks at that location. For example, one cell increased its firing rate markedly when the animal looked at a particular corner of the room regardless of where it was located in the room itself and regardless of the orientation of gaze required to look there. Some of these cells continued to respond when the target location is screened off by curtains, suggesting that the cells are not responding to particular sensory features in that location. This group has also reported the existence of whole body motion cells (O'Mara et al., 1994), which may be related to the speed cells in the rat described above. In contrast, this group has looked for but not found place cells comparable to those seen in rats. The existence of spatial-view cells might be an indication that primates have developed the ability to identify places and their contents without physically visiting those places, an important step in the evolution of the spatial mapping system.

Ono and his colleagues (1993) found place-coded neurons in the hippocampal formation of monkeys that could visit different locations in an environment while performing different tasks. The monkeys were trained to sit in an enclosed cart and to move it to nine different locations in the testing environment by pressing a lever. About 13% of the cells fired more when the animal was at one location than when it was in other locations. In a subsequent task, the animals were required to perform an object-in-place discrimination. The cart was moved to a particular location and the view window was opened, allowing the animal a sight of an object at that location. About one-fourth of cells responded when objects were shown to the animal in this task. A subset of these cells (5% of the total) were object-in-place cells that responded differentially when the animal was shown an object in a particular location and not in other locations. These cells were also not interested in a different object in the preferred location. They appear to have properties similar to those of the place and object-in-place cells described in the rat. Further evidence that the cells are appropriately described as place cells comes from an experiment by Nishijo et al. (1997) in the same laboratory. Here the animal in the cart was moved backward as well as forward through the environment, and the cells continued to fire at the same location. This manipulation reverses the cues in egocentric space but leaves allocentric cues unchanged. This group has also used virtual reality environments to provide testing environments more related to the open field tasks used with rodents (Hori et al., 2005). Monkeys were trained to use a joystick to move between five reward locations in a large 100 m virtual diameter space containing a 20 m diameter arena surrounded by landmarks such as a tree, a house, and the building. Almost one-third of the hippocampal units displayed spatial fields. When the distal cues were rearranged, two-thirds of the cells tested remapped by either ceasing to fire or by changing the spatial pattern of firing. The

monkeys were also trained in a two-dimensional screen-based task in which they had to move a pointer to different parts of the screen. A subset of cells were recorded in both the virtual reality task and the screen-based task. Of the cells with spatial responses in either or both tasks, about one-third had spatial activity in both, one-half in the virtual reality task alone, and only 15% in the screen-based task. It appears that large-scale allocentric spatial tasks are better for activating primate hippocampal neurons than are screen-based egocentric tasks.

If we are to compare hippocampal physiology in rodents and primates appropriately, more recordings are needed from primates whose heads are unrestrained and who are free to locomote around a complex environment (see Section 11.2). There has been some interesting progress along these lines. In the first study in completely freely moving monkeys, rodent-like place cells with high signal-to-noise ratios in the hippocampus proper were found in squirrel monkeys performing a spatial memory task in three dimensions (Ludvig et al., 2004). Interestingly, many of these cells had fields that involved the walls of the wire-mesh testing cage, areas that would not have been sampled in the floor-bound experiments of Rolls and Ono.

Another approach has been to record units from human epilepsy patients (awaiting determination of seizure foci). In early studies the responses to faces, objects, and scenes were studied (see Section 11.11.9). Of relevance here is a study of unit activity during virtual locomotion in a taxi-driver game (Ekstrom et al., 2003). This study recorded units from the temporal lobe and frontal cortex and looked for evidence of cell activity responsive to the variables of place, view, and goal-seeking and of conjunctions between these variables. Place responses clustered in the hippocampus to a greater extent than in the parahippocampus (24% of hippocampal cells being "pure" place cells versus 8% in the parahippocampus), and "pure" location-independent spatial-view cells clustered in the parahippocampus (17% vs. 5% in the hippocampus). The goal cells were distributed evenly throughout the temporal and frontal cortices (see above). The place-responsive cells were found to be nondirectional, as would be predicted from the rodent literature, given that the subjects were free to move through areas in the virtual town from different directions. In an important control, Eckstrom et al. looked for unit responses to isolated landmarks before the patients learned to use them to navigate in a virtual reality environment; they failed to find any.

## 11.8 Place Cells Are Memory Cells

A role for the hippocampal formation in memory is suggested by activity-dependent synaptic plasticity, such as long-term potentiation (LTP) and long-term depression (LTD) (see Chapter 10) and the profound amnesia associated with damage to the medial temporal lobe (see Chapters 12 and 13). Is this mnemonic capability also reflected by place cells? This

chapter presents evidence that these cells can maintain their firing fields over a period of a few minutes in a working memory task, that place field characteristics can change with experience over the course of a day, that sensory control of place cell firing can become more differentiated with experience over days and weeks or can shift from exteroceptive to interoceptive cues when the animal learns that the former are unstable, that place cell activity during sleep reflects experience in the prior waking period and may be involved in consolidation of recently acquired spatial memories, and finally that several properties of normal place cell behavior in familiar and novel environments, such as place field stability, are based on memory and depend on the NMDA receptor implicated in LTP.

### **11.8.1 Hippocampal Place Cells “Remember” the Animal’s Location for Several Minutes During a Spatial Working Memory Task**

When discussing the properties of place cells, we saw that they displayed “memory” properties such as continuing to fire in appropriate places when the lights have been turned off. The cells use environmental cues to set up their firing pattern, but once established the pattern is sometimes surprisingly free of environmental influences. The clearest demonstration of this “memory” phenomenon was in experiments in which the environmental cues controlling place fields have been identified; and it was shown that place fields were maintained following the removal of these cues (Muller and Kubie, 1987; O’Keefe and Speakman, 1987; Save et al., 2005). We concentrate here on the O’Keefe and Speakman experiment in which place cell firing pattern was shown to be correlated with the animal’s behavior.

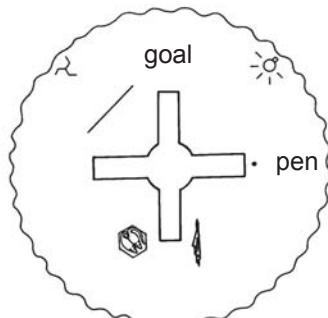

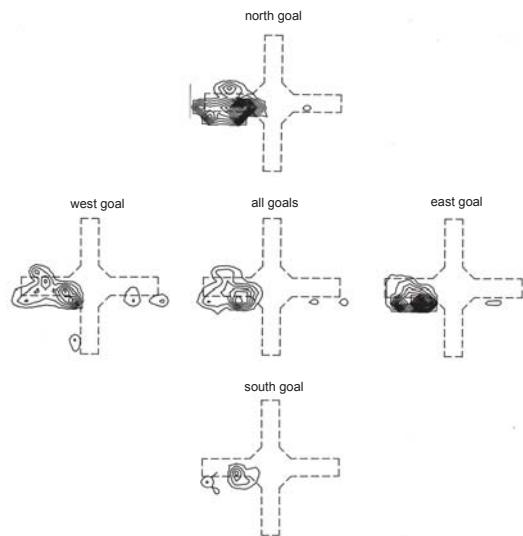

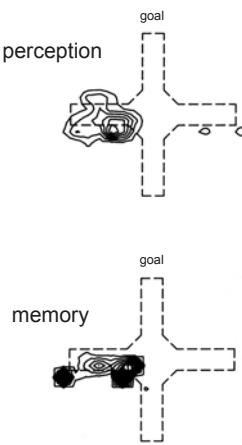

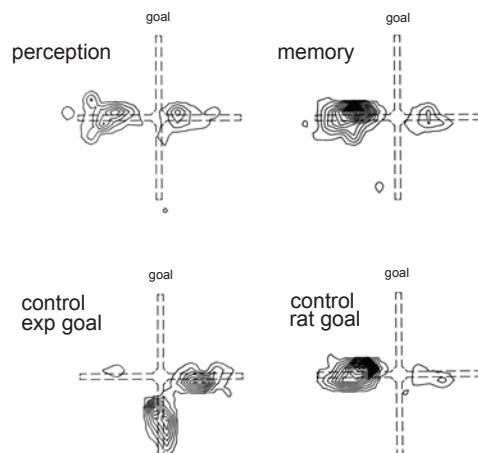

O’Keefe and Speakman (1987) recorded cells during a spatial memory task in a cue-controlled environment (Fig. 11–12). Rats were first trained on a plus shaped elevated maze to go to a goal defined by a set of cues within the curtained environment (Fig. 11–12A). Rotation of the cues and goal between trials ensured that the rats learned to use these cues. Place fields rotated in step with the cue rotations (Fig. 11–12B). On some trials, the cues were removed while the rat was still in the start arm before it was allowed to choose. Tests on normal rats had established that well trained animals could remember the location of the goal for periods as long as 30 minutes after the cues were removed. Of 30 cells with fields on the maze, 27 maintained these fields following removal of the cues (Fig. 11–12C). Cells with fields on the nonstart arms for a particular trial also fired in the correct place, demonstrating that place cell “memory” is more than the continuous persistence of a trace set up during the registration period; the system can, in addition, compute the correct location on the maze of place fields for cells that are inactive in the start arm. One explanation for this memory phenomenon points to a role for the distal cues at the periphery of an environment in orienting the head direction system. Once this has been set by the orientation of the control cues on a given trial, exterocep-

tive and interoceptive cues other than these might be capable of maintaining it (see Section 11.9). As we saw in Section 11.7.11, a role for the parietal cortex in this short-term spatial memory has been demonstrated (Save et al., 2005).

A final observation on these cells was made during control trials in which the animal was not placed in the start arm until after the controlled cues had been removed, preventing the animal from knowing which arm contained the reward. Under these circumstances, choice performance falls to chance levels, but the pattern of place cell firing still stayed appropriate for the animal’s choice of goal (Fig. 11–12D). This constitutes strong evidence that these cells are not firing to the actual environmental location but to where the animal “thinks” it is. Other studies have also found a good relation between place field activity and behavioral choices (Zinyuk et al., 2000; Lenck-Santini et al., 2001a, 2002; Rosenzweig et al., 2003) but there has also been failure to find this (Jeffery et al., 2003). In the latter experiment, rats continued to perform a hippocampus-dependent spatial task, albeit at a reduced level, following a change in the testing box that caused remapping of most of the CA1 place fields. Here, it is plausible to assume that place cells in other areas of the hippocampal formation did not remap and continued to support the behavior.

### **11.8.2 Place Field Plasticity During Unidirectional Locomotion**

One interesting line of investigation has involved changes in place field characteristics over time as rats run along a track. When animals are run on narrow tracks, many of the fields are directional, firing in one direction of movement but not the other. The experiments described in this section test models describing the effects of temporally asymmetrical LTP and the encoding of sequence-related information (see discussion in Chapter 14; see also Section 11.7.3). Mehta and colleagues (1997, 2000) have shown that over the course of a few dozen traverses in the same direction along a track, CA1 place fields shift backward relative to that direction of motion and become larger. They also found that an experience-dependent skewness develops in the place fields; that is, on the animal’s first runs of the day a given cell’s place field is symmetrical, but with continued exposure the place cell tends to fire at a higher rate when the animal leaves the place field than as it enters it. However, this increased skewness in CA1 place fields has not been found by others (Huxter et al., 2003). The development of place field expansion and backward shift has been shown to depend on NMDA receptors (Ekstrom et al., 2001). An intriguing aspect of the phenomenon in CA1 is that the effect resets overnight, as if the cells do not remember the previous day’s experience on the track (Mehta et al., 2000). Evidence from Lee et al. (2004) confirms and extends this finding but in addition shows a difference between the CA3 and CA1 fields: CA3 fields develop skewness and shift backward immediately on exposure to a newly altered track and maintain these changes on subsequent days, whereas CA1 fields shift back-

**A** Plus maze with 6 distal cues**B** Place fields rotate with distal cues**C** Place cells remember locations**D** Place cells predict spatial choice

**Figure 11–12.** Place cell activity during a spatial working memory task. *A*, Layout of the testing environment showing an elevated plus-shaped maze surrounded by six cues and a set of curtains. *B*, Place cell with a field on the arm 90° counterclockwise to the goal ( $-90^\circ$ , inner panel). The firing field remains constant with respect to the distal cues and goal as they are rotated by multiples of 90° relative to the laboratory frame (outside panels). Trials have been rotated so the goal is always shown at the top. More contours indicate a higher firing rate. *C*, Same cell as in *B* maintains its field dur-

ing the perceptual (top) and memory (bottom) phases of the experiment. *D*, A different place cell fires strongly in the  $-90^\circ$  arm and weakly in the  $+90^\circ$  arm on both perceptual and memory trials (upper left and right). During control trials, it fails to fire with correct relation to the (unknown) goal (lower left) but fires with correct relation to the animal's choice of goal arm at the end of the trial (lower right). In *B* and *C*, each contour = 0.7 spikes s<sup>-1</sup>; in *D*, each contour = 1.5 spikes s<sup>-1</sup>. (Source: After O'Keefe and Speakman, 1987, with permission.)

ward only from the second day of testing and do *not* maintain the changes. Lee et al. interpreted these findings as suggesting that the CA3, but not the CA1, network can store sequence information in the long term, and that CA1 is more involved in novelty detection. Note that CA1 cells can show long-term plasticity in other paradigms (see Section 11.8.3).

### 11.8.3 Cue Control over Hippocampal Place Cells Can Change as a Function of Experience

Experience with an environment can change which features of that environment control place fields. Such features include the color of a polarizing cue and the geometrical shape of the

environment. Bostock et al. (1991) studied place fields in two recording chambers that were identical except for a white or black polarizing card at the periphery. They found that when the black card was first substituted for the white card most of the place fields remained the same. However, as the rat continued to experience the white and black card environments, the place cells began to distinguish between them. The remapped fields fell into three classes: (1) the field in the black card environment was a rotation of that in the white card environment, or (2) the cell ceased to fire in the black card environment, or (3) the fields in the two environments were completely different in location and shape. The second and third classes were described as “complex remapping” and were found to be all-or-none: If one place cell showed complex remapping, so did another simultaneously recorded cell. Learned remapping can also occur between environments of different geometrical shapes (Muller and Kubie, 1987).

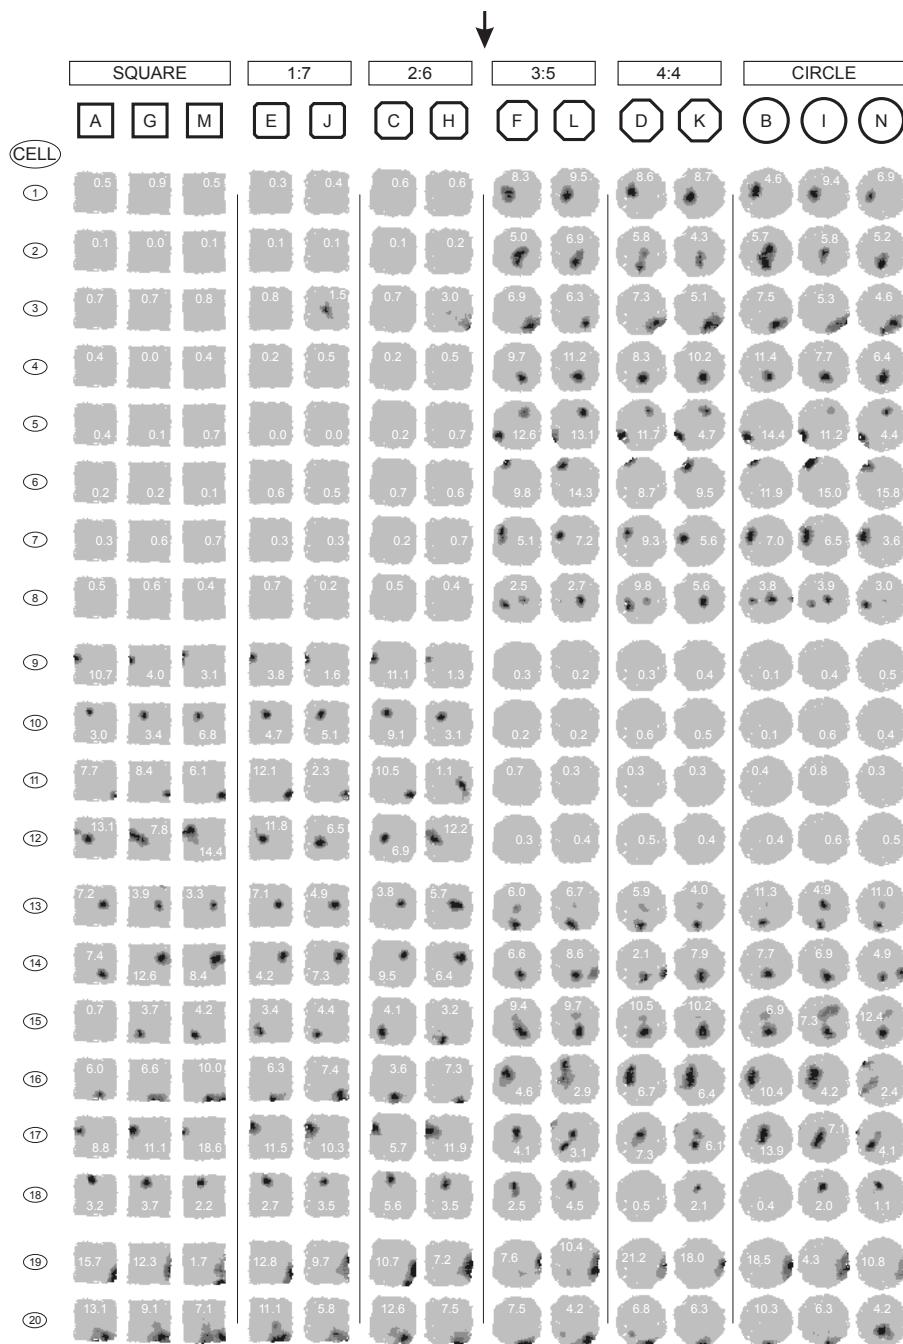

Lever et al. (2002) and Wills et al. (2005) studied the development of shape remapping in CA1 place cells in detail. Both experiments studied remapping between square and circular enclosures. In the Lever et al experiment, the enclosures differed only in shape and were identical in color, texture, and odor; in the Wills experiment they differed across all four dimensions. The activity of several hippocampal place cells was recorded on each day of the experiment; often they were different cells, but in some cases recordings were taken from the same cells over many consecutive days. Remapping was rapid and coherent in the latter experiment but slow and individualistic in the former. As in the Bostock et al. experiment described above, Lever found that on first exposure to a circular and a square environment most place fields were identical in the two shapes. With continued exposure, however, the cells began to differentiate between the environments. Unlike Bostock et al., they found that different cells differentiated between the environments at different rates, so after a few days some of the place fields were still similar in the two environments whereas others had clearly remapped. After 1 to 3 weeks of exposure to both environments, most of the cells had different fields in the two. Recording from individual cells through their remapping transition period showed that it took one of three forms. The most common form involved a gradual reduction of firing rate in one of the two shapes until it reached zero. Other forms of remapping involved the development of a new field in one of the shapes in tandem with the decline of the original field in that shape or, more rarely, a shift of the field in one shape to a new location. Once the cells had learned to differentiate between the two different-shaped boxes, rats were placed back in their home cages for delay periods of up to 39 days without any exposure to the shapes; upon reexposure, most of the cells continued to discriminate the two shaped boxes. CA1 place cells thus demonstrated long-term memory for this learned discrimination. Note that in both this and the Bostock et al. study the rats were not trained to discriminate the environments but were equally rewarded in both. Thus, the learning is *incremental* (see also

Tanila et al., 1997b), *latent* because it does not necessarily manifest in behavior, and *incidental* because it takes place in the absence of explicit reward.

In the Wills et al. study (2005a), the boxes were more different from each other to begin with, differing not only in shape but also in the color, odor, and texture of the walls. Original training took place in a white wooden circle and a brown morph square. Under these circumstances, the remapping took place over a period of minutes, and most of the cells had differentiated between the two environments by the end of the first few exposures. Furthermore, the remapped cells act in a unitary ensemble fashion, as was revealed by challenging them with shapes intermediate between the circle and the square. After several days’ experience with the original training enclosures the animals were transferred to circles and squares constructed from the same brown morph box. It was then possible to probe the basis for each cell’s differentiation between circle and square by recording in a series of octagons that vary systematically from the circle-like (regular octagon, adjacent side ratio 4:4) to the square-like (adjacent side ratio 7:1) (Fig. 11–13). Most of the remapped cells shifted abruptly from a square to circle firing pattern (for example, by treating the 6:2 octagon as a square and the 5:3 octagon as a circle). Furthermore, in all animals tested on this probe, all of the simultaneously recorded cells show the abrupt shift at exactly the same point in the sequence of octagons. This suggests that there are two mechanisms at work: pattern separation and pattern association (see Chapter 14). The first would permit the abrupt switch from the circle to square pattern despite a very small change in the geometry of the boxes. The second would be based on some type of cooperation among the active subset of place cells, perhaps revealing the operation of an attractor network and would account for the coherent behavior of the network.

#### **11.8.4 Control of the Angular Orientation of Place Cells in a Symmetrical Environment Can Be Altered by the Animal’s Experience of Cue Instability**

In a symmetrically shaped environment such as a cylinder, an animal’s sense of direction can be controlled by distal polarizing cues, such as a card on the wall of the environment, or by internal path integration cues, such as the amount it has turned around. Commonly, the visual information provided by a distal cue overshadows the internal cues, and rotating the cue causes an equal rotation of the fields (see Section 11.7.6). Jeffery and colleagues (Jeffery et al 1997; Jeffery 1998) showed that given certain experiences the animal could learn to give priority to internal path integration signals over the external cue. They tested the effectiveness of the cue card by rotating it when the animal was out of the enclosure and the effectiveness of the internal path integration system by slow rotations (subvestibular threshold) of the animal relative to the framework of the enclosure. As expected, they found that, initially, the visual cue card controlled place field orientation.

**Figure 11-13.** Abrupt coherent switch from square-like pattern to circle-like pattern in an incrementally changing series of octagons. Fields of 20 simultaneously recorded place cells following fast remapping training. Cells 1–17 met the criterion for remapping, and all switched abruptly from the square-like to circle-like

pattern at the same point in the series between the 2:6 and 3:5 octagon (arrow at top). The order in which the octagons were experienced is indicated by the letters A to N in the second row. Numbers in panels are peak rates. (Source: After Wills et al., 2005, with permission.)

However, following experience in which the rat could see the cue card move relative to the background environment and therefore was not a stable landmark, control of place field orientation passed from this visual cue to the interoceptive path integration system. Now the fields were no longer controlled by rotations of the visual cue but could be shifted by slow rotations of the animal relative to the framework of

the enclosure, demonstrating that they were under the control of the vestibular system. Rotations of the cue when the animal could not see it move did not produce the shift away from cue control. It seems likely that the site for this cue-instability learning is in the head-direction system itself (see Sections 11.9 and 11.10), perhaps in the presubiculum. This is suggested by two key features of the data. First, all the cells

behave as a map-like ensemble, following either exteroceptive cues or interoceptive cues. Second, once the path integration system surplants the visual cue card in the control of orientation, it generalizes to novel situations. Following remapping induced by changing the color of the environment's walls, the newly remapped population of CA1 cells immediately follows the interoceptive rather than the visual cues, without needing to relearn the cue instability (Chakraborty et al., 2004).

### **11.8.5 Complex-spike Cell Firing and Connectivity During Sleep Is Modulated by Prior Spatial Learning Experiences**

It has been suggested that consolidation of memories might take place during sleep and, in particular, during REM sleep (Maquet, 2001; Stickgold et al., 2001). Therefore, one might expect neuronal firing patterns to reflect this consolidation activity. Furthermore, if consolidation involves the transfer of information from hippocampus to neocortex (an idea developed further in Chapters 12 and 13), one might expect there to be increased interaction between cells in these brain areas during and after sleep. Experiments have suggested that the cell activity during ripples and sharp waves, or that related to the theta waves of REM sleep, could be the neural signature of this information transfer/consolidation process.

Pavlides and Winson (1989) recorded pairs of place cells in rats during sleep sessions that followed experience on a radial arm maze. The rats were allowed to visit the place field of one of the two cells prior to each sleep session but not the other. Remarkably, there was a selective increase in firing during both the slow-wave sleep and REM sleep periods of the cell that had been allowed to be active in its place field prior to sleep. The other cell showed no change in firing rate. In another study following place cell activation on a runaway during waking, the theta phase at which these cells fired during subsequent REM sleep shifted to the positive peak (Poe et al., 2000). Because LTP is more likely to occur at this phase, this finding might be an indication that recently experienced cells are more susceptible to plastic modification. Evidence for such changes comes from studies on changes in cell connectivity. Wilson and McNaughton (1994) examined the effects of spatial experience on changes in functional connectivity between CA1 cells. Using cross-correlation techniques (see Box 11–2), they found an increase in the correlation between pairs of cells with overlapping place fields in slow-wave sleep *after*, compared to before, the environmental experience; these correlations were more pronounced during ripples (see also (Kudrimoti et al., 1999). There was evidence from another study (Qin et al., 1997) that some of this increased connectivity takes place between cells that were already connected prior to the environmental experience. Skaggs and McNaughton (1996) ran rats in one direction on a narrow triangular track and found that the temporal ordering of firing between cells with partially overlapping fields was replicated in a compressed form during slow wave

sleep. Firing sequence replay has been replicated by Wilson's group for slow-wave sleep (Lee and Wilson, 2002) and for REM sleep (Louie and Wilson, 2001). It should be emphasized that the replay time scales relative to the waking spatial experience differ markedly for these types of sleep, involving about 20-fold compression during slow-wave sleep and basically no compression during REM sleep. Second, it seems that slow-wave sleep replays sequences immediately after they were experienced, whereas REM sleep replays experience at least a day old. Finally, cross-correlational analysis showed that increased correlations were found between pairs of neocortical cells as well as pairs of hippocampal cells and, most intriguingly, between pairs of hippocampal and neocortical cells (Qin et al., 1997; Siapas and Wilson, 1998). The latter finding may be taken as evidence for increases in the "functional connectivity" between, as well as within, structures.

In all, these results indicate selective, orderly reactivation of cells that have recently taken part in a spatial experience. They also suggest that co-activation of place cells during the waking experience might lead to increased connectivity and further consolidation during sleep states. These studies have involved CA1 cells. A future goal is to compare CA3 and CA1 cells and relate these findings to the experience-dependent place field changes during unidirectional track running described above in this section. The mechanisms that immediately produce sequence replay during sleep in CA1 appear to reset (Lee and Wilson, 2002), like the CA1 place field changes such as skewness and backward shift. Given that these are maintained on subsequent days in CA3 cells (Lee et al., 2004), one might predict that experience-dependent changes in CA3–CA3 connectivity in sleep would also be less transient.

What is needed to take these results forward and demonstrate a causal relation between the sleep phenomenon and subsequent memory capacity is a physiological or pharmacological technique for selectively disrupting postexperience LIA or REM theta activity or, even better, altering the patterning of place cell activity during these periods.

### **11.8.6 NMDA Receptor Confers Mnemonic Properties on Place Cell Firing**

Several studies have pointed to a role for the NMDA receptor (NMDAR) in conferring mnemonic properties on place cell function (reviewed by Nakazawa et al., 2004). McHugh et al. (1996) studied the place cells of mice in which the NMDA receptor subunit NR1 had been knocked out only in CA1 pyramidal cells. Deletion of this subunit renders the receptor inoperable. Rotenberg et al. (1996) looked at the fields of place cells in animals that transgenically expressed a mutated calcium-independent form of CAMKII, part of the intracellular signaling pathway that mediates the effects of the NMDA receptor. Both groups of animals had deficits in LTP and spatial memory (Rotenberg et al., 1996; Tsien et al., 1996). In both experiments fewer place cells were found in the mutants and the quality of the mutant place fields was degraded, a result that has also been seen in other mutant mice with disrupted

NMDAR-dependent plasticity (Cho et al 1998). In a different mutant, Rotenberg et al found that place fields were less stable over repeated exposures to the environment (Rotenberg et al., 2000). In the McHugh et al. experiment, the place cells showed an interesting loss of the usual temporal relation between the firing patterns of cells with overlapping place fields. As we saw in Section 11.7.9, place cells fire with a theta-like bursting pattern as the animal runs through the firing field, which is revealed by strong periodicity in the cross-correlogram of the two spike trains (see Box 11–2). The absence of this periodicity in the McHugh et al. experiment suggests a fundamental breakdown in the temporal firing pattern of the place cells or the temporal relations between cells lacking a functional NMDA receptor.

The global role of the NMDA receptor in the long-term stability of place fields was studied by Kentros et al. (1998). They showed that systemic administration of the competitive NMDA channel blocker CPP had no effect on established place fields in an environment long familiar to the rats or on the formation of newly “remapped” place fields in a novel environment, nor on the short-term stability of these new, remapped place fields, as measured over a couple of hours. However, on the second day of exposure to the novel environment, the previous day’s place fields had been “forgotten”: Again the cells remapped the new environment, but the new patterns of firing bore no relation to those of the previous day. This finding suggests that the NMDA receptor is more important for the stability of place fields in the long term than it is in their initial establishment or their short-term maintenance.

Highly informative studies have used conditional CA3-restricted NMDA receptor knockout mice to explore the contribution of long-term CA3 plasticity to CA1 place cell firing and spatial behavior (Nakazawa et al., 2002, 2003). These studies suggest two important roles for CA3 plasticity: pattern completion (see Chapter 14), whereby only a subset of cues are sufficient to reinstate a pattern of firing originally associated with the full cue set; and rapid, single-exposure, learning. Pattern completion is suggested by the finding that although CA1 cells in the mutants showed normal firing in full-cue reexposures to an environment they showed significantly reduced levels of firing (albeit in the appropriate locations) in partial-cue reexposures. Impaired behavior was also seen in probe trials during the watermaze task under partial-cue conditions. A CA3 plasticity-dependent role in rapid environmental learning is suggested by the poorer quality of the mutants’ CA1 place fields in novel environments and by impaired performance in the delayed match-to-place version of the watermaze (see Chapter 13).

### 11.8.7 Summary of Place Cell Plasticity

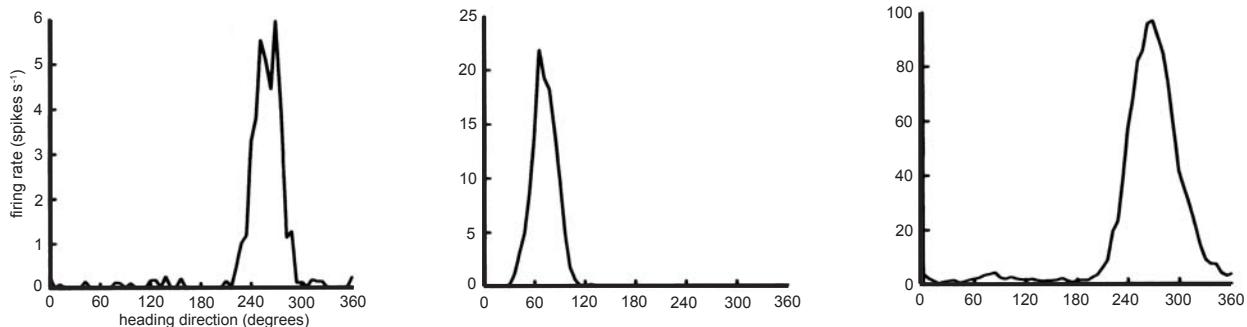

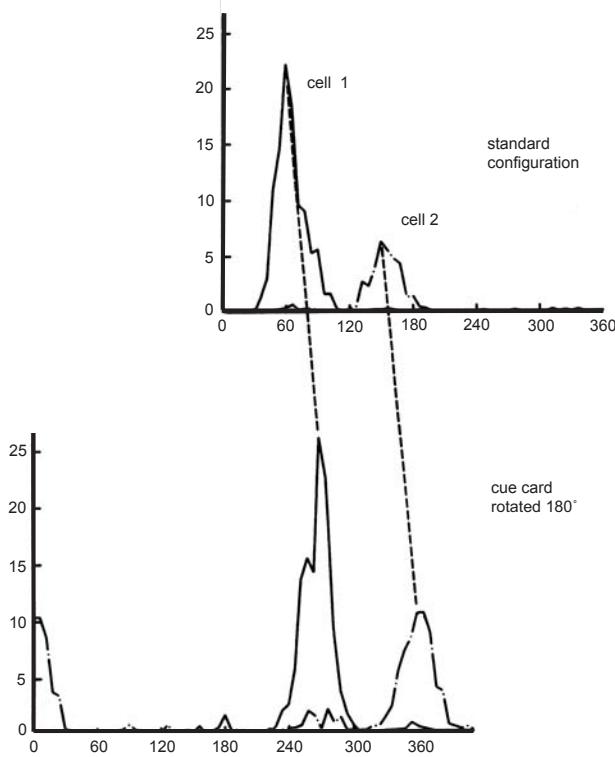

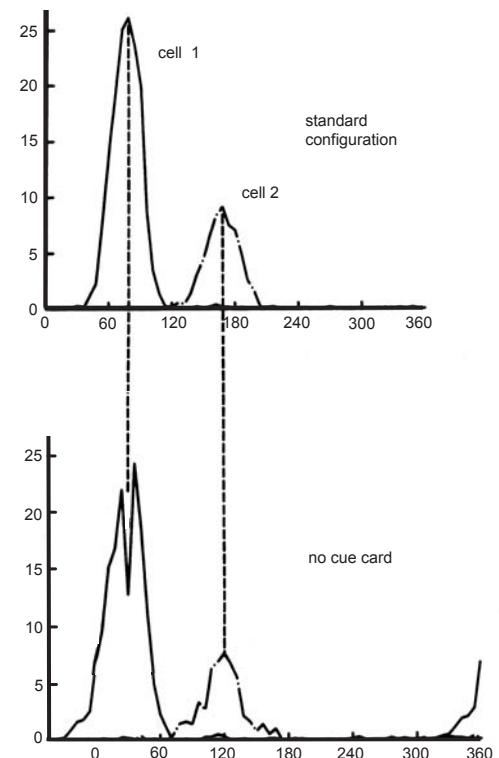

The evidence summarized in this section indicates that place cells show several forms of plasticity, some of which can be correlated with the animal’s behavior in spatial memory tasks. These various forms of plasticity last for markedly different periods of time, ranging from a few minutes to longer than a

month. Some of them are activity-dependent and temporary, lasting only the length of a single trial in a working memory task or a session on a maze, whereas others appear to be permanent, such as the differentiation between two boxes following slow remapping. Some of these changes clearly depend on the integrity of the NMDA receptor in different parts of the hippocampus, but others may not. Indeed, for many of these changes it has not yet been firmly established that the underlying synaptic plasticity takes place in the hippocampus itself rather than in structures afferent to the hippocampus and is merely being passively reflected by the cells there. Finally, there is substantial evidence that some type of consolidation process takes place during sleep following an experience, and it is reflected in place cell firing. Whether this involves intrahippocampal processes, such as the strengthening of synapses between cells with overlapping fields, or involves the transfer of information from hippocampal stores to neocortical ones, must await further experimentation. It is clear that there are sufficient examples of plasticity reflected in place cell firing to make them one of the more fruitful targets in the study of the neural basis of memory. In a subsequent section (see Section 11.11), we examine the evidence for changes in hippocampal cell activity during nonspatial learning and memory tasks.

### 11.9 Head Direction Cells

Another well characterized class of spatial cells recorded in the hippocampal formation of freely moving awake animals is the head-direction (HD) cells, found in the dorsal presubiculum and regions connected with the presubiculum, such as the anterior thalamus (Ranck, 1984; Taube et al., 1990a; Taube, 1995a, 1998). As already noted, HD cells fire whenever the rat’s head points in a specific direction relative to the environment, irrespective of its location or whether it is moving or still (see Fig. 11–21C, color centerfold). The primary correlate is the azimuthal orientation of the head in the horizontal plane. Pitch and roll appear to be relatively unimportant, as is the orientation of the rest of the body. Figure 11–14A shows the firing rate for three of these HD units plotted as a function of the direction of heading. Each cell has a single preferred direction, and firing falls off rapidly, symmetrically, and almost linearly as the head direction rotates away from the preferred direction. We refer to these directions in terms of compass headings but do not imply that these cells are sensitive to geomagnetism. The portion of the 360° circle covered by a given cell ranges from about 60° to 140°, with the average being about 90° (Fig. 11–14A). An impressively Euclidean property of HD cells is that the preferred direction is remarkably independent of position (Taube et al., 1990a; Burgess et al., 2005); the preferred direction vectors in the various parts of an environment appear *not* to converge (e.g., upon a salient distal cue, as one might have expected) but are parallel. The distribution of peak firing directions across the population of cells is uniform, with no direction preferred over any other.

**A 3 Head Direction Cells Firing Fields****B Fields rotate with cue card****C Fields shift after cue card removal**

**Figure 11–14.** Head direction cells in the dorsal presubiculum. *A*, Firing fields of three cells as a function of the animal's heading direction. Note that each firing field subtends an angle of about 90° but that the firing rates differ. (*Source:* After Taube et al., 1990a.) *B*, Rotation of a cue card on the wall of the cylindrical enclosure by 180° rotates the angular orientation of two simultaneously recorded fields by a similar amount. Note that the relative angle between the two fields tends to remain the same, as shown by the dashed parallel

lines. *C*, Removal of the cue card shifts firing fields of two cells recorded at the same time. Again, both fields shift by approximately 40° and maintain a constant difference in their preferred heading directions. The x axes in the bottom figures of *B* and *C* have been extended beyond 360°, and part of the field is duplicated to show the entire shape of the firing fields around 0/360°. (*Source:* *B, C*. After Taube et al., 1990b, both with permission.)

Similarly, there does not appear to be any topography to the directions represented by neighboring neurons, an arrangement reminiscent of the lack of environmental topography in the layout of place cells. Importantly, unlike hippocampal place cells, which signal location in some locations but are silent in others, HD cells fire in all environments tested.

### 11.9.1 Head Direction Cells are Controlled by Distal Sensory Cues

Taube et al. (1990a) found that rotations of a cue card fixed to the apparatus wall by multiples of 90° produced almost commensurate rotations of the directional firing field (Fig.

11–14B). Slight deviations from perfect rotation, however, suggested that in the experimental setup used the card was not the only environmental cue exerting stimulus control over the preferred direction. This was confirmed in tests in which the card was removed altogether. Card removal revealed two interesting properties of these cells (Fig. 11–14C). First, the width of the directional firing field remained the same, as did the peak firing rate. This suggests that these properties depend on factors intrinsic to the cell itself or to the network in which it is embedded, not on environmental inputs. Second, the preferred direction shifted to a new unpredictable compass point in almost two-thirds of the cells. Shifts ranged from 108° in the clockwise direction to 66° in the counterclockwise direction. The preferred direction appeared to remain approximately the same in the remaining one-third of cells. Zugaro et al. (2001) tested the relative influence of distal and proximal cues in determining the orientation of HD cells. As Cressant et al. (1997) had shown with place field orientation, Zugaro found that the rotation of three distinct objects at the periphery of a platform, bounded by a cylindrical enclosure, caused an equal rotation in the preferred directions of all anterior thalamus HD cells tested. The cylinder prevented the rats from seeing more distal background cues, such as geometrically configured black curtains along the walls of the room. When the same object-set rotation was performed in the absence of the cylinder, the preferred directions of all the HD cells were essentially unaltered. Although the cylinder-absent, background-visible condition was always performed second, the consistency of the responses provides further evidence that the orientation system is preferentially controlled by the most distal cues available.

In addition to cue card shifts, Taube and colleagues (1990b) found that changing the shape of the testing enclosure from a cylinder to a square or rectangle also caused changes in the preferred direction. In both right-angled boxes, the polarizing cue card occupied the same location relative to the environment as it had in the cylinder. When tested in the rectangular enclosure, most cells (8/10) shifted directions by large amounts; but on subsequent testing of these cells in the square enclosure, fewer than half (3/8) had preferred directions shifted relative to those they had displayed in the cylinder. As with card removal, the peak firing and angular width remained constant. Golob and Taube (1997) found that only 2 of 11 cells changed their preferred direction by more than 18° from the standard cylinder to a square box. As previously, more radical shape changes (i.e., from the cylinder to triangular or rectangular enclosures) caused large shifts in directional preference; all 17 cells tested shifting by at least 36°. (One minor caveat: This study tested HD cell activity in hippocampal-lesioned animals only.)

Goodridge et al. (1998) looked at the role of sensory modalities other than vision on the firing of head direction cells. Whereas a simple auditory cue, such as a localized series of clicks or bursts of noise, was ineffective, a localized smell did exert a small but significant control over the preferred direction. Rotation of the walls and floor of the testing chamber in

blindsighted rats also had a small effect that subsequent tests revealed was mostly attributable to the floor. There was also some evidence that the preferred direction in blindsighted rats was less stable.

### 11.9.2 Angular Distance Between any Given Pair of Head Direction Cells Always Remains Constant

An important property of HD cells is “obligatory coupling”—the angular distance between the preferred directions of pairs of HD cells is remarkably resistant to alteration (Fig. 11–14B,C). Regardless of the cue-control manipulation, both cells of a simultaneously pair are always found to rotate by the same amount. Figure 11–14C illustrates this nicely: Following cue removal, the preferred head direction of cell 1 rotates by approximately 40° accompanied by a similar rotation in cell 2. The important implication of this coupling of preferred directions between cells is that there must be some kind of “hard-wiring” of the network of HD cells such that the population of cells firing at any one time gives an accurate and, above all, unambiguous representation of heading direction. The maintenance of a constant angular distance between HD cell pairs in the face of environmental change is well modeled by attractor networks (e.g., Redish and Touretzky, 1996; Zhang, 1996) (see Chapter 14).

### 11.9.3 Head Direction Cells Can also Be Controlled by Idiopathic Cues

In a fashion similar to the place cells, some HD cells maintain their preferred direction following removal of the cue card. One interpretation of this finding is that the sense of direction is continually updated in the absence of environmental cues on the basis of idiopathic or inertial navigation cues including those from the vestibular and proprioceptive systems. Consistent with this possibility is the finding that vestibular lesions cause cells to lose their preferred direction (Stackman and Taube, 1997). It must be stressed, however, that idiopathic cues *alone* are almost certainly insufficient to maintain a constant preferred direction over a long period of nonstereotyped locomotion. For instance, in darkness, olfactory signals from the cylinder and/or floor are probably required in tandem with idiopathic cues for stable orientation, as suggested by the place cell results of Save et al. (2000) (Section 11.7.7).

Additional evidence for the role of vestibular cues on preferred heading direction comes from experiments in which the floor (and therefore the rat) and the black-and-white striped walls of the recording chamber were rotated together in tandem or independently (Blair and Sharp, 1996). There were two rates of rotation, one above and the other below that assumed to be detectable by the vestibular system. These manipulations were carried out both in the light and in the dark in an attempt to dissociate visual motion cues from vestibular effects. In the light, slow rotation of the wall and floor together resulted in the comparable rotation of the

preferred heading direction in all cells tested. In contrast, rapid rotation of the wall or floor individually or together was ignored by most cells, which maintained their preferred direction relative to the laboratory frame. A few cells did show partial or complete rotations under these conditions, revealing some influence of idiothetic cues. The picture was different in the dark. Now both fast and slow rotations changed the preferred heading direction for many but not all of the cells. This pattern of results suggests that the preferred direction is controlled by several factors, which include visual information from the laboratory itself and visual motion and vestibular information derived from the animal's movements. The latter become more effective in the absence of the distal visual cues.

Disorientating or disruptive rotations of the animal carried out before it is placed in the environment have also been examined. If these are carried out on a routine daily basis for several weeks prior to recording, HD cells have a less stable relation to the frame of the laboratory both within and across recording sessions. They are also less well controlled by explicit visual cues (Knierim et al., 1995). Even in animals that had not been disorientated in this way and that displayed strong stable control by visual cues, subsequent introduction of the disorienting procedure prior to each daily recording session caused the HD cells to become progressively uncoupled from strong visual control. Knierim and colleagues suggested that this is evidence that path integration navigation cues predominate when an animal first enters a new environment and that environmental cues gain control over the head direction system only after a period in which they maintain a stable relation to the path integration system. Stability, it is thought, initially derives from the path integration system. On this argument, the association of the head direction system to environmental cues would provide corrections for the inevitable accumulation of errors to which the path integration system is subject. This requires that the system, which originally used the path integration system as the basis for assigning stability (or a direction) to the visual cue, would then be able to use that cue to correct the drift in the system. This boot-strap operation appears to require rapid association of specific cues (e.g., those provided by a cue card) to an otherwise stable but preexisting framework. The amount of exposure time for a visual cue card to gain control over preferred orientation was studied in passing in earlier studies. Goodridge et al. (1998), for instance, found that 8 minutes was sufficient for all cells tested, but that as little as 1 minute sufficed for some cells. Zugaro et al. (2000) found that preferred directions shifted to a new, fairly stable orientation within 15 seconds of a cue card rotation. More recently, an interesting study designed specifically to examine this issue (Zugaro et al., 2003) has shown that reorientation induced by 90° rotation of a peripheral cue card in the dark can occur with a latency on the order of 100 ms after the cue-card shift becomes visually apparent. The authors reasonably concluded that such latencies are more compatible with an abrupt jump from one preferred direction to another than with a gradual

rotation through intermediate directions. In familiar environments, control of the head direction system by visual stimuli can be rapid indeed. Perhaps the slower figures are due to the time it takes for the animal to notice the changed position of the cue card.

#### **11.9.4 Head Direction Cells Are Found in Different Anatomically Connected Brain Areas**

Head-direction cells have been recorded in areas of the brain in addition to the dorsal presubiculum, where they were first discovered. These areas include the anterior dorsal thalamic nucleus (Taube, 1995a), lateral mammillary nucleus (Stackman and Taube, 1998), lateral dorsal thalamic nuclei (Mizumori and Williams, 1993), retrosplenial cortex (Chen et al., 1994; Cho and Sharp, 2001), and striatum (Wiener, 1993). Apart from the striatum, these areas are all strongly interconnected. The HD cells in the lateral mammillary nucleus, anterior thalamus, and dorsal presubiculum have been most studied, and this section concentrates on the differences in their properties. Do they tell us anything about the way in which the head direction signal is constructed? What is the contribution of each part of the circuit? In addition to the characterization of the properties of the HD cells in each area, two additional approaches to these questions have been used. The first looks at the relative timing of the signal in the various areas, and the second asks what the effect of a lesion in one area is on the activity in another. With the first approach, the best temporal correlation between the HD cell firing and the animal's heading direction is computed. The idea is to see whether cell firing is better related to the animal's current heading or to its heading in the immediate past or future. The assumption is that if the best correlated cell firing precedes the current heading direction, it is more likely to reflect some aspect of neural activity in the motor system that is producing the head movements; conversely, if the best correlated cell firing lags behind the behavior, it is more likely to reflect sensory feedback generated by the movement. The latter assumption is not infallible, however, because it is equally possible that lagged cell firing represents aspects of the neural control of movement shifted by a time delay.

The second use of time shift correlation analyses is to compare the temporal relations between the areas in which HD cells are found. If the cells in one area show a firing pattern that is earlier relative to the current heading direction than those of a second area, it is reasonable to suppose that the first brain area makes computations that come "earlier" in the circuit than the second. In a modular system with strictly serial connections between the modules, the relative latencies with respect to an external event may be taken as an indication of the functional and perhaps causal connectivity between brain areas.

There is a clear consensus that, on average, the firing of HD cells in the dorsal presubiculum is approximately in synchrony with the current direction of heading. HD cells in the lateral

mammillary nucleus lead those of the anterior dorsal thalamus (by about 60–70 ms), and the anterior dorsal thalamus leads the dorsal presubiculum (by about 20–30 ms) (Blair et al., 1997; Stackman and Taube, 1998; Taube and Muller, 1998). Although it is clear that there are average time shifts between the areas, there is also a wide distribution of shifts within any area, resulting in an overlap of shifts between areas. The pattern of temporal correlations suggests a functional pathway that originates in the lateral mammillary nucleus, passes information to the anterior dorsal thalamic nucleus, and thence to the dorsal presubiculum. Remarkably, this is part of the classic Papez circuit originally believed to provide the neural substrate for emotions (see Chapter 2), and there is abundant evidence of its anatomical basis from numerous tract tracing studies (see Chapter 3). It is important to remember, however, that there are also substantial connections in the opposite direction and, as we shall see in the next section, good reason to be cautious when putting forward any simple serial theory of the elements of the head direction system in rodents.

A similar story emerges from lesion experiments. Lesions of the anterior dorsal thalamic nucleus abolish the head direction signal in the dorsal presubiculum (Goodridge and Taube, 1997). In contrast, lesions in the dorsal presubiculum do not abolish the anterior dorsal thalamic nucleus signal but have more subtle effects on it. The clearest of these is an increase in the amount of time by which anterior dorsal thalamic nucleus HD cell firing anticipates the animal's heading direction. This suggests that a contribution of the feedback from the dorsal presubiculum to the anterior dorsal thalamic nucleus is to reduce the anticipatory interval expressed in the anterior dorsal thalamic nucleus leg of the system. A second effect of dorsal presubiculum lesions is to abolish the control of a cue card over the preferred heading direction of anterior dorsal thalamic nucleus cells (Goodridge and Taube, 1997) and to reduce the consistency and stability of the preferred heading direction between recording sessions.

Blair and colleagues (1999) investigated the effects of bilateral or unilateral lesions of the lateral mammillary nuclei on the properties of HD cells in the anterior thalamus. Following unilateral lesions, thalamic cells still had preferred directions, but they sometimes differed from prelesion ones, the peak firing rates were often reduced, and the turning curves were broader. In general, the HD cell firing properties shifted to resemble those in the mammillary bodies. Following bilateral lesions, no directional cells could be found in the anterior thalamus.

The overall pattern of changes following lesions of various nuclei support the notion that directional signals travel from the hypothalamus through the thalamus to the cortex. Furthermore, they are consistent with the idea that the dorsal presubiculum is the site at which visual sensory information gains access to the HD system, and the lateral mammillary nucleus/anterior dorsal thalamic nucleus pathway is the source of path integration control based on vestibular information.

### 11.9.5 Dorsal Tegmental Nucleus of Gudden Provides Information About the Direction and Angular Velocity of the Animal's Head Rotation

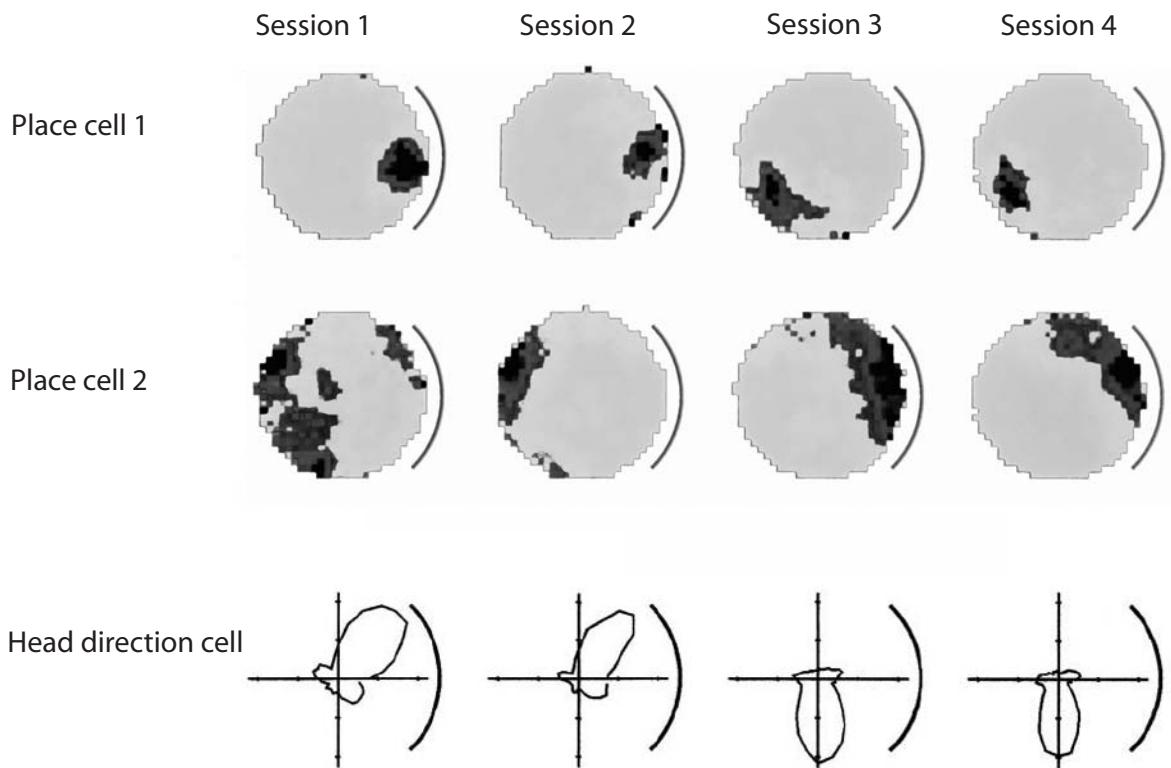

The midbrain nucleus called the dorsal tegmental nucleus of Gudden (DTN) is reciprocally connected to the lateral mammillary nucleus and contains cells whose firing rate correlates with the angular velocity of the head (Bassett and Taube, 2001; Sharp et al., 2001). Integration of the angular velocity over time would produce a signal proportional to the change in angular direction, which could be used to update the current heading direction. There appear to be several types of angular velocity cell in the DTN: Many show strong correlations with velocity of movement regardless of the direction of the movement, increasing their firing rates in both directions, whereas others are asymmetrical, increasing their firing rates in one direction and decreasing them or firing at a constant rate in the other. In addition to these angular velocity cells, the DTN contains a small number of HD cells, and there is evidence that some of the angular velocity cells also show head direction or head pitch correlates.

### 11.10 Interactions Between Hippocampal Place Cells and Head Direction Cells

What is the relation between place cells and HD cells? In the original formulation of the cognitive map theory, O'Keefe and Nadel suggested that the map of an environment consisted of a set of place representations bound together by information about the direction and distance between them (O'Keefe, 1976; O'Keefe and Nadel, 1978) (see Section 11.7). In this view a place representation could be activated either by direct sensory information impinging on the animal when it occupied that place or by activation of a different place representation together with the appropriate distance and direction inputs between that place and the target place. The theory was extended in 1991 (O'Keefe, 1991a,b) by the suggestion that place cells were dependent on the input from two or more HD cells for directional information and that rotation of the HD system relative to the environmental frame would produce the rotation of place fields seen in these experiments. McNaughton and colleagues (1996) suggested that the place cell firing field was determined by the distance to a single object in a specific direction and that this directional signal was provided by the HD system. Evidence in favor of the idea that the place system is dependent on the HD system comes from the following.

Both place and HD cells respond similarly to rotation and removal of polarizing cues, such as the cue card in the standard cylinder (Muller and Kubie, 1987; Taube et al., 1990b; Cressant et al., 1997; Zugaro et al., 2001). Vestibular lesions abolish anterior thalamic directional firing and location-specific firing in hippocampal place cells (Stackman and

**Figure 11-15.** Place and head direction cells recorded simultaneously maintain the same angular orientation despite both rotating relative to the environment. Top two rows show the place fields of two cells that rotate by about 135° following disorientation of the animal by gentle spinning between sessions two and three. Bottom row shows the field of a head-direction (HD) cell recorded at the

same time, which also rotates. Both place fields and preferred direction of the HD cell are stable before (sessions one and two) and after (sessions three and four) the intervention. Note that the fields of both place cells and the HD cell maintain a constant angular relation to each other. (Source: After Knierim et al., 1995, with permission.)

Taube, 1997; Stackman et al., 2002; Russell et al., 2003). In the one experiment (Knierim et al., 1995) in which HD cells and place cells were recorded simultaneously, they stayed in register even under circumstances where the control by environmental stimuli was lost: Rotating the animal prior to the recording session often led to unpredictable rotation of both the preferred heading direction of the HD cell and the angular orientation of the place cell, but they maintained their fixed relation to each other (Fig. 11-15).

Lesions to the anterior thalamus or the dorsal presubiculum significantly increased the directionality of place fields recorded in the cylinder in comparison with control animals (Calton et al., 2003). Recall that in normal rats the place fields are essentially nondirectional in this testing apparatus (Muller et al., 1994) (see Section 11.7). Such lesions also reduce the spatial coherence of the place fields. The relation between the standard cue card and the place fields depends on the lesion locus. Note that in intact animals, as discussed above, rotation of the card causes the preferred direction of most HD cells to reorient rapidly so as to maintain a fixed relation to the card. Calton et al. (2003) found that in animals with lesions of the dorsal presubiculum the angular locations of hippocampal place fields were not controlled by the cue card but shifted unpredictably from trial to trial. Although intertrial

variability was also reliably seen in anterior thalamus-lesioned animals, the effect was mild in these cases. Similarly, removing the cue card caused large shifts in the place fields' angular location in the dorsal presubiculum animals but minor shifts in the anterior thalamic lesioned animals.

In contrast to the large effect that dorsal presubiculum lesions have on hippocampal place cells, there is little evidence that hippocampal lesions have a major effect on the basic firing characteristics of HD cells. Golob and Taube (1997) reported that about the usual number of HD cells were recorded in the anterior thalamic nuclei and dorsal presubiculum following hippocampal lesions, and that they were under control of the visual cue card to the same extent. Furthermore, changes in the preferred firing direction in novel enclosures of different shapes were broadly similar to previous studies of nonlesioned animals. In a follow-up experiment, the effect of combined lesions of the hippocampus and overlying neocortex on the control of the HD cells by idiothetic path integration signals was examined (Golob and Taube, 1999). The preferred head direction was monitored as the animals moved from a familiar environment to an unfamiliar one. In normal animals, the self-movement cues provided sufficient information to maintain the heading direction in the new environment consonant with that in the old familiar one, con-

sistent with previous work (Taube and Burton, 1995). HD cells in lesioned animals, however, were not able to do this and, furthermore, took up to 4 minutes to reach a stable preferred orientation in the new environment. On the other hand, a cue card in the new environment was capable of establishing control over the HD preferred orientation, showing that there was no deficit in this part of the system. The primary influence of the hippocampus on the head direction system appears to be to maintain a consistent preferred direction in the HD cells as an animal moves between different enclosures in the same laboratory, presumably on the basis of path integration signals or context information about the laboratory. The only caveat here is that lesions of the overlying neocortex resulted in effects that were similar but of lesser magnitude, and it is not possible therefore to rule out a role for the neocortex or a more general, nonspecific effect of the lesions.

As we shall see in Chapter 13, there is evidence that hippocampus-lesioned rats can learn an allocentric spatial memory task in which they are required to go to a location defined by its distance from a single object in a specific environmental direction. This capability appears to depend on the HD system but not, because it depends on a single vector, on the hippocampal system.

In summary, the evidence strongly suggests that the place system relies on the HD system to provide it with the directional basis of a fixed framework, which acts as the scaffolding for the representation of an environment. Two HD cell characteristics are crucial to this: First, the angular distance between HD cells remains constant; and second, the vectors created by the signaling of each HD cell firing in different portions of an environment are parallel. Whereas environmental changes can cause the distance between different place fields to shift relative to each other, the HD cells appear to be rigidly fixed relative to each other, and it is only the relation between the total constellation of cells and the environment that can be altered. Rotation of the HD system rotates the entire place system. The most likely route for the influence of the HD system on the hippocampal place cells is via the medial entorhinal cortical grid cells whose orientation relative to the environment is also controlled by distal cues (see Section 11.7.7). The contribution of the hippocampal place system to the HD system is less clear. It may be the origin of information about the wider context that allows the animal to maintain a constant heading direction relative to distant cues as it moves from a familiar part of a territory to an unfamiliar one.

## 11.11 Hippocampal Complex-spike Cells Have Been Implicated in Nonspatial Perception and Learning

In addition to the widely reported spatial and movement correlates of hippocampal cells, there have been reports of other correlates from several laboratories. They have suggested to some that the functions of the hippocampus are more general

than the processing and storage of specifically *spatial* information. We return to this question in Chapter 13 on lesion results, as a successful theory must account for the data from several experimental domains. Suffice it to mention here that nonspatial responses in hippocampal units do not per se argue against a spatial function for the hippocampus. A spatial system would need to incorporate information about the locations of objects, rewards, and dangers as well as using nonspatial information in the construction of place representations.

The data on nonspatial unit responses fall into two primary classes: those suggesting a role in nonspatial sensory processing and those showing a correlation with some aspect of a nonspatial learning process. They are discussed in separate sections.

### 11.11.1 Hippocampal Cells Have Been Implicated in the Processing of Nonspatial Sensory Information

Studies by McLean, Ranck, and O'Keefe during the 1960s and early 1970s looked for, but could not find, selective sensory inputs to the hippocampal complex-spike cells. On the other hand, Vinogradova (1977) and colleagues reported a nonspecific effect of sensory stimulation in the awake rabbit; however, it appears likely from the firing rates of her cells, the absence of complex spikes, and subsequent work on the correlates of theta cells in the rabbit (Sinclair et al., 1982) that many of her cells were theta cells. As pointed out above, theta cells in the rabbit increase their firing during theta EEG episodes, and in the rabbit these episodes occur during non-movement arousal as well as during movement.

Ranck (1973) and O'Keefe (1976) studied the role of sensory inputs in the freely moving rat and, aside from a few olfactory responses reported by O'Keefe, neither found much evidence for these inputs. However, some of the unit responses to the cues used in more recent learning experiments could be interpreted as unlearned responses to the stimuli themselves. For example, Wood et al. (1999a) reported that 8% of cells in the rat hippocampus responded to the olfactory cues in an olfactory recognition task. Likewise, Tamura et al. (1992) reported that 10% of units in the hippocampus and surrounding regions of the monkey responded to specific objects. Creutzfeldt and colleagues (Vidyasagar et al., 1991; Salzmann et al., 1993) found that as many as 38% of hippocampal and parahippocampal units in the monkey changed activity in response to arousing stimuli such as the presentation of a raisin or the sight of the experimenter. It is not clear whether these are perceptual, learned, or general arousal responses. These studies are examined in more detail in the section on nonspatial learning, below.

Perceptual responses to stimuli have also been reported in studies on the human hippocampal formation. In one experiment (Kreiman et al., 2000b), subjects viewed a series of pictures drawn from nine classes: household objects, unknown faces portraying different emotions, famous faces,

spatial layouts including the facades of houses and natural scenes, animals, drawings of famous people or cartoon characters, cars, food items, and abstract drawings. Overall, 14% of units from medial temporal lobe sites showed a visual response to one or more stimuli. Interestingly, of the 32 hippocampal units responsive to visual stimuli, 29% responded selectively to spatial layouts, 12% to famous faces, and less than 10% to stimuli drawn from the other categories. Therefore, although hippocampal cells responded to famous faces and other stimuli, pictures portraying the layout of environments or buildings were by far the most effective of these visual stimuli. The human hippocampus, like that of the rodent and nonhuman primate, appears to prefer information about spaces over faces and objects.

### **11.11.2 Hippocampal Unit Activity May Show Correlations with Different Aspects of Nonspatial Learning Tasks**

In pioneering studies conducted during the 1960s, Jim Olds and Menahem Segal recorded unit activity in the hippocampus during classical conditioning to a tone. They saw an increase in firing to the tone following conditioning. These studies were the first of a number that have looked at the responses of hippocampal neurons during or after nonspatial learning, primarily using conditioning paradigms or discrimination learning. Some of these studies were carried out using multiunit recording techniques, which, like EEG, register only the collective properties of a group of neurons. As we have seen, the spatial coding of environmental features in complex-spike cells is carried out at the single-cell level, and group recordings would not reveal this spatial code. We therefore concentrate primarily on studies that have recorded single-unit activity and refer to the multiunit studies only when they add something different.

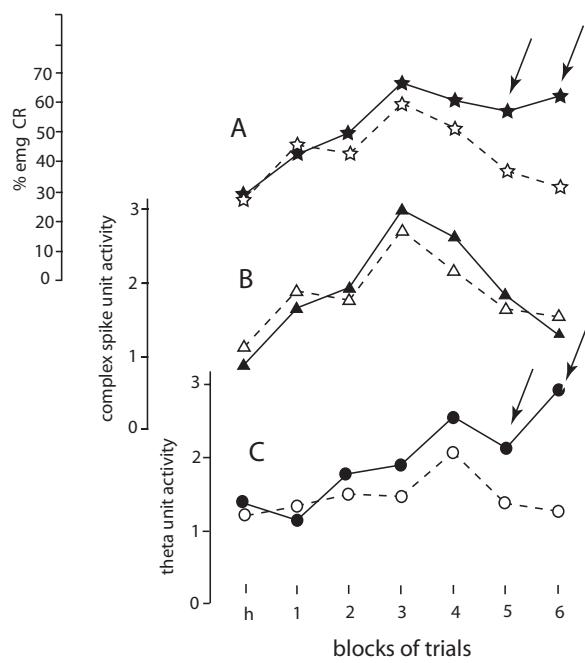

Two types of behavioral paradigm have often been used to look at nonspatial learning: (1) classical conditioning in which the animal's response has no effect on the stimulus-reward contingencies and (2) signaled operant conditioning in which it does. A good example of the former are experiments on classical conditioning of the rabbit nictitating membrane (NM) response; a good example of the latter would be a nose poke, go/no-go instrumental task taught to a rat. In the sections that follow, we turn first to classical conditioning experiments in the rat and rabbit and then examine the somewhat more extensive literature on operant conditioning in rats and monkeys.

### **11.11.3 Hippocampal Unit Activity During Aversive Classical Conditioning**

Hippocampal unit activity has been recorded during aversive classical conditioning: a single conditioned stimulus (CS) followed after a short period by an unconditioned stimulus (US) consisting of a shock or other noxious stimulus. After sufficient pairings, the CS comes to elicit a conditioned response

(CR) such as an eyeblink or suppressed heart rate. In a more complicated differential conditioning paradigm, two stimuli ( $CS^+$  and  $CS^-$ ) are interspersed randomly, one followed by the US and the other not. In this latter paradigm, the animal learns to discriminate between the stimuli, coming eventually to respond to the first but not the second. Typically, during the early stages of learning, both stimuli elicit responses and only subsequently does the animal learn to inhibit its response to the  $CS^-$ . In addition, there is a learned arousal response that is not specific to the hippocampus but can be reflected in the activity of hippocampal cells.

Delacour (1984) trained rats on an aversive differential conditioning paradigm. During slow-wave sleep two different tones served as the conditioning stimuli and mild electric shock to the neck as the unconditioned stimulus. He recorded increased neck muscle tone as the conditioned response (CR) and the cortical EEG as an independent measure of arousal. During the early stages of training, both the  $CS^+$  and  $CS^-$  elicited a muscle activation CR that was associated with cortical arousal; during the later stages, there was a decrease in the cortical arousal to both stimuli as well as the development of a differential neck muscle response, with the response to the  $CS^+$  remaining high and that to the  $CS^-$  steadily declined to baseline (Fig. 11–16A). The initial increase in the EMG activation to both stimuli was thought to reflect general arousal, whereas the later differentiation between them reflected movement to the  $CS^+$ . Unit responses to the CSs of single hippocampal complex-spike cells, hippocampal theta cells, and dentate granule cells were monitored. During the early phase of training, all cell types increased activity to both stimuli in parallel with EMG activation, the complex-spike cells somewhat faster than the theta cells. During the latter phases, however, they acted differently: The hippocampal complex-spike cells ceased firing to both positive and negative conditioning stimuli, paralleling the decrease in cortical arousal. Like the cortical arousal, at no time during training did they differentiate between the two CSs (Fig. 11–16B). In contrast, the responses of the hippocampal theta and dentate granule cells followed the pattern of the EMG response and began to differentiate between the stimuli as the behavioral differentiation developed (Fig. 11–16C). As a control for the specificity of these responses, Delacour recorded from thalamic cells as well and found that they also divided into two classes: Those in the centre median acted similar to the complex spike cells, whereas those recorded in the dorsomedial nucleus resembled the theta cells. On the basis of these results, Delacour argued rather convincingly that the response of the complex-spike cells was a reflection of general arousal, whereas the pattern of activity of the theta/granule cells was a reflection of the learned differential increase in neck muscle activation to the two conditioned stimuli. The latter response may reflect the movement correlates of the hippocampal theta cells. He further argued that these were not specific responses but were representative of more general responses in arousal and movement systems that could be recorded elsewhere in the brain as well. Laroche and Bloch (Bloch and Laroche, 1981; Laroche et

**Figure 11-16.** Two types of response in hippocampal unit activity during classic conditioning of the arousal response to positive and negative tones. *A*, Neck electromyography (EMG) increases during the early trials and then begins to differentiate between the CS<sup>+</sup> (black stars) and CS<sup>-</sup> (open stars) by the last two blocks of trials (arrows). *B*, Principal hippocampal neurons increase their firing rate during the early part of the trial in parallel with the EMG response but then fall off to both stimuli. *C*, Hippocampal theta cells and dentate granule cells also show an initial increase but then differentiate between the CSs in a manner that parallels the EMG activity. Solid symbols are CS<sup>+</sup> responses, and open symbols are CS<sup>-</sup> responses in all panels. h, habituation trials. (Source: Delacour, 1984.)

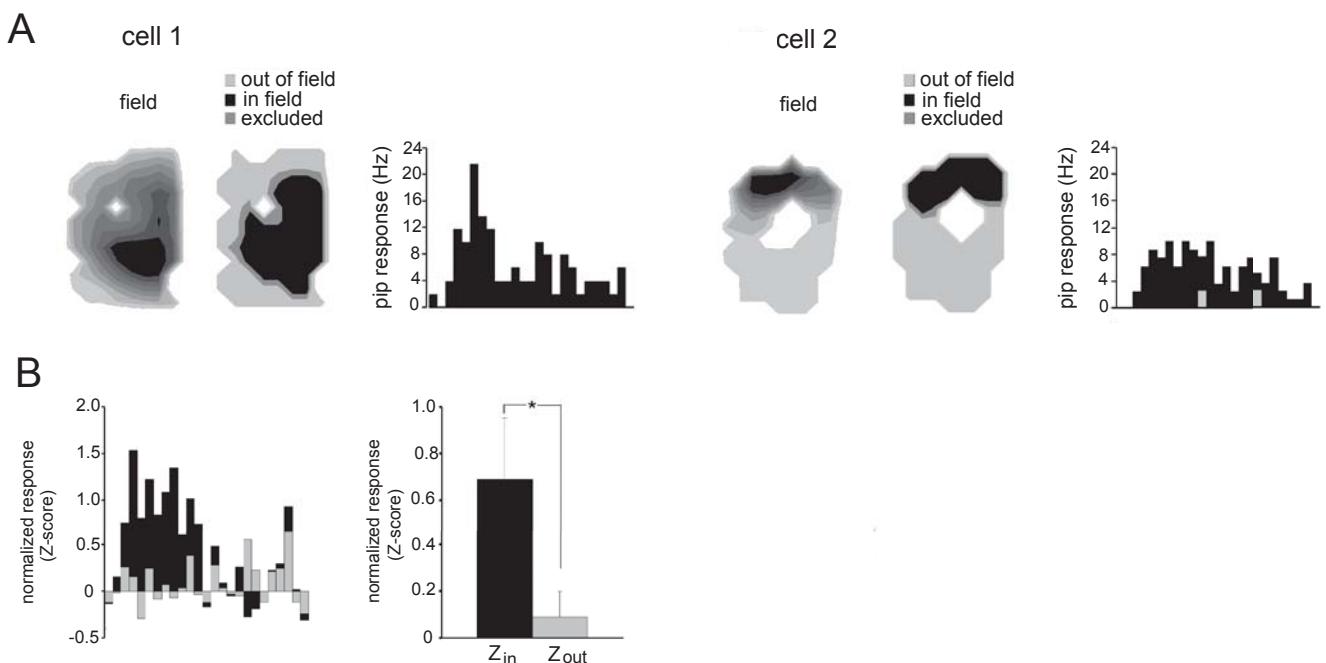

al., 1983) found a similar increase to a CS in the dentate multiple unit response after conditioning.

Moita and colleagues (2003, 2004) have carried out an important classical conditioning experiment in the rat that may throw further light on the role of hippocampal cells in these tasks. They recorded the responsiveness of complex-spike and theta cells to an auditory stimulus before and after delay classical conditioning in which the stimulus was paired with a brief electric shock to the eyelid. No complex-spike cells responded with a short latency to the tone prior to conditioning, but many did so after conditioning. However, they did so only if the animal was located in the place field of the cell during CS presentation (Fig. 11-17). As Figure 11-17 shows, the same cell might give a strong, brisk response to the auditory stimulus when the animal was in the place field but respond little or not at all to the same stimulus when the animal was outside the field. The animal's location in the place field appeared to gate the response to the CS rather than simply summate with it. Moita and colleagues (2004) also found that place cells can develop a place field or can shift field location in the conditioning box following conditioning, and this

effect was greater following conditioning to the context of the box than when there was an explicit auditory stimulus. These results may give some insight into the role of the hippocampus in this behavioral paradigm, at least in the rat. It is possible that, in addition to the conditioning of arousal responses, some conditioned responses in hippocampal units in immobile animals reflect the fact that during conditioning some cells shift their place fields to the animal's location and begin to respond to the CS in that location. Against this interpretation is the fact that restraining the rat abolishes the firing in the place field (Foster et al., 1989). However the possibility remains that restraint may not abolish the gating function on conditioned stimuli. We return to this possibility following a discussion of unit activity during the nictitating conditioning paradigm.

#### 11.11.4 Nictitating Membrane Conditioning in the Rabbit: Role of Theta

Conditioning of the rabbit nictitating membrane (NM) has been used successfully as a model system for studying the neural bases of learning and memory since it was introduced by Richard Thompson in 1976 (Thompson, 1976). In this paradigm, the CS (e.g., a 6 KHz tone) is paired with a US, which can be a puff of air to the eye or a small electric shock to the orbit. By varying the temporal relation between the CS and US, one can investigate various types of classical conditioning. In delay conditioning, the US overlaps the last portion of the CS, so both terminate together. In trace conditioning, the CS ends before the US begins, and there is a temporal gap between the two. As we saw with classical conditioning in the rat (Delacour, 1984), there is an important role for arousal in this form of learning. There is clear evidence that theta activity gets conditioned to various aspects of the task during classical conditioning experiments in the rabbit. Powell and Joseph (1974) conditioned the corneoretinal potential in the rabbit using a mild electric shock to the eye as the US. This was preceded by a CS. A second stimulus was not followed by the US and served as a CS<sup>-</sup>. During the early stages of learning, before differential responses to these two stimuli had been established, there was a high incidence of theta to both CSs; after differential conditioning, when the CS<sup>+</sup> but not the CS<sup>-</sup> consistently elicited the US, a considerably higher amount of theta occurred to the CS<sup>+</sup>. During this second phase of conditioning there was a differential response of the neck EMG to the CS<sup>+</sup>. This pattern of responses is similar to that seen in the rat (see above) and indicates that the early theta activity was related to general arousal, and the later theta activity was related, at least in part, to the motor response. Experiments that manipulate the animal's arousal have shown that it has a strong effect on learning rates and that this effect may be mediated in part via its effect on the baseline rate of theta activity. Berry and colleagues (Berry, 1989) showed that the pretraining background amount of hippocampal theta was a good predictor of NM conditioning rates and that this variable was strongly influenced by the level of arousal. Following

**Figure 11-17.** Response of hippocampal complex spike cells to auditory CS following classic eyeblink conditioning. The cells respond only when the animal is in the place field. *A*. Responses in two individual cells. On the left of each panel, place fields are shown with the higher firing rates in the darker colors; on the right of each panel are histograms of the unit responses while the animal is inside the place field (black color) and outside the field (light color). The middle panels show the portion of the environment included as part of the field, the portion considered to be outside the field, and

an immediate zone not considered as part of either. Both cells showed a strong response to the stimulus inside the field and no (cell 1) or few (cell 2) spikes outside the field. *B*. Population response histograms to stimulus presented inside (dark shading) and outside (light shading) the field of each cell. Across the population there is a significant difference between the in-the-field and out-of-field responses (histogram, right). The x-axes in the unit response histograms are 250 ms in total, which was the period of CS presentation. (Source: Moita et al., 2003.)

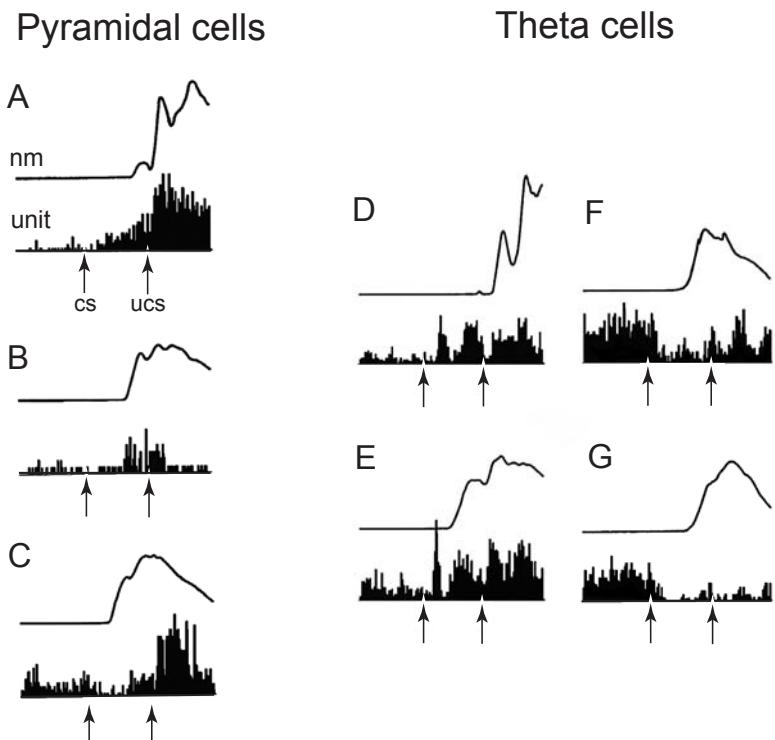

mild water deprivation, there was a faster rate of learning. A similar pattern was found with trace conditioning (Kim et al., 1995).

#### 11.11.5 Single-unit Recording in the Hippocampus During Nictitating Membrane Conditioning of Rabbits

Several laboratories have recorded the activity of single units and multiple units from the hippocampus of rabbits during classical conditioning of the NM response. Berger and colleagues (1983) recorded single units in the rabbit hippocampus during simple delay NM conditioning. Pyramidal cells were identified by their antidromic activation from fornix stimulation. They comprised the largest proportion of cells recorded; and following conditioning, many increased their firing rates during the CS period (Fig. 11-18A–C). They typically emitted one or more bursts of spikes during each trial, some showing a pattern of activity that closely modeled the NM response (Fig. 11-18A) whereas others were more selective, firing during different time epochs of the trial (Fig. 11-18B,C). One type of theta cell increased its overall level of activity during the trial (Fig. 11-18D,E), whereas another type showed an overall decrease in activity (Fig. 11-18F,G). Theta

cells were typically activated by the CS to fire a series of theta-like bursts, which often continued throughout the trial and in some cases continued beyond the termination of the trial. Berger and colleagues also reported a third category of cells, “silent” cells, which constituted 11% of the neurons recorded; they had exceptionally low spontaneous firing rates ( $< 0.2/\text{second}$ ), were not activated by fornix stimulation, and did not participate in the conditioned response. As we shall see below, this estimate of the percentage of cells in this category may be low.

Weiss et al. (1996) recorded single units from rabbit hippocampus during trace conditioning of the NM, a version of the conditioning task that is sensitive to hippocampal lesions: Either the CR is abolished, or its timing is altered (see Chapter 12). They also reported the existence of the same three classes of cells reported by Berger and colleagues in their delay conditioning experiments; but in other respects the results differed markedly. Weiss et al. found a much larger percentage of cells that did not participate in the conditioning (40% in contrast to Berger’s 11%) and relatively few units that were significantly excited (in contrast to inhibited) during the CS or trace period in the conditioned animals in comparison with unpaired controls. Thus, in CA1, 14% of pyramidal cells were excited during the CS period in contrast to 9% of the unpaired

**Figure 11-18.** Firing patterns of hippocampal units following nictitating membrane conditioning in the rabbit. *A–C*, Pyramidal cells. *D, E*, Excited theta cells. *F, G*, Inhibited theta cells. Top trace in each panel is the nictitating membrane record; bottom trace is the histogram of the average unit response. The first arrow indicates CS onset and the second arrow UCS onset, an interval of 250 ms. Note the theta bursting at approximately 8 Hz following the CS onset in the theta cells. (Source: Berger et al., 1983.)

controls; and 11% were excited during the trace period in contrast to 9% of the controls. In contrast to the findings of Berger and colleagues, the increase in inhibitory responses relative to the controls was twice as large as the increase in excitatory responses. McEchron and Disterhoft (1997) obtained similar results in animals conditioned in a trace paradigm when recordings were taken after asymptotic performance had been reached. In addition, they recorded from some animals during the earlier stages of learning. They found that the maximal activation in complex spike units occurred on the trials just *prior* to the onset of learning; as behavioral conditioning proceeded and the conditioned responses appeared more frequently, these unit responses actually diminished. Finally, when looked at on a trial-by-trial basis, there was no correlation between the unit activity and the occurrence of the conditioned response. This pattern suggests that the hippocampus may not be involved directly in the generation or timing of the motor response. Rather, it may be involved only indirectly, perhaps playing a role in the creation of a temporary behavioral state that precedes the motor learning but is a necessary condition for it to occur. Lesions of the hippocampus do not generally affect delay conditioning but do affect trace conditioning, changing the timing of the conditioned response in the trace version of the task (for a review see O'Keefe, 1999). Thus, if we compare the effects of hippocampal lesions on the NM conditioning with the results of single-unit recording experiments, we are left with a paradox. Delay conditioning, in which there are a sizable number of pyramidal cells whose temporal activation profile precedes and models the CR, does not require the hippocampus,

whereas trace conditioning, during which few such unit responses are found, does require an intact hippocampus.

How might the hippocampus be involved in trace but not delay conditioning? There are three distinct but related possibilities. The first suggests that the hippocampus provides the information that the animal is in a frightening place, the second that the animal is in a place where frightening events happen, and the third that it provides information about the timing of the unpleasant event. The first two make clear links to the spatial functions of the hippocampus, whereas the third does not necessarily do so. We deal with these in turn.

Our first two mechanisms relate to ones suggested by Nadel and colleagues (1985). According to them, the spatial functions of the hippocampus might lead to its being involved in conditioning in two ways: as the substrate for a direct association between the background cues and the US or less directly as the basis for an association between the CS-US event and the overall context. Evidence for a hippocampal role in conditioning to the background cues (the fearful context hypothesis) comes from experiments showing that animals with hippocampal lesions do not condition to the context (Phillips and LeDoux, 1994; Kim et al., 1995). This could come about either because there is an association of fear with the entire testing box or with specific locations in it. Recall that the ventral hippocampus contains place cells with large fields that may extend to an entire testing environment, and they could provide the basis for context conditioning. An alternative is that the more localized place fields in the dorsal hippocampus could shift following context conditioning so

the overall pattern of place cell firing was different, perhaps signifying a dangerous environment (Moita et al., 2004).

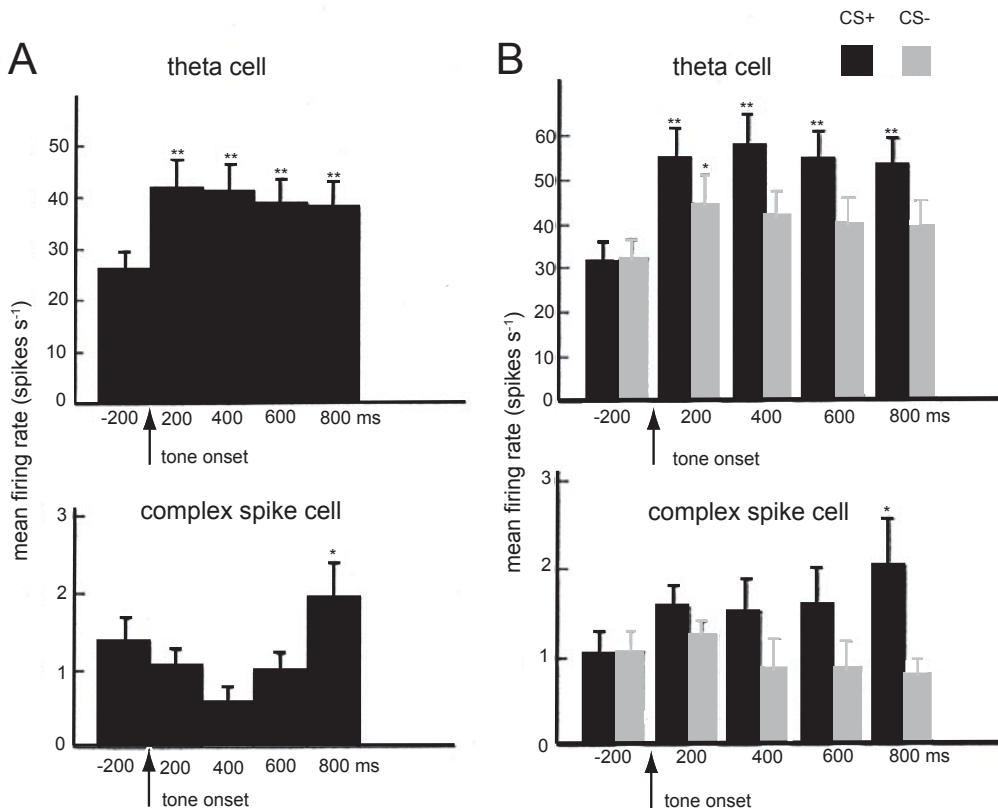

The second possibility is that the cells showing conditioned responses are place cells whose fields coincide with the location of the testing box, and the responses to the CS are signaling the occurrence of an event in that place. As we have seen above in the experiments of Moita and colleagues (2003), complex-spike cells in the rat, which are normally not responsive to auditory stimuli, begin to respond to the CS following delay conditioning but only if the animal occupies the firing field of that cell. If the same changes are occurring in the rabbit, this might explain the increased responsiveness of cells with fields in the conditioning location; moreover, the fields of some cells might shift to that location following conditioning. With this interpretation, the increased responsiveness might reflect the fact that the hippocampus is now signaling that the animal is in a dangerous location and, furthermore, that the auditory cue predicts the onset of danger in that place. More evidence for a role for the hippocampus in contextual gating of CS-US events comes from a context shift experiment. Although lesions of the hippocampus have no obvious effect on simple delay conditioning, they do affect the role the background cues (i.e., the room in which conditioning takes place) play in that conditioning. Penick and Solomon (1991) showed that simple delay conditioning was disrupted in normal rabbits when the animal was moved into a new room after conditioning was completed but hippocampal-lesioned animals were not affected. This result fits nicely with the idea that the hippocampus provides spatial contextual information that gates the conditioning of fear to the CS. This information might not be necessary for simple delay conditioning, but it might be essential for trace conditioning.

The third possibility is that the hippocampus provides information about the timing of the US. The interpretation of the altered timing response in trace conditioning following dorsal hippocampal lesions is unclear. Why, for that matter, does the conditioned unit response occur just prior to the unconditioned stimulus in normals? The original rationale of the NM learning paradigm was to rule out any instrumental contribution to the learning and in particular the possibility that the conditioned response would protect the eye from the US or otherwise attenuate its impact (Thompson, 1976). If, on the other hand, one accepts that the conditioned response in these conditioning paradigms is a reflection of the prediction of the US, the timing of the CS is important; and the lesion results suggest that the hippocampus is involved in setting up the conditions under which the short-term prediction of stimuli can occur. Both Rawlins (1985) and Wallenstein and colleagues (1998) have suggested that the hippocampus is needed to bridge a temporal gap between two stimuli to be associated. This role would be particularly important in paradigms such as trace conditioning, where there is a CS-US interval and normal animals generate a CR just prior to the US. What might the underlying mechanism be? One possibility is that hippocampal a-theta is being used as a timing mechanism to allow a short-term signal to bridge the CS-US

gap. Theta oscillations, with their relatively constant period, could act as a clock over short intervals. During conditioning of the rabbit NM response, this clock signal can be reset by the CS and could therefore be used to predict the occurrence of the US. Even here there might be a secondary role for the spatial functions of the hippocampus. Recall that a-theta in the rabbit can be driven by arousing stimuli (e.g., the CS) much more easily than in the rat (see Section 11.3). That required level of arousal might be based on conditioning to the apparatus and other nonspatial cues, but it might also be driven by hippocampus-mediated fear conditioning to the background context as well. Under circumstances where the arousal level is appropriate, pyramidal cells may be able to count theta cycles and use this clock signal to predict the timing of the US. This timing signal would then be available to brain stem regions to control the occurrence of the CR. In the absence of this signal (e.g., following hippocampal damage), conditioning would still occur but the timing of the CR would be controlled by other factors. Some support for this view comes from an experiment on trace conditioning of the heart rate in rabbits (McEchron et al., 2003). Pairing a CS with an aversive US results in slowing of the heart rate in anticipation of the US; this can be conditioned with trace intervals as long as 20 seconds. McEchron and colleagues used trace intervals of 10 and 20 seconds in two groups of animals and found that one-fourth of complex-spike cells showed a burst of activity timed to coincide with the end of the trace interval. The effect was weak on any given trial; but when summed over trials there was a discernible response. The problem for the theta-counting hypothesis is that 10 seconds is a long time to count theta cycles. For further discussion of the contributions that contexts make to learning, see Chapter 13.

### **11.11.6 Hippocampal Unit Recording During Operant Tasks**

During operant conditioning tasks, the animal must emit a response to gain a reward or avoid punishment. Often the availability of reinforcement is signaled by a sensory stimulus such as a tone. Christian and Deadwyler (1986) recorded from complex-spike and theta cells during an appetitive operant conditioning task. They trained thirsty rats to poke their noses into a small antechamber in the wall of a box to receive a water reward. For some animals, the availability of reward was signaled by a tone, and no sensory discrimination was required; for others, a differential CS<sup>+</sup>/CS<sup>-</sup> procedure was used. Following successful conditioning to the single tone stimulus (Fig. 11–19A), theta cells showed a consistent increase in firing rate during the 200 ms following tone onset (Fig. 11–19A, theta). In contrast, no change from the background rate was seen in the complex spike cells (Fig. 11–19A, complex spike). During two-tone differential conditioning, the theta cells showed an increase to both stimuli with a greater increase to the CS<sup>+</sup> (Fig. 11–19B, theta). In contrast, the pyramidal cells registered a marginal but nonsignificant change to the CS<sup>+</sup> (Fig. 11–19B, complex-spike). Recordings

**Figure 11-19.** Theta and complex spike cell responses following nose-poke conditioning to tones. Theta cells (top) show increased firing above the pre-tone background rate in response to the tone in both simple (A) and compound (B) conditioning paradigms. In the latter, the unit response to the CS<sup>+</sup> is more marked than to the CS<sup>-</sup>. Complex spike cells (bottom) do not respond in either the simple conditioning paradigm (A) or the complex compound conditioning

paradigm (B). Single asterisks indicate a significant difference from pre-tone firing rates at the 0.05 level of significance and double asterisks at the 0.01 level of significance. The apparent increase in firing rate in the complex spike cells 800 ms following the tone in both A and B is an artifact from the reward dispenser. (Source: Christian and Deadwyler, 1986.)

taken from animals while they acquired the task showed that the changes in theta cell firing occurred in parallel to acquisition of the conditioned EMG response and disappeared with subsequent extinction. Again no changes were seen in complex-spike cells during the course of acquisition.

In a subsequent experiment from the same laboratory, Foster and colleagues (1987) did find a small but significant increase in firing in their population of complex-spike cells to both conditioned stimuli but still no differential activity to the CS<sup>+</sup>. A more detailed look at the differential response that did occur in the theta cell group revealed that the difference in response to the two stimuli was due to an initial increase in firing to both stimuli, which peaked at about 80 to 100 ms after tone onset and was then maintained throughout the 1-second tone period to the CS<sup>+</sup> but fell back to baseline in response to the CS<sup>-</sup>.

The simplest explanation for the pattern of results observed in these studies is that there are two independent factors operating during conditioning: arousal and preparation for the motor response. Both contribute to the firing of theta cells, but only one of them, arousal, influences the

pyramidal cells. The initial short-latency response of hippocampal interneurons and granule cells to either a CS<sup>+</sup> or a CS<sup>-</sup> is presumably activation reflecting an arousal input from the brain stem; at about the same time, a small percentage of pyramidal cells, in some studies, also show an arousal response. Depending on the stage and type of training, this can either be an inhibitory or a weak excitatory response. The later phase (> 200 ms after CS onset) of the unit activity is related to the behavioral response. For the theta and granule cells there is prolonged activation continuing throughout the CS<sup>+</sup> period but no such response to the CS<sup>-</sup>. The pyramidal cells do not participate in this second longer-latency phase.

Eichenbaum and his colleagues have studied the behavioral correlates of hippocampal cells in various olfactory recognition and discrimination tasks. They recorded two major behavioral correlates: Some cells fired when the animal sniffed at the odor cues, whereas others changed their firing rates during various stages of the approach to the cues or to the goal. In a successive go/no-go discrimination task (Eichenbaum et al., 1987), the rat was presented with one odor of a pair and had to poke its nose into the single-odor

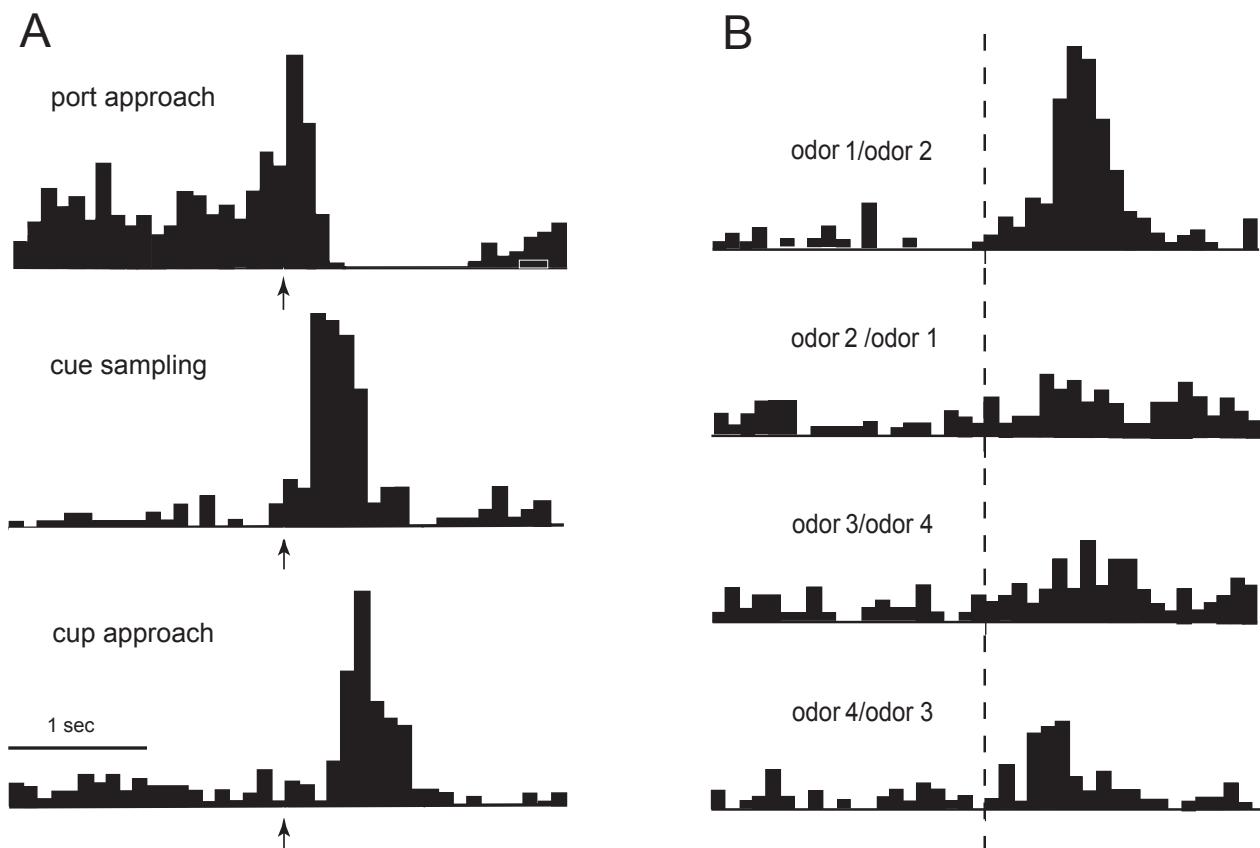

port in response to the CS<sup>+</sup> but not to the CS<sup>-</sup>. Water reward was available on the other side of the testing box, requiring the animal to shuttle continuously between opposite sides of the box. Three behavioral correlates of unit response were identified: cells that fired when the animal was sniffing at the odor ("cue sampling" 15%); cells that fired when the animal approached the sniff port or ran from the sniff port to the water cup at the other end of the box ("reward/port approach" 60%) (Fig. 11–20A); and theta cells (10%). Many of the cue sampling units had firing patterns that were maximally synchronized to the onset of cue sniffing. No evidence was found for cells that preferred one odor over others. Almost all cue sampling cells fired more to the positive stimulus that signaled the availability of water reward in another part of the environment. In addition, there was evidence that in the trials that followed a CS<sup>-</sup> trial the cells gave a larger response than in those that followed a CS<sup>+</sup>. A follow-up study (Otto and Eichenbaum, 1992) looked at complex-spike cell firing during a continuous recognition olfactory memory task in which any one of 32 odors could be presented, and the availability of

water nearby was signaled by a mismatch between the current and previous stimulus. Again, cells that had peak firing rates at different points in the task were found, including 12% that peaked during the cue sampling period. Somewhat disappointingly however, only eight cells (3%) had firing patterns that could be unambiguously classified as signaling a mismatch between successive stimuli. As we shall see below in the section on primate studies of delayed nonmatch to sample, there are also very few cells in these studies that responded selectively to the familiarity or unfamiliarity of a stimulus.

In a forced-choice discrimination trial, Wiener and colleagues (1989) used simultaneous rather than successive odor discrimination. Both the CS<sup>+</sup> and CS<sup>-</sup> were presented at the same time from two adjacent odor ports. In total, 22% of complex-spike cells had increased activity during cue sampling (Fig. 11–20A, center panel). However, closer examination of these data showed that only 13% of cue-sampling cells discriminated between odors irrespective of location, and 44% took the stimulus location into account. Figure 11–20B

**Figure 11–20.** Hippocampal cell firing correlates with various aspects of an odor discrimination task. *A*. Firing rate histograms of cells that fired best when the animal approached the odor sampling port (top trace), sniffed at the odors (middle trace), and approached the reward cup (bottom trace). Arrows in the top two traces indicate initiation of the behavior; arrow in the bottom trace indicates a nose-poke into the reward cup. *B*. Firing pattern of an odor/spatial

cell that responded maximally when the animal sniffed at a particular odor (odor 1) on the left side of the odor sampling port and a second (different) odor (odor 2) on the right side. Top trace: best response to odor 1 on the left and odor 2 on the right; second trace: same odors from the opposite ports gives a lower response; third and fourth traces: different odors are also less effective. Dotted line marks initiation of the trials. (Source: Wiener et al., 1989.)

shows an example of a cell that had a strong spatial component. It fired best to a particular odor pair when one was presented on the left and the other on the right. Somewhat more surprising, 44% of cup-approach cells signaling approach to the reward cup on the opposite side of the box also had responses that depended on the position of the prior nose poke or the odor/position interaction. It is difficult to interpret these data, but one possibility is that the rats may have been turning in different directions away from the odor port as they headed toward the reward. If this is true, the cup approach response in this ostensibly nonspatial task may depend on whether the animal turns toward the left or right on its exit from the sniff port and thus passes through a place field on one side of the sniff port as it turns in one direction but not in the other. Alternatively, this may be an example of the dependence of some place cells firing on the prior turn taken by the animal before entry to the place field (see Section 11.7.3). One can conclude that a small number of complex-spike cells respond to the CS<sup>+</sup> in a differential go/no-go discrimination but that, in general, few hippocampal cells code for the specific odor quality, and that many cells take the location of the odor into account.

On the basis of these and other results (see Chapter 13), Eichenbaum and his colleagues proposed that the hippocampus stores information about a wide range of relations, both nonspatial and spatial. Unit responses to odors and approaches to the odor port or reward dispenser might be taken as evidence of nonspatial representations and unit responses signaling the identity between two successive stimuli as evidence of one type of nonspatial relationship: the identity relation between two stimuli experienced at different times.

As described earlier in the chapter (see Section 11.7.1), many place cells fire more when the animal sniffs at a location when the stimulus in that location has been altered in some way, and these results from odor discrimination paradigms may provide additional information about the conditions under which this mismatch response occurs. To identify cell responses as being due to the odor cue independently of its location, it is necessary to present the same odor in two or more locations. The demonstration that place fields can be rather large, encompassing a large part of the testing box (see Section 11.7.2), means that it may be necessary to test the same odors in two different laboratories as well as in two testing boxes in the same laboratory before concluding that hippocampal cells do not have a spatial correlate. Similarly, the cells that fire selectively during port approach and cup approach have much in common with place cells recorded on linear tracks. Recall that under conditions that constrain the animal to move along narrow pathways, the place cells are unidirectional. To distinguish a goal-oriented response from a motivationally neutral place response, it is necessary to have two identical goals in the environment or two different goals that can be interchanged. O'Keefe (1976) reported that interchanging the water and food at the end of a three-arm maze did not change the location of complex-spike firing fields on

the maze. O'Keefe and Recce (1993) used a linear track with identical food reward at both ends and found that some cells fire in one direction and other cells fired in the opposite direction. Even if one were tempted to describe these cells as goal approach cells, it is not the approach to the food or the food container per se that is being signaled but their locations at different ends of the track. It does not seem warranted to describe the cells reported in the experiments of Eichenbaum and colleagues as cue-sampling or goal-approach cells in the absence of similar manipulations.

Two experiments have provided evidence about the efficacy of cues and goals in isolation from their location (Wiebe and Straubli, 1999; Wood et al., 1999). Wood et al. recorded from hippocampal cells during a variant of a continuous olfactory recognition task in which they tried to dissociate location, odor, and the match/mismatch aspects of the task. Rats were trained on an open platform to approach a small cup containing sand scented with one of nine odors. In each trial the cup was placed in one of nine locations. If a cup had an odor different from that of the previous one, it contained food for which the animal could dig (nonmatch); if the odor was the same, there was no food (match), and digging went unrewarded. Cells were recorded during the 1 second prior to arrival at each cup. An analysis of variance showed that of the total 127 cells, 8% responded to odor in the absence of any other correlate, 11% solely to location, and 10% solely to the match/mismatch aspect of the task. The remainder of the responsive cells took interactions between these variables into account. In all, 20% of cells had nonspatial correlates, and 32% took location into account. (Another 20% changed their firing rate as the animal approached any of the cups. The latter may simply be movement- or speed-related—because this was not measured, it is not discussed further.) These results are notable as a higher percentage of cells with a match/mismatch correlate irrespective of location was found than in the previous reports from the same laboratory (see above). Furthermore, there are fewer purely spatially coded cells than are usually found. This may be because the experimental design required the animal to approach each cup from a different angle during different trials and therefore via different locations; this might lead to a significant underestimation of the number of place cells. Approaching a cup from the north would not force the animal to cross the same region of space as approaching the same cups from the south. It is also not clear how much of the difference between cellular match and nonmatch responses can be attributed to the different behaviors of digging and turning away from the cup that were used as the response measures, rather than the relational judgment itself. Nevertheless, taken at face value, these results provide evidence for the more general relational theory. Significantly, this task has been shown by the authors of the Wood et al. study themselves (Dudchenko et al., 2000) not to be disrupted by selective hippocampal damage.

Wiebe and Straubli (1999) used a Y maze task that forced the animal to traverse the same locations on the approaches to the goals and came to a conclusion different from that of

Wood and colleagues. Animals were trained on a delayed nonmatch-to-sample odor task with each trial comprised of three discrete periods: a sampling period during which the animal sniffed one of two odors in the start arm, a delay period during which it was confined to the start arm and had to remember the recently smelled odor, and a test period during which it was required to choose one of the other two arms containing the odor it had not recently experienced. During the first two periods, everything happened within the same arm, and cellular activity could be correlated only with the odor presented on that trial and with subsequent correct or incorrect performance on the choice part of the trial. During the third (test) period the animal could enter one of two goal arms, and therefore a correlation with location as well as odor and performance could be sought. Overall, most of the 1101 cells recorded from the dentate gyrus, CA3, and CA1 had significant correlations with one or more aspects of the task. Some of the results are shown in Table 11–1. Several conclusions can be drawn from these results. First, during the sample phase, which always took place in the same arm and therefore did not allow the contribution of location to be examined, a small percentage of cells had significant changes in firing rate to the specific odor presented (5%), to whether the subsequent choice would be correct or incorrect (2%), or to the interaction between two (4%). None of these firing rate changes, however, carried over into the delay phase of the trial (Table 11–1, delay) suggesting that the hippocampus does not maintain an active trace of the correct odor choice, as it does of location in a comparable spatial memory task (O'Keefe and Speakman, 1987). Second, in marked contrast to what was seen in the sample phase, during the test phase only a tiny percentage of cells fired to the odor, to the correctness of the choice, or to the interaction between them (all < 1%). This represents a large discrepancy with the odor and performance correlates found in the sample arm. Third, in contrast to the

weak representation of odor or performance in the test arms, there was a strong representation of the animal's location. Of the 571 cells with behavioral correlates in the test arms either alone or as an interaction with another correlate, 70% had a spatial correlate, whereas only 27% had an odor correlate and 21% a performance correlate. More significantly, 37% of the cells with spatial correlates were pure place cells with no other correlates, whereas most of the cells with olfactory and performance correlates also had spatial correlates (92% and 93%, respectively). It is difficult to escape the conclusion that when the testing situation allows them to be identified spatial responses predominate either as pure place responses or as place combined with some other aspect of the task, even in tasks where the spatial component is irrelevant to the solution.

A potential criticism of the Wiebe and Straubli experiment is that they only used two odors, but there might be more than one location in each of the test arms. This points up an important methodological problem in these studies. To equate two tasks on the number of odors and locations, it is important to have an accurate measure of these items. It might be thought, for example, that the number of place fields in each arm of the maze is greater than the number of odors, but the odors used in the tasks are typically compounds and may be distinguished on the basis of many different elemental aspects of the compound. In the absence of more information about the elemental components of locations and smells in any given task, the best one can do is try to vary each variable systematically to see what effect it has on the results.

### 11.11.7 Comparison of Hippocampal Cells During Operant Conditioning and Place Tasks in Rats

Are the neurons that show place responses the same as those that take part in nonspatial learning tasks conditioning, or are there two separate populations of cells? Several studies have compared the response of the same hippocampal neurons during place tasks and conditioning tasks. Three studies have asked whether complex-spike cells might be specifically involved in the place task and the theta cells might be specifically involved in the conditioning tasks. Christian and Deadwyler (1986) used antidromical stimulation of projection pathways to identify complex-spike cells as pyramidal cells. They found a clear double dissociation of the cells involved in the two tasks. In total, 81% of complex-spike cells had place fields in the place task in comparison with none of the theta cells. Conversely, 81% of the theta cells participated in the conditioning task whereas none of the complex-spike cells did. In two experiments, Eichenbaum and his colleagues (Eichenbaum et al., 1987; Wiener et al., 1989) asked whether cells that were related to events in their olfactory discrimination task also had place fields in the same or different tasks. In the first study, they found that 43% of cells with correlates in the odor discrimination task had place fields in the same

**Table 11-1.**  
**Percentages of Total Number of Recorded Cells with Significant Correlates to Various Aspects of an Olfactory Delayed Nonmatch-to-Sample Task**

Parameter	Sample phase (%)	Delay phase (%)	Test phase (%)
Odor	4.8	0	0.9
Performance	2.1	0	0.6
Odor × performance	4.3	0	0.2
Position	—		26.8
Position × odor	—		8.4

environment; in the second study, they recorded some complex-spike cells in a spatial task, some in the odor discrimination task, and a third group in both tasks. They found 75% of the complex-spike cells had place fields in the spatial task compared to 58% with correlations in the odor discrimination task. Of cells collected in both tasks, 85% had place fields in contrast to 54% that had correlates in the odor task.

We can conclude that in conditioning tasks involving rats that were not required to move around the environment to any great extent, most or all hippocampal cells taking part in the conditioning response were theta cells. Complex-spike cells, by contrast, either did not take part or showed slight inhibition of their resting firing rate. In discrimination conditioning tasks in which the animal is required to move, the complex-spike cells also become engaged. The clearest example of cells that may not have a spatial correlate are the cue-sampling cells reported in the Eichenbaum studies. However, even some of these responses may be covert place responses, as clearly suggested by the Wiebe and Straubli experiments.

#### **11.11.8 Hippocampal Units During Nonspatial Learning in Nonhuman Primates**

Tamura et al. (1991) reported that 10% of cells in the hippocampal formation responded differentially to the presentation of three-dimensional objects, some of which had been conditioned to rewarding (3%) or aversive (2%) stimuli. In a follow-up study (Tamura et al., 1992), they showed that 61% of object-responsive cells tested in the same apparatus varied their response as a function of the location of the stimulus in egocentric or allocentric space. The latter study indicates that apparently perceptual responses in the hippocampus may be spatially modulated. Such responses may underlie object-in-place associativity, which like odor-place associativity, is often shown to be hippocampus-dependent, unlike odor-object associativity, which is hippocampus-independent (Gilbert and Kesner, 2002).

Hippocampal units have been recorded from primates while they performed in one of the paradigmatic relational tasks: delayed match or non-match-to-sample. On these tasks, the animal must signal whether two successive stimuli separated by an interval are the same or different. It is now widely accepted that these tasks can be solved in two ways. The animal can either assess the strength of the familiarity of the two stimuli presented during the test phase and choose the least familiar, or it can remember which stimulus was previously presented in the present situation or context and choose the one it has not experienced there before. The second strategy is clearly both spatial and relational, but it could be argued that the first strategy is also relational although clearly nonspatial. To judge a stimulus as familiar or novel, it is necessary to compare it to the representation of a previous stimulus and to decide whether the relation between the two is one of equality. Recognition tasks of this sort were originally thought to depend on the integrity of the hippocampus but are now

known to depend on the perirhinal/parahippocampal cortices and only minimally (Alvarez et al., 1995) or not at all (Murray and Mishkin, 1998) on the hippocampus itself (see Chapter 13) (Aggleton and Brown, 1999). In keeping with the lesion results, it has been found that only a small number of cells show a differential response to the familiarity of the stimuli (0%–2.3% in various studies (Riches et al., 1991; Tamura et al., 1992; Rolls et al., 1993; Salzmann et al., 1993; Brown and Xiang, 1998). In contrast, Wilson et al. (1990) found that 40% of their hippocampal cells in this task correlated with the response, signaling whether the animal was reaching to the left or right position during their task. Salzmann and Creutzfeldt (Salzmann et al., 1993) reported that 28% of hippocampal and 33% of parahippocampal neurons responded to both presentations of the visual stimuli in a delayed match-to-sample task but that even more cells (38% in each area) fired when the animal was presented with a raisin. Vidyasagar and Creutzfeldt (Vidyasagar et al., 1991) reported similar results but that arousing events such as the cage door being opened or closed or the experimenter entering or leaving the room also produced a response in these cells. On the basis of these findings, they attributed hippocampal single-unit activity to the animal's behavioral state rather than to any specific memory. These studies provide no evidence for the representation of stimulus familiarity in the hippocampus.

In contrast and in keeping with the lesion results, there is evidence that cells in the rhinal cortex are involved in familiarity judgments. Brown and colleagues (Brown and Xiang, 1998) reported that about one-fourth of cells in the rhinal cortex and area TE showed a decreased response to the second presentation of the stimulus in a delayed match-to-sample task.

Rolls and his colleagues (Rolls et al., 1993) have tested monkeys on object recognition tasks and compared unit responses to object familiarity with those to object location. Only a small percentage (2%) of cells responded to familiar objects (see above). In contrast, they reported that about 9% of cells in the hippocampal region responded differentially to the location of the stimulus on a display screen. As part of a study of the place properties of primate hippocampal neurons, Ono and his colleagues (1993) found that 17% of cells responded to objects such as a moving experimenter or apple when presented in a particular part of the visual field. Just over half of these were object-in-place cells, which responded differentially when the animal was shown the object in a particular location and not in other locations. They appear to have properties similar to those of the misplace cells described in the rat (O'Keefe, 1976).

#### **11.11.9 Hippocampal Units During Nonspatial Learning in Humans**

Single units have been recorded from medial temporal lobe regions in patients with intractable epilepsy during both recognition and recall memory tasks (Heit et al., 1988; Fried et

al., 1997, 2002; Cameron et al., 2001) as well as during the perceptual categorization tasks described in Section 11.11.1. In general, a sizable percentage of hippocampal units was found to participate in both types of memory task. In a recognition memory task, Fried and colleagues (2002) presented a set of male and female faces portraying various emotions; and after an interval of 1 to 12 hours they showed the same faces again together with an equal number of foils. A significant number of hippocampal neurons responded to faces during encoding (25%) and a somewhat larger percentage during the recognition phase (41%). Perhaps surprisingly, a large proportion of the hippocampal responses (62%) consisted of firing rate decreases. Almost one-half the hippocampal neurons with an excitatory response but only one-sixth of those with an inhibitory response showed some selectivity for gender or emotion. Similar findings were reported by Heit and colleagues (1988), who used lists of words to be remembered and found most hippocampal units selective for one of the words on the list. When tested with a second list of different words, slightly less than half of these cells (13/30) were also selective for a word in that list. As the authors remarked, this suggests that rather than being preordained to respond to specific stimuli the cells were tuning into the current context and selecting one aspect of it (such as position along a list?). The result is reminiscent of the way in which a given pyramidal cell in the rat hippocampus may have unrelated place fields in two or more environments. Hippocampal units have also been recorded during a paired-associate recall task (Cameron et al., 2001). A series of word pairs were presented, and after 1 to 2 minutes the subject had to respond with the second of the pair when prompted with the first: 29% of hippocampal units responded during stimulus encoding and 44% during recall. These percentages are similar to those found in the entorhinal cortex and amygdala in the same study and in the face recognition study of Fried et al. (2002) but significantly higher than the response to faces and other nonspatial visual stimuli in the perceptual classification study of Kreiman et al., 2000a), suggesting a specific role for learning. An interesting aspect of the study was that one-fifth of the hippocampal cells showed a differential firing rate during encoding between word pairs that were subsequently remembered correctly and those that were forgotten. Most intriguingly, most of these cells showed a *smaller* increase in firing rate to the word pairs that were subsequently remembered than to the ones that were forgotten. Whatever the role being played by the hippocampus in these tasks, it cannot simply be that increased firing in hippocampal neurons during encoding leads to a stronger memory trace and therefore to better recall.

Although one must be cautious when comparing across studies, even from the same laboratory, the results can be summarized as follows. (1) The percentage of cells responding to faces and words is higher when they are part of a memory task than when they are simply perceived; (2) these stimuli are equally well represented in both recognition and recall memory tasks; and finally (3) the response of hippocampal units to a stimulus during the encoding phase of a recall test correlates with subsequent recall of that stimulus but in a counterintu-

itive fashion. The cells increase firing to both remembered and forgotten stimuli but the increase is smaller to the subsequently remembered stimuli than to those forgotten.

### 11.11.10 Conclusions

In all species tested, a small percentage of hippocampal cells have been reported to fire to nonspatial stimuli. The data are clearest in humans, where about 12% of cells responded to the sight of famous faces, but this fell well below the proportion (29%) that responded to spatial stimuli such as pictures of houses or interiors. Hippocampal unit responses to stimuli used as discriminanda in learning experiments have been reported in all species tested: rats, rabbits, monkeys, and humans. There is some suggestion that the responses in the rat may be due to a place-gated mechanism because the one study that tested this carefully found that the conditioned stimuli only elicited a pyramidal cell response after conditioning if it was presented while the animal was in the place field of the cell (Moita et al., 2003). Theta cells are much less sensitive to location and may account for a large percentage of the responses reported in the early studies, which did not distinguish between cell types. In general, monkey experiments reported few cells responding to objects per se but more to location or object-in-places. In keeping with the lesion results (see Chapter 13), units responding to objects and their familiarity were more plentiful in the rhinal cortex than in the hippocampus.

There are clearly cells in the human medial temporal lobe that respond to words as well as faces and other stimuli in both recognition and recall paradigms. Furthermore, in one study of verbal paired associate learning, hippocampal unit responses during encoding of a pair predicted the success of subsequent recall (Cameron et al., 2001). Somewhat surprisingly, there was only a hint of lateralization of these responses to the left hemisphere, as might be expected from the lesion data. It is clear that the human hippocampus is involved in the storage of verbal as well as nonverbal material.

In general then, there is evidence that nonspatial information is represented in the hippocampus but that the number of cells involved is considerably smaller than those involved in spatial information and often the nonspatial responses are secondary to a primary spatial correlate. The larger percentage of responses to nonspatial stimuli reported in humans is consonant with the wider function attributed to the human hippocampus in narrative and episodic memory (O'Keefe and Nadel, 1978; O'Keefe, 1996, 2001; Burgess et al., 2002).

### 11.12 Other Distinctive Cells in the Hippocampal Formation and Related Areas

As we have seen, the hippocampal formation is part of a widespread system of anatomically related regions involved in memory and navigation. In addition to the CA fields and the dentate gyrus, the hippocampal formation contains two

anatomically distinct regions: the subiculum complex and the parahippocampal cortex. Response properties of cells in some of these other regions have been touched on at different points in this chapter where appropriate. For example in Sections 11.9 and 11.10, we summarized the properties of head-direction (HD) cells found in the presubiculum and, in addition, regions of the Papez circuit, which forms the inputs to these cells. In this section, we briefly summarize the properties of cells in some of these other related brain regions and touch upon the question of whether these cells are afferent to the hippocampal formation, providing spatial information, or alternately should be thought of as efferent output structures, receiving spatial and memory information from the hippocampal formation.

There are three ways this question might be approached. The first is to look at the effects of lesions elsewhere in the circuit on hippocampal place cell firing (Brun et al., 2002; Calton et al., 2003) and presubiculum HD cell firing (Golob and Taube, 1997) as described in Sections 11.7.4 and 11.9/11.10, respectively. The second examines the relative latency of the neurons in each area to respond to the stimulus or behavior under study. This approach depends on the assumption that neurons in a region that projects to a second region in a serial fashion, on average, fire earlier in response to the appropriate stimulus or during the relevant behavior than the neurons in that second region. On the assumption that many cells in the hippocampal formation and related areas have spatial aspects of behavior as their primary correlate, it is possible to compare the temporal correlation of cells in different hippocampal regions in response to manipulations of these spatial variables to estimate the temporal relation between cells in different regions indirectly. For example, one might study the latency to onset of firing of HD cells with the same preferred orientation in different parts of the Papez circuit. Ideally, this ought to be done with simultaneous recording from the two (or more) regions in question to control for variations between rats in behavior and location of the tracking lights on the head. The third method is based on a comparison of the place correlates of the neurons in the two areas. If one has a serial model of place field construction, it might be possible to attribute some neuronal responses to earlier stages in that process than others. For example, Barnes and colleagues (1990) compared the field sizes of place cells in different regions of the hippocampal formation and subiculum. As we shall see, some generalizations arise from this third type of analysis. The locational code in the CA fields of the hippocampus is more environment-specific than in other regions. Hippocampal place cells often fire in distinct patterns in different environments ("remapping"); indeed, many hippocampal cells are or become silent in a given environment (see Section 11.7.4). By contrast, the locational region(s) signaled by nonhippocampal cells are much more likely to be in similar places across dissimilar environments. Moreover, in other regions, such as the subiculum and superficial entorhinal cortex, principal cells are never silent.

Taking the results of all three methods into account, it is difficult but not impossible to make suggestions about the

functional circuit diagram of the interconnections between these regions of the hippocampal formation that underlies spatial behavior and memory.

### **11.12.1 Subiculum Region Has Fewer Place Cells than the Hippocampus Proper, and Their Properties Differ**

Place cells and theta cells have been recorded from several subdivisions of the subiculum region. We consider the similarities and differences between cells in the next sections. The subiculum contains both place cells and theta cells (Sharp and Green, 1994; Sharp, 1997). The percentage of theta cells is approximately the same as found in the hippocampus proper (10%), and most of the remaining cells have strong spatial signals. There are no complex-spike cells, but one group (29% of total) shows a bursting pattern with a peak interspike interval of 2 to 4 ms. These cells do not seem to differ in any other respect from the nonbursting types except that they have a stronger theta modulation. The field sizes and average firing rates of the subiculum place cells are much larger when compared to those in the hippocampus. A typical subiculum cell fires over the entire environment with an average rate of 5 to 15 Hz (in contrast to 0.5–2.5 Hz in the hippocampus) and has one or more areas of increased firing. Like the place cells of the hippocampus, subiculum place cells recorded in a cylinder are under the influence of a cue card on the wall and rotate in step with it. It has been claimed that the subiculum cells have a stronger directional component than the hippocampal cells, but this claim must be treated with caution. The amount of variance in subiculum firing rate that is explained by direction is actually very small (Sharp and Green, 1994).

One important difference from hippocampal place cells is that subiculum cells are far less likely to remap across environments that differ in shape (Sharp and Green, 1994), shape and visual markings (Sharp, 1997), or size (Sharp, 1999b). For instance, whereas many of the hippocampal cells displayed markedly different fields in a cylinder and a rectangle, the subiculum fields were similar in the two environments. This is reminiscent of what is found in the spatially coded cells in the superficial layers of the entorhinal cortex (see below) and to hippocampal place cells during the animal's initial experiences of the two (see Section 11.8.3). A study of the timing of subiculum cell firing relative to the animal's location suggests that subiculum cells fire slightly earlier on average than CA1 cells (70 vs. 40 ms), perhaps indicating that they come earlier in the computational chain (Sharp, 1999a). This result may seem paradoxical in light of the strong connections from CA1 to the subiculum, but it is consistent with the data showing that subiculum cells do not remap the environments that CA1 cells do.

In conclusion, various approaches to the functional relation between the subiculum and the hippocampus proper suggest that the subiculum place cells cannot receive their spatial properties solely by virtue of their inputs from the hippocampus proper. They may be more dependent on direct

inputs from the entorhinal cortex and/or they themselves may provide a source of spatial inputs to the entorhinal cells.

### 11.12.2 Presubiculum Contains Several Classes of Spatial Cell

The dorsal presubiculum (or postsubiculum in some authors' terminology) contains other types of spatial cell in addition to the HD cells described above (see Section 11.9). A survey study (Sharp, 1996) of presubicular cells in the standard cylinder also reported cells with correlates for angular velocity, running speed (see also Lever et al., 2003), location and direction, and location. The nature of these correlates suggests an important role for the presubiculum in navigation and spatial memory. One class of these cells, called theta-modulated place-by-direction (TPD) cells, has been examined in detail (Cacucci et al., 2004) (Fig. 11–21B, see color insert). TPD cells generally have a strong tendency to fire at or just before the trough of the local theta oscillation. Their depth of theta modulation is high and comparable to that of cells in the medial septum/diagonal band of Broca (King et al., 1998). The quantitative analyses of Cacucci et al. indicate that both loca-

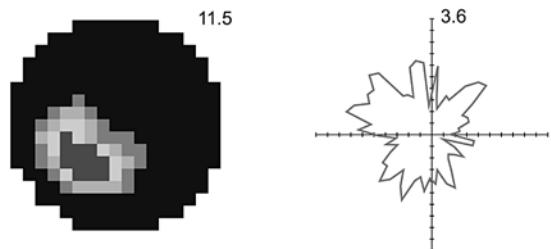

tional and directional signals are stable and robust in TPD cells, with the directional signal carrying more information. The directional and locational signals are dissociable in different environments. The preferred direction of a given TPD cell appears to be environment-invariant, being similar across different locations in the testing room (like the HD cells) and across different enclosures in the same location (cylinder versus an open circular platform). In contrast, the locational fields tend to differ more between environments; notably, TPD cells generally have different locational fields in the cylinder and open circular platform. TPD cell firing represents an integration of location-related and direction-related information. It is possible that directional information may have to be incorporated into and distributed in theta wave packets to be used by the navigation system. Neither anterodorsal thalamic nor presubicular HD cells show theta modulation. Cacucci et al. provided evidence that a robust orientation signal operating in theta mode exists in the hippocampal formation.

There have been no published reports of cells recorded from the ventral portions of either the presubiculum or the parasubiculum. By analogy with the differences between dor-

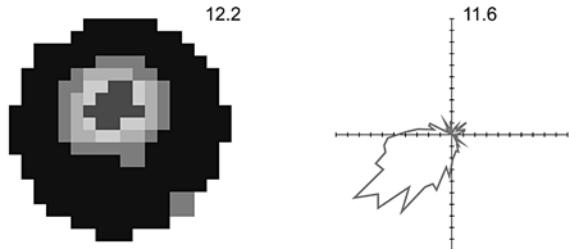

**Figure 11–21.** Four spatial cell types in the hippocampal formation. False color firing field maps (left) show the firing rate as a function of the animal's location in cylindrical environments irrespective of heading direction; directional polar plots (right) show the firing rate for the same cell as a function of the animal's heading direction irrespective of location. A. Place cell has single localized field and no directional selectivity. B. Place by directional cell has single localized field and strong directional selectivity. C. Head

direction cell does not have localized firing but has strong directional selectivity. (Source: A–C. Courtesy of Francesca Cacucci.) D. Grid cell has multiple place fields and no directional selectivity. Directional grid cells also exist. Numbers associated with the firing rate plots represent the maximum firing rate (red regions in firing rate maps and peak x and y values in polar plots). Diameter of cylinders in A–C is 79 cm; diameter in D is 2 m. (Source: Edward and May-Britt Moser.)

sal and ventral hippocampus (Jung et al., 1994), these ventral regions might be expected to contain lower levels of spatial signaling and/or larger spatial fields.

### 11.12.3 Parasubiculum

The parasubiculum contains location-specific neurons, although in much lower percentages (ca. 10%) than are found in the hippocampus proper or the subiculum (Taube, 1995b). In contrast, it contains a much higher percentage of theta cells (41%). No complex-spike cells have been found there. In comparison with the hippocampus, the firing fields of the parasubicular place cells are significantly larger and have less spatial information content. In common with all place and HD cells recorded thus far, their place fields rotate in step with the rotation of the cue card on the wall of the environment. Analysis of the temporal relations of the firing fields of these cells to the animal's location showed a variety of relations, but on average the cell firing preceded the animal's location by about 60 ms. This is less than the average of about 120 ms for hippocampal cells, suggesting that the parasubicular neurons may be later in the circuit than the hippocampal cells.

### 11.12.4 Spatial Cells in the Entorhinal Cortex

Quirk and colleagues (1992) recorded from cells in layers 2 and 3 of the medial entorhinal cortex under conditions similar to those in which hippocampal place cells have been recorded (Muller et al., 1987). They found both place-coded and theta cells. Two properties of the spatial cells were different from those displayed by the hippocampal place cells but similar to those found in the subiculum. The entorhinal cortex (EC) fields were larger and less spatially compact; and unlike the hippocampal cells but like the subicular cells, they showed less sensitivity to the shape of the enclosure. Whereas many of the hippocampal place cells displayed markedly different fields in the cylinder and the square, the EC cell fields were similar in the two environments. Unlike the hippocampus, where this similarity between fields in the two boxes occurs only during the initial experience of the environments, the EC cells appear not to learn to discriminate. As we saw earlier (Mizumori et al., 1992; Jeffery et al., 1995), the theta cells in the EC are dependent on the integrity of the medial septum in the same way as the hippocampal theta cells.

As discussed in Section 11.7, work by Fynn, Hafting, and colleagues (Fyhn et al., 2004; Hafting et al., 2005) suggests that at least one class of cells in the superficial layers of the medial entorhinal cortex lays a grid-like structure on every environment the animal visits. Each grid cell fires in several locations in each environment, with the locations forming a regular pattern as though they were nodes on a triangular grid (see Figs 11–10 and 11–21D, see color insert). Different cells recorded at the same location have the same grid spacing and orientation relative to the environment but differ in the location of the nodes, such that the firing peaks of one cell are slightly shifted from those of its neighbor. The result is that

the overall set of fields of several such cells covers the entire environment. For each cell, the size of the grid appears to be independent of the size or shape of the environment. As one goes more ventral in the medial entorhinal cortex, the size of the grid gets larger. This grid system appears to be based on path integration inputs generated by the animal's own movements and may provide the hippocampal mapping system with distance and directional information on which to construct maps of individual environments.

Frank and colleagues (2000) recorded from neurons in the hippocampus proper and in the superficial and deep layers of the entorhinal cortex while rats ran along single or double U-shaped tracks (the latter termed W-shaped tracks). On the single U-shaped track, the animal shuttled back and forth between the two prongs of the U to receive rewards at each end; on the W track it shuttled first between the left-hand and middle prongs and then between the middle and right-hand ones and vice-versa. Similar to the findings of Quirk et al. (see above), they found that: (1) EC cells fire at rates about five times those of CA1 cells; (2) the locational fields of cells in both the superficial and deep layers of the entorhinal cortex were larger (by about three times) and contained less locational information than those in CA1. Deep EC cells contained more locational information than superficial EC cells. Some cells in all three regions were sensitive to the place from which the animals had recently come (retrospective coding) or to which they were intending to go (prospective coding) (cf. Section 11.7.3 for a discussion of retrospective and prospective coding in hippocampal cells). However, the deep entorhinal cortex contained a significantly higher proportion of prospectively coding cells than the CA1 or the superficial entorhinal cortex. Cells in the deep entorhinal layers were also more likely to reflect environment-invariant aspects of the paths taken along these tracks. For instance, one deep EC cell fired on both the U and W tracks as the animal ran away from a prong and turned left into the adjacent arm. These findings suggest that the deeper layers of the entorhinal cortex, which receive strong inputs from the CA1 field and the subiculum, may be using spatial information provided by these regions to construct routes between known locations. Alternatively, the results may be related to the regular field structure of grid cells reported by Hafting and colleagues (see above).

### 11.12.5 Cells in the Perirhinal Cortex Code for the Familiarity of Stimuli

Cells in the perirhinal cortex of the monkey and rat (Brown et al., 1987) are sensitive to the familiarity of the stimulus. The amplitude of the cell's response to the second and subsequent repetitions of an object is smaller than that to the first presentation, and this decreased response recovers as a function of the time and number of intervening items since the previous exposure to that stimulus. This fits with the suggestion that the deficit in delayed non-match-to-sample in the monkey or human following large lesions in the mesial temporal lobes is due primarily to the involvement of these rhinal structures

(Brown and Aggleton, 2001) (see Section 11.11.8 and Chapter 13 for further discussion).

### 11.12.6 Cells in the Medial Septum Are Theta Cells

Cholinergic and GABAergic cells in the medial septum and diagonal band of Broca (DBB) supply the driving inputs that set the frequency of hippocampal theta. As we saw in Section 11.3.3, lesions of this region abolish hippocampal theta. Ranck (1973) recorded from cells in the medial septum of freely moving rats and confirmed earlier reports by Petsche and Stumpf that cells there had a rhythmical bursting pattern that was phase-locked to hippocampal theta. About 50% of the septal cells showed this pattern. Attempts have been made to classify septal cells into those likely to be cholinergic or GABAergic on the basis of their waveform (Matthews and Lee, 1991; King et al., 1998). Cells have also been classified on the basis of the strength of their correlation to the hippocampus theta. In one study (King et al., 1998), 47% showed a strong phase relation to the hippocampal theta with strong peaks in the auto-correlation at the theta period. Each cell had its own individual preferred phase, which was constant over days. The rest of the septal cells show weaker relations to theta. There is, however, only a slight preference for a particular phase across the whole population with all phases represented. Putative cholinergic cells (on the basis of wave shape) tended to be concentrated in the less rhythmical class than putative GABAergic cells. On the other hand, GABAergic medial septal neurons, which selectively target hippocampal interneurons, appear to form two distinct populations tightly coupled either to the trough ( $178^\circ$ ) or the peak ( $330^\circ$ ) of hippocampal theta waves (Borhegyi et al., 2004).

As we saw in Section 11.3.4 on the theta rhythms and the EEG, there is some evidence that the frequency of theta is correlated with the speed with which an animal moves in an environment. A similar correlation was found in the rhythmical theta cells of the septum (King et al., 1998). Rhythmical cells showed a burst frequency that was correlated with the speed of movement on a linear track. The slope of the regression linear curve was about  $0.9 \text{ Hz/m/s}$  with an intercept at  $8.4 \text{ Hz}$ . A small number of rhythmical septal cells had an interesting directional response. They fired with a strong rhythmicity when the animal ran in one direction but lost their rhythmicity when it ran in other directions.

### 11.12.7 Summary of Extrahippocampal Place Field Properties

The firing of extrahippocampal cells tends to be more environment-invariant than hippocampal place cell firing, generalizing across the various environments explored and routes taken. Thus, cells in the subiculum and entorhinal cortex may signal broadly equivalent locations, or similar points along a route, in different environments. Whereas extrahippocampal cells generalize, hippocampal place cells basically discriminate (especially after experience). This is revealed at the population

level: In any single environment, half or more of the cells in the hippocampus proper are silent. Outside the hippocampus proper, principal cells are generally not silent and indeed tend to fire at higher rates than hippocampal place cells. Further study is required to disentangle the particular role played by each of the regions in the hippocampal formation.

Relative to hippocampal place cells, cells in some neighboring extrahippocampal regions tend to have larger fields, and are less sensitive to environmental changes such as alterations in the shape of the enclosure. It seems reasonable to suggest that the presubiculum HD cells are afferent to the medial EC grid cells, which in turn are afferent to the hippocampal place cells; and the anatomical connections between these regions are consonant with this functional relation. Less clear is the relation between the subiculum and the hippocampus. The greater susceptibility of hippocampal place cells to environmental change and the latency data suggest that the subiculum provides environmental inputs to the hippocampus perhaps in the form of the distance to one or more boundaries; on the other hand, the anatomy suggests a strong projection from the CA1 field to the subiculum that is not reciprocated. The perirhinal and lateral entorhinal cells most likely provide information about environmental landmarks and other objects to the hippocampus where it is integrated with the place information to support behavior based on object-in-place knowledge. The deeper layers and the lateral septum are the major efferent targets of the CA1 and CA3 pyramids, respectively. Little is known about the behavioral correlates of deep layers of the entorhinal cortex and the prefrontal cortex, but they may be the first stages in the transformation of the hippocampal signal into environmentally specific route information or where it is used to program the approach to goal locations. The hippocampal projection to the EC may stabilize the grid cell location relative to a given environment.

### 11.13 Overall Conclusions

This chapter has focused on the neural correlates of hippocampal EEG and single-unit activity. We found that the EEG could be categorized into several frequency bands: theta, beta, gamma, and the high-frequency ripples. Each of these has a different behavioral correlate and is reflected by different firing patterns in hippocampal interneurons. In rodents, the beta and gamma oscillations relate primarily to olfactory stimuli, but theta and the ripples have much broader correlates. There are two types of theta, which are differentially sensitive to cholinergic drugs: a-Theta is activated during periods of arousal or attention, and t-theta is related to movements (e.g., walking, swimming, jumping) that translate the animal's position relative to the environment. Hippocampal interneurons fire in synchrony with the concurrent theta; and various types of interneuron, targeting different parts of the pyramidal cell, preferentially fire on different phases of theta. One function of theta activity is to coordinate and perhaps bind

together neural activity in different parts of the nervous system. Theta-related firing patterns have been found in cells in such disparate regions of the nervous system as the prefrontal cortex, amygdala, and inferior colliculus. Theta also organizes the temporal relation between the firing of cells in the hippocampus such that inputs to a cell at one phase of theta produce larger synaptic modifications (LTP) than at other phases. Finally, each theta cycle acts as a timing cycle against which the phase of hippocampal pyramidal cell firing can be measured. This phase coding complements the locational signal carried in the gross firing rate and allows rate modulations above the baseline to code for variables such as the speed of running in addition to location (see below). Dual phase and firing rate coding may be a general strategy for binding together the representations of different aspects of the world in the train of action potentials of a single cell. The high-frequency ripples occur in conjunction with the large irregular activity (LIA) state of the hippocampal EEG, which occurs during nontranslational activities such as sleeping, quiet resting, grooming, drinking, and eating. Theta and LIA/ripples appear to be mutually exclusive states of the hippocampus, never occurring at the same time. It has been suggested that the synchronized bursts of activity that occur in hippocampal neurons during the ripples may reflect the transfer of information from the hippocampus to the neocortex as part of a memory consolidation process.

Three classes of cells with spatial correlates have been reported in the hippocampal formation: the place cells in the hippocampus itself (Fig. 11–21A, see color insert); the head direction (HD) cells in the dorsal presubiculum (Fig. 11–21C, see color insert); and the grid cells in the medial entorhinal cortex (Fig. 11–21D, see color insert). In addition, there are cells that combine two types of information, such as the “place by direction” cells found in the presubiculum (Fig. 11–21B, see color insert). Place cells signal the animal’s location, HD cells signal the animal’s direction of heading, and grid cells provide information about distances moved in particular directions. It seems reasonable to assume that the place cell firing patterns are constructed from combinations of grid cell inputs, which in turn get their directional orientation from the head direction input. Together these three cell types provide the information required to construct a mapping system that identifies the animal’s location in an environment and relates these locations to each other on the basis of the distance and direction from one to the other. It should also allow the animal to move from one location in that environment to another along any available path, supporting flexible navigation. As we mentioned above, hippocampal pyramidal cells also code for events or stimuli that occur in particular places, laying the basis for the more general episodic memory system seen in the human hippocampus. A true episodic memory system would incorporate the time of occurrence of events as well as their location.

Encoding of events as well as locations in hippocampal pyramidal cells is made possible by a dual coding strategy: Location is conveyed by a combination of increased firing rate above a low-level baseline and the phase of firing relative to

the ongoing hippocampal EEG theta activity; events and stimuli occurring in that location are signaled by variations in the firing rate above the baseline. The existence of temporal coding strategies in the nervous system means that one must be cautious when interpreting the results of recording techniques that reflect only relative rates of neural activity in contrast to the timing of action potentials. This is especially true when the representation is distributed across a population of cells with some cells increasing and others decreasing their firing rates in addition to shifting phases.

Several types of learning have been demonstrated in hippocampal pyramidal cells: short-term changes in the orientation of place fields relative to the environment lasting for the duration of the trial; longer changes in the shape of the place field lasting for the duration of the testing session; and long-term discrimination between similar environments that appears to be permanent. One type of environmental discrimination appears to involve the collective behavior of pyramidal cells, perhaps operating as a discrete attractor in which the behavior of neighboring pyramidal cells, in addition to environmental inputs, is taken into account in the final representation.

The location of place fields depends on factors in addition to the animal’s physical location in an environment. Under certain circumstances, fields may depend on the animal’s previous behavior, such as the turn that it has just made at a choice point or one that it intends to make. Training on aversive tasks such as eyeblink conditioning in the rat has also been shown to shift the location of fields. Whether this means that the animal conceives of these environments as different is not clear at present.

It has also been reported that pyramidal cells respond to nonspatial stimuli such as the odors used in a running recognition task or the auditory cues in a nictitating membrane conditioning task. The existence of such responses together with deficits in some types of conditioning tasks (e.g., trace conditioning following hippocampal lesions) has suggested a broader function for the hippocampus than purely spatial. On the other hand, several studies have suggested that when the locations in which these stimuli occur are varied, these “non-spatial” responses are gated by the animal’s location. In a rat eyeblink conditioning experiment, the auditory conditioned stimulus only elicited short latency response in hippocampal cells when the animal was in the place field of that cell. In an olfactory delayed match-to-sample task, cells appeared to respond to the olfactory cues alone when position was not varied in the start arm of a Y maze; in contrast, only olfactory responses gated by position were seen in the two goal arms where position was available as a factor. To rule out position as a contribution to hippocampal unit responses, it is important to provide the stimulus in more than one location.

Studies of single-unit activity in monkey hippocampus suggest that although place responses also dominate there is evidence of nonspatial inputs as well. As primate research moves in the direction of the use of freely moving monkeys, and especially when the animal can explore the walls as well as

the floor of the environment, we will begin to get a better picture of the relation between these nonspatial and spatial inputs. There are also a small number of studies of hippocampal unit activity in humans. Units responding to pictures of faces and household objects have been reported, but the percentage of cells responding to pictures of houses and locations in the same studies has been higher. Responses to words have been reported frequently, especially when they are presented in a learning paradigm. This may be an indication that the function of the human hippocampus is broader than purely spatial. This is in line with the original suggestion of the cognitive map theory that the incorporation of verbal and temporal inputs into its original spatial functions would result in employment of the hippocampus as an episodic and narrative memory system as well a spatial one.

## ACKNOWLEDGMENTS

I am grateful to my co-editors for extensive and helpful comments on earlier drafts of the chapter. I also thank Dr. Colin Lever (Leeds University) who made extensive comments and suggestions on an earlier version. Support for the research from my own laboratory cited in this chapter came from the Medical Research Council UK, Wellcome Trust, and the BBSRC.

# Functional Role of the Human Hippocampus

## 12.1 Overview

This chapter examines data from human amnesic patients, data from electrophysiological recordings in humans, and data from functional neuroimaging studies that attempt to shed light on the question, *What does the human hippocampus do?* In broad terms, we have learned a great deal about the kinds of memory in which the hippocampus is and is not involved. The hippocampus is part of a system that plays a critical role in the encoding and retrieval of long-term memory for facts and events. As a whole, the system is vital for this “declarative” or “explicit” form of memory but is not involved in other forms of long term memory, in nonmnemonic aspects of cognition, or in immediate (or “working”) memory. Furthermore, its involvement in declarative memory is not permanent but is time-limited in nature (the bases for each of these conclusions are laid out later in the chapter).

We therefore know a great deal about the role of this system in human memory. Our understanding of the roles played by the individual components of the system is much less complete. In the human, the system is often described as consisting of two major sets of structures. One set of structures, often defined as the “hippocampal region,” consists of the CA fields of the hippocampus itself, the dentate gyrus, and the subiculum. For obvious reasons, most of the studies in humans do not contain histological analyses. Unfortunately, without histological analyses, it is quite difficult to isolate these components from each other (see Sections 12.3.3 and 12.3.5), so most studies that report data from the “hippocampus” include data from the more extended hippocampal region. The second set of structures consist of the adjacent cortical structures that lie along the parahippocampal gyrus. This set consists of the entorhinal, perirhinal (occasionally

divided into temporopolar and posterior regions), and parahippocampal cortices.

As is discussed here and in Chapter 13, there have been a number of attempts to arrive at a description of hippocampal function. One class of theories proposes a functional distinction that qualitatively sets the hippocampal region apart from the adjacent structures in the medial temporal lobe, defining what it is that the hippocampal region specifically does that other structures do not and vice versa. Such theories have linked the function of the hippocampal region to conjunctive (e.g., Sutherland and Rudy, 1989; O'Reilly and Rudy, 2000), relational (e.g., Cohen et al., 1997), and/or episodic, recollective, or associative (e.g., Brown and Aggleton, 2001) forms of memory. A second theory (the declarative memory hypothesis—see Chapter 13) is more quantitative in nature in suggesting that the hippocampal region “combines and extends” the processing of the adjacent cortical structures that together form the medial temporal lobe memory system (Squire and Zola-Morgan, 1991).

The conclusion on this question is that the data from human studies do not unambiguously support any of the existing theories. In particular, the data suggest differentiation of function within the medial temporal lobe but not along versions of any of the binary dissociations proposed. The differentiation of function is likely to be a complex and graded one that is most consistent with the second theory—that the hippocampal region combines and extends the processing of the adjacent cortical structures. However, this theory is still underspecified, as we do not have the data at hand to understand the precise nature of the way in which the hippocampus combines and extends adjacent processing or of the dynamic interplay among the structures. Thus, although we have certainly learned a great deal about the human hippocampus and its role in memory, but it would be a mistake to believe that we

have a full and satisfactory answer to the fundamental question: What does the human hippocampus do?

## 12.2 Patient H.M.

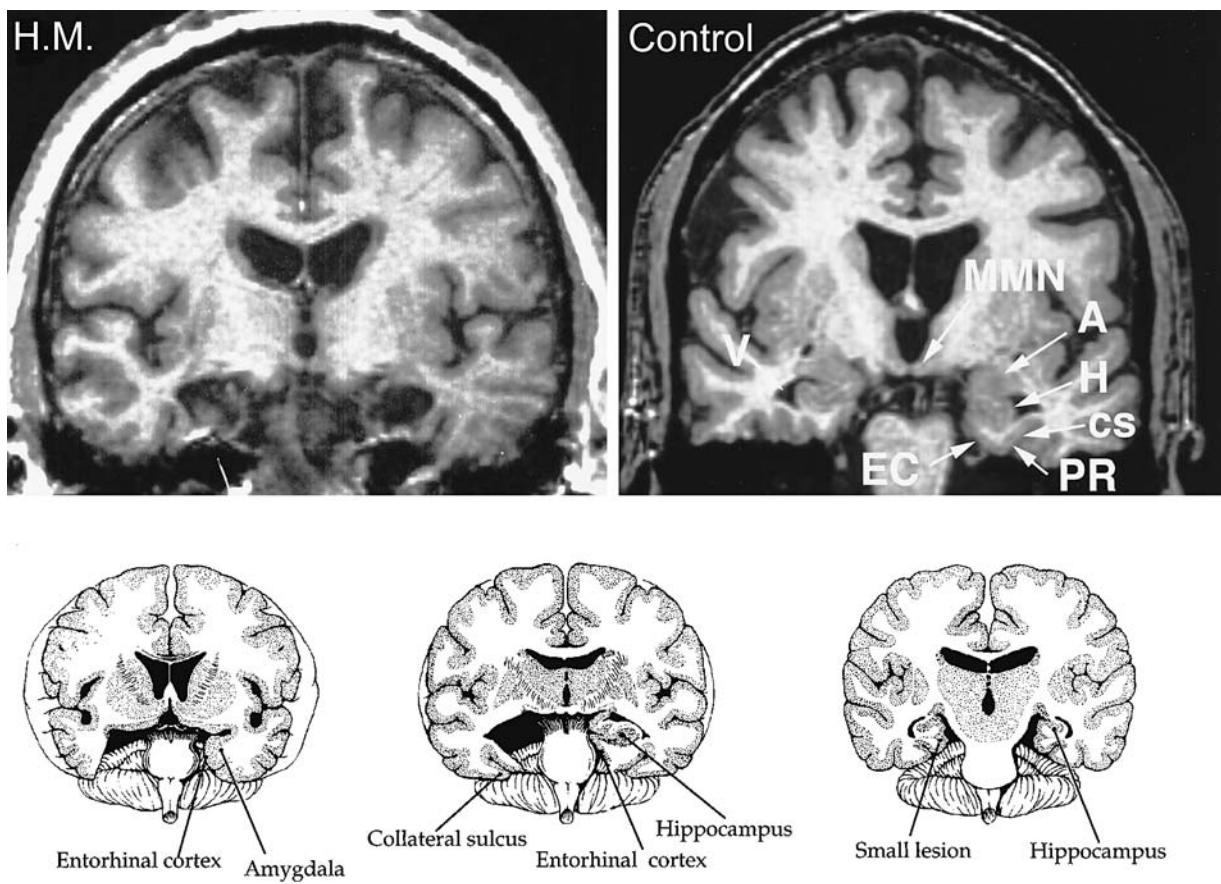

It would be almost impossible to begin a discussion of the role of the hippocampal region in human memory without considering the patient H.M. In a successful attempt to relieve otherwise intractable epilepsy, H.M. underwent bilateral resection of the medial portions of the temporal lobe (Fig. 12-1). Although scattered hints in the literature prior to this suggested that damage to the hippocampal region might affect memory, the detailed study of H.M. had an influence on both the study of memory and on neurosurgical practice that was unprecedented. Following a brief initial report (Scoville, 1954) describing the profound memory loss that resulted from the surgery, Scoville and Milner (1957) presented a detailed neuropsychological assessment of H.M. and nine

other patients with varying degrees and locations of resection. This seminal work concluded with the following text.

Bilateral medial temporal lobe resection in man results in a persistent impairment of recent memory whenever the removal is carried far enough posteriorly to damage portions of the anterior hippocampus and hippocampal gyrus. ... In two cases in which bilateral resection was carried to a distance of 8 cm posterior to the temporal tips the loss was particularly severe. ... The memory loss in these cases of medial temporal lobe excision involved both anterograde and some retrograde amnesia, but left early memories and technical skills intact. There was no deterioration in personality or general intelligence, and no complex perceptual disturbance such as is seen after a more complete bilateral temporal lobectomy. It is concluded that the anterior hippocampus and [para]hippocampal gyrus, either separately or together, are critically concerned in the retention of current experience. It is not known

**Figure 12-1.** Top. Extent of H.M.'s lesion is shown by comparing the coronal magnetic resonance imaging (MRI) scan of H.M. (left) with that of a matched healthy volunteer (right). The hippocampus (H), amygdala (A), collateral sulcus (CS), perirhinal cortex (PR), entorhinal cortex (EC), and medial mammillary nucleus (MMN)

are identified, and all show signs of damage in H.M. Bottom. Summary of the extent of the lesion. Both hemispheres are damaged, with one shown intact for comparison only. (Source: Corkin et al., 1997, with permission. © 1997 Society for Neuroscience.)

whether the amygdala plays any part in this mechanism, since the hippocampal complex has not been removed alone, but always together with uncus and amygdala. (Scoville and Milner, 1957, p. 21)

Subsequent testing of H.M. was able to reveal not only the breadth and severity of H.M.'s memory impairment but, critically, it also showed a vast array of cognitive and mnemonic function that was unaffected by his large bilateral lesion. The pattern of data allowed Milner (Milner et al., 1968; Milner, 1972) to make several conclusions that expanded on those noted above and helped lay the foundation for subsequent investigation into the amnesic syndrome.

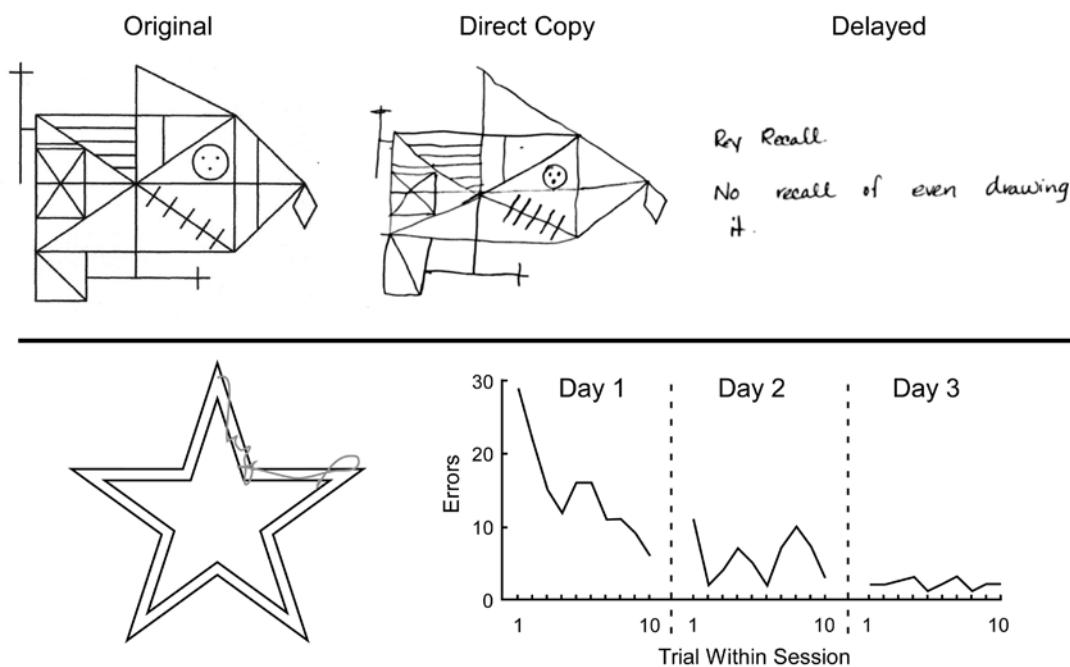

First, Milner noted that damage to the medial portions of the temporal lobe results in profound inability to acquire long-term memory for new facts or events (anterograde amnesia) although memories from early life appear to be intact. Conversely, there was some clear loss of memory of information acquired for some time prior to the operation (retrograde amnesia). Together, these observations indicated that the medial temporal lobe might not be a permanent repository for memory but that it plays a time-limited, albeit critical, role in memory. Second, she noted that there was no loss in general intellect or perceptual ability, indicating clear dissociation between memory and other aspects of cog-

nition. Third, she noted that short-term memory remained intact, indicating clear dissociation between immediate, or "working," memory and permanent, long-term memory. Finally, she noted that damage to the medial portions of the temporal lobe did not abolish all forms of long-term learning and memory, indicating that the medial temporal lobes were not required for at least some forms of long-term memory (Fig. 12–2).

Overall, subsequent data from severely amnesic patients such as H.M. and data from animal models of amnesia (see Chapter 13) have supported Milner's basic conclusions rather well (although there is still no consensus as to whether each claim is entirely or only largely true). In a more recent extension of these conclusions, Squire and Zola-Morgan (1991) identified what they referred to as a medial temporal lobe memory system (MTL), consisting of the hippocampal region (defined as the CA fields of the hippocampus proper, the dentate gyrus, and the subiculum) and the adjacent entorhinal, perirhinal, and parahippocampal cortices (which together form the parahippocampal gyrus—see Chapter 3). Together, this system is posited to be critically involved in the acquisition of new fact ("semantic") and event ("episodic") memory. Notably, this system is not the permanent storage site for this "declarative" or "explicit" memory, nor is it the locus of other cognitive functions or other forms of memory. For example, it

**Figure 12–2.** Patient H.M.'s performance on the Rey-Osterreith figure-drawing task (*top*). With the original drawing in front of him, his direct copy is accurate, demonstrating intact perceptual abilities and a range of intact cognitive abilities. After an hour delay, H.M. was unable to produce any drawing and did not remember having previously seen and copied the figure. (Data provided by Suzanne Corkin, personal communication, March 6, 2005.) In contrast, H.M. showed learning that lasted over multiple days in

the mirror-drawing task (*bottom*). A typical stimulus is shown on the left. Participants view the shape in a mirror and attempt to trace the shape while staying inside the lines (gray line shows the author's first attempt). H.M.'s performance improved steadily both within testing sessions and across 3 days of testing (right), despite having no conscious memory of having performed the task on previous days. (Source: Adapted from Milner et al., 1998, with permission. © 1998 Elsevier.)

is not involved in immediate (or “working”) memory, and it is not involved in a wide range of “nondeclarative” (or “implicit”) long-term memory tasks (e.g., delay conditioning, perceptual repetition priming, habit learning). These ideas amplify and develop Milner’s suppositions in several ways.

As a component of this interconnected system, the hippocampal region participates in declarative memory in some way. However, the exact nature or particular memory functions in which it participates cannot be unambiguously determined from patients such as H.M. or other severely amnesic patients with extensive damage to the medial temporal lobes or from animal models with analogous lesions. Thus, knowing that H.M. is impaired regarding tasks of recognition memory (e.g., Milner et al., 1968) or that a similar patient (E.P.) is entirely at chance during tests of recognition memory (Hamann and Squire, 1997; Stark and Squire, 2000b; Stefanacci et al., 2000) does not definitively implicate the hippocampal region in recognition memory (or any other individual MTL region, as the entire MTL is extensively damaged). Indeed, many researchers have proposed functional dissociations within the MTL such that extrahippocampal structures (e.g., perirhinal cortex) support recognition memory (or at least one form of recognition memory) and that the hippocampal region is not involved in recognition memory tasks (see Section 12.4.5). Of course, the study of what is not impaired in patients with more extensive damage (e.g., H.M. or E.P.) can be informative as well in letting us determine what forms of memory do not require the hippocampal region (see Section 12.4.1).

To move beyond an understanding of what is and what is not impaired overall in the amnesia that follows damage to the medial temporal lobe to an understanding of the specific contributions of the components of the MTL (e.g., the hippocampus), we must shift our focus. We must turn our study to patients (and animals) with lesions to specific structures of the medial temporal lobe and to recording or imaging techniques that allow us to measure signals confidently from these structures. Three sources of such data exist for studying the human hippocampus. First, anoxia or ischemia can lead to fairly selective bilateral damage to the hippocampal region. Although this damage is incomplete and although anoxia is by no means certain to damage only the hippocampus (see Section 12.3.3), when it does the study of the memory impairments in such patients can inform our understanding of the role of the hippocampus itself. Second, advances in diagnostic techniques for localization of epileptic seizure foci have led to several cases in which depth electrodes have been placed into the hippocampal region and recordings made during various memory tasks. The study of such patients provides a clear bridge between electrophysiology in animal models (e.g., rats or nonhuman primates) and studies of the human hippocampus. Finally, recent advances in noninvasive neuroimaging techniques have led to several methods by which correlates of neural activity can be localized with sufficient precision to differentiate signals from the components of the MTL. In particular, positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have become popular

tools for noninvasive monitoring of neural activity (in the form of local blood flow or oxygenation) throughout the brain. When data analysis techniques are applied that respect and account for the morphological variability of MTL structures across individuals, fMRI data in particular can provide highly valuable data for understanding normal human hippocampal function (see Section 12.3.5).

What follows is first an overview of these methods, with particular attention to their strengths and limitations for the study of the human hippocampus. This serves as the background for the rest of the chapter, which focuses on the function of the human hippocampus. Particular attention is paid to the role of the hippocampus in declarative memory and how it might be functionally dissociated from the adjacent cortical structures of the parahippocampal gyrus.

## 12.3 Methods for Studying Human Hippocampal Function

Each of the three sources of data discussed in the following sections (hippocampal lesions, electrophysiology via depth electrodes, functional neuroimaging) has its own particular strengths and limitations in providing data to help us understand the function of the human hippocampus. Moreover, none of them can produce meaningful insight into understanding hippocampal function without an understanding of the behavioral tasks used to assess memory performance. As such, the cognitive and behavioral tasks used to assess memory in humans are discussed first. In addition, none of the three methods alone is sufficiently free of limitations to be able to answer the fundamental questions surrounding the hippocampus. In Chapter 13, general theoretical concerns from these lines of data are discussed (e.g., the interpretation of correlational datasets—see also Henson, 2005), but several specific concerns exist for each. These strengths and weaknesses are discussed below (see Sections 12.3.3–12.3.5).

### 12.3.1 Behavioral Tasks and Terms

Unlike assessing memory in nonverbal animals, assessing memory performance in humans (or at least adult humans) can be exceptionally straightforward. If we want to know whether a participant remembers a previously seen list of items, we can simply ask him or her to recall as many items as possible. The simplicity of this *free recall* task and the fact that it is an obvious test of human memory but not of animal memory should not be overlooked. No training on the task is required, as it is perhaps the archetypal everyday memory task. Despite the prevalence of free recall, or its cousin *cued recall* (in which some portion of the to-be-remembered item is provided) in everyday life, neither task is easily captured in animal studies of memory.

A second style of memory task, called a *recognition memory* task, is more easily captured in animal models. Like tests of recall, recognition memory tasks begin with a study phase that

can either be *intentional* (participants are explicitly instructed to learn the item for a later test) or *incidental* (no instructions are given to learn the items and no mention is made of a later test, often using an entirely unrelated task to serve as a disguise). During the test phase, unlike recall tasks, entire items from the study list (*target* or *old* items) and entire items that were not on the study list (*foil* or *new* items) are presented. In the simplest version of a recognition memory task, *yes/no recognition*, single items (either targets or foils) are presented to the participant with the instructions to indicate whether each item was on the study list. In a second typical version, *two-alternative forced-choice recognition*, a target item and a foil item are presented, and the participant is instructed to indicate which of the two items was on the study list.

In making their responses to recognition memory probes, participants are thought to use two types of memory or sources of information: *recollection* and *familiarity* (for review see Yonelinas, 2002). Recollection provides information about a specific prior event or episode and gives one the sense of being placed back in that moment in time. Certainly, if this is the reaction one has to an item presented during a recognition memory task, the item is endorsed as having been on the study list. In contrast, one can still have a strong sense that the item is familiar without having a recollective experience. Such a feeling that the item is familiar, albeit with no specific information about the study episode, can still lead to endorsing the item in a recognition memory test. Thus, two sources of information can be used when endorsing an item at time of recognition. A variant on the yes/no recognition memory task, known as the *Remember/Know* task (Tulving, 1985), asks participants to split their endorsements into recollective (“Remember”) and familiarity-based (“Know”) responses in an attempt to isolate the two sources of information.

A key question that arises when discussing recollection and familiarity is whether these two types of information represent the operation of two separate neural systems. If they do, a second question that arises is whether this functional dissociation maps onto a division of labor in the medial temporal lobe: for example, that the hippocampus is particularly

involved in recollective-based memory and the structures of the adjacent parahippocampal gyrus are particularly involved in familiarity-based memory. This possibility is discussed in Section 12.4.5.

Many variations on these basic tasks exist, each designed to assess different kinds of memory. For example, for a *paired-associates* task two stimuli are presented and the participant is instructed to learn the association between the two items. For the test, a single item can be presented and the participant asked to recall the target member of the pair (cued recall) or to pick out the target item from a list of choices that include one or more foil items (forced-choice recognition). Furthermore, pairs of items can be presented at the test that are either intact or recombined versions of the studied pairs. As such, each trial presents only familiar components, and performance must be governed by memory for the associations between the individual items. Finally, just as the study phase can be conducted in an incidental way, the test phase can be an incidental test of memory. For example, participants may be asked to complete the word-beginning *win*\_\_\_\_\_ with the first word that comes to mind (*stem-completion task*), making no reference to the prior study episode. Such *implicit*, or *non-declarative*, tests of memory are forms of long-term memory that do not appear to rely upon the MTL (see Section 12.4.1).

### 12.3.2 Behavioral Measures

In any of these tasks, performance can be quantified in several ways. The most straightforward is to calculate an overall percent correct—simply the percentage of correct trials out of the total number of trials. In a yes/no recognition task with 20 target items and 20 foil items, 16 correct “yes” responses to the targets and 16 correct “no” responses to foil items would result in 80% correct (Table 12–1). Although quite straightforward and intuitive, percent correct has significant difficulty in accurately capturing the underlying strength of the memory when participants exhibit a strong bias toward one response. An uneven distribution of “yes” and “no” responses can arise quite easily from either natural individual participant biases or task instruction and result in an underestimation of the true

**Table 12–1.**  
**Comparison of Various Measures of Recognition Memory Performance**

Memory capability	Hits (rate)	False alarms (rate)	% Correct	Pr	Br	d'
Normal	16 (0.8)	4 (0.2)	80	0.6	0.5	1.7
Normal, “no” bias	10 (0.5)	1 (0.05)	72	0.45	0.1	1.6
Normal, “yes” bias	19 (0.95)	10 (0.5)	72	0.45	0.9	1.6
Moderate	14 (0.7)	6 (0.3)	70	0.4	0.5	1.0
Chance	10 (0.5)	10 (0.5)	50	0	0.5	0
Chance, “yes” bias	16 (0.8)	16 (0.8)	50	0	0.5	0

Typical behavioral measures—hit rate, false alarm rate, percent correct, “corrected rejection” (Pr), “bias” (Br), and “discriminability” (d')—are shown for three levels of underlying memory capability (Normal, unimpaired memory; Moderate, mildly impaired memory; Chance, no actual memory); and under conditions of response biases.

strength of the memory. For example, if one were to reward participants with a small sum of money for each correct “yes” response but administer a strong shock for each incorrect “yes” response, participants would be generally less likely to respond “yes” and do so only when they are quite confident they are accurate. In our above example, this might reduce the correct “yes” responses to 10 and increase the correct “no” responses to 19, with a resulting percent correct of 72%. There is good reason to believe, however, that the actual memory is the same in these two cases, and this change in response rates is the result of a shift in the participant’s response bias.

Several measures are commonly used to measure or remove the detrimental effect of response biases. Response biases can be easily seen by dividing the recognition responses into four categories: (1) *hits*, defined as correct “yes” responses to studied target items; (2) *misses*, defined as incorrect “no” responses to studied target items; (3) *correct rejections*, defined as correct “no” responses to unstudied foil items; and (4) *false alarms*, defined as incorrect “yes” responses to unstudied foil items. Comparing the hit rate and correct rejection rate is one method for determining whether a bias is present. A second method uses the “corrected recognition” score, often denoted  $Pr$ .  $Pr$  is simply the probability of a correct “yes” response (a “hit”) minus the probability of an incorrect “yes” response (a “false alarm”).  $Pr$  scores are in a range between 0 and 1, with 0 indicating chance performance. By themselves,  $Pr$  scores do not fully remove the effects of response biases; however, a complementary measure of bias,  $Br$ , accurately estimates any response bias that exists.

$$Br = \text{false alarm rate} \div (1 - Pr)$$

The most common method to correct for any bias that exists is to calculate  $d'$ , the discriminability measure from the signal detection theory (Green and Swets, 1966). Here, it is assumed that there are two normal distributions of stimuli (a distribution of targets and a distribution of foils) that differ along a single parameter (e.g., some representation of perceived memory strength or familiarity at time of retrieval). It is further assumed that participants set a threshold or criterion value for this single parameter and respond “yes” if the stimulus presented for recognition exceeds this threshold and “no” if the stimulus does not exceed this threshold. Thus, there are four categories of responses corresponding to the hits, misses, correct rejections, and false alarms defined above.

With respect to memory tasks, the amount of memory present is viewed as the distance between the target and the foil distributions along this axis of familiarity (e.g., Morrell et al., 2002). That is, the effect of studying the target stimuli is to shift the distribution away from the unstudied distribution. The amount it has been shifted corresponds to the amount of memory the participant has for the studied items. If the distribution has been shifted a lot, it is easy to discriminate the target from the foil distributions, whereas if the distribution has been shifted very little, it is more difficult to discriminate whether a given item presented at test was drawn from the target or foil distribution. The measure  $d'$  is the distance between

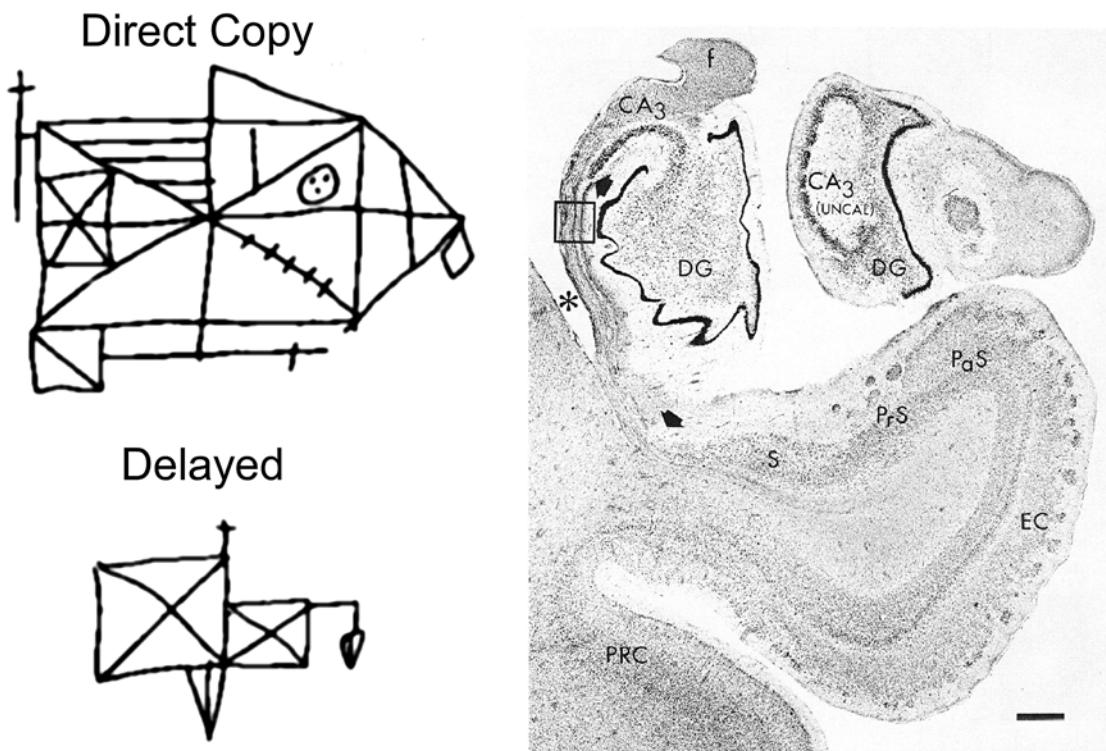

the two distributions and, as such, does not depend on where the participant decides to set the criterion threshold. Values of zero represent no memory, and positive values represent accurate memory (negative values indicate a propensity to say “yes” to foil items and “no” to target items and, when reliable, indicate reliably below-chance performance). Different thresholds result in different biases (different propensities to respond “yes” or “no”) but merely represent different values of this single parameter that are used to threshold both distributions. As such,  $d'$  can index memory in a manner that is independent of individual response biases.

Finally, one more means of quantification must be discussed because simply knowing the overall percent correct or  $d'$  in a memory task only tells a part of the story. For example, if we measured recognition memory performance in a task and obtained an average of 85% correct for a group of healthy control participants and 75% correct for a patient with damage to the hippocampus, it is still unclear whether this patient’s performance is impaired. If the control participants’ scores ranged from 80% to 90%, the patient is likely to be truly impaired, but if the control scores ranged from 60% to 100%, the participant is likely to be performing at a normal level.

In addition to the ubiquitous *t*-tests and analyses of variance (ANOVAs) used throughout behavioral testing, analysis by *z-scores* is prevalent in the memory literature and in particular in the analysis of small numbers of memory-impaired patients covered in Section 12.4. A *z-score* is simply the number of standard deviations away from the mean a given observation lies. As such, it gives a way to determine how aberrant a single observation is (e.g., a single amnesic patient’s recognition memory score). Critically, this analysis relies on an accurate estimate of both the average performance of the control population and an accurate estimate of the variance in control performance. A *z-score* of 0 represents performance equal to the mean of the control population. A *z-score* of  $\pm 1.0$  corresponds to a likelihood that the patient’s score was, in fact, drawn from the normal population (alpha level, two-tailed) of 0.32. A *z-score* of  $\pm 1.96$  has this probability drop to the traditional threshold of significance (0.05).

### 12.3.3 Anoxia and Bilateral Hippocampal Lesions

Neuropsychology—study of the relation between brain and behavior—has a long history of studying the cognitive and behavioral results of brain lesions and using this information to help understand the function of specific brain regions. Many common etiologies, and even many etiologies that produce memory impairments, do not provide data that cleanly isolate hippocampal function. For example, although a common and valuable source of neuropsychological data, patients who have suffered damage due to stroke are not common sources of restricted bilateral hippocampal damage, as the vasculature does not provide a mechanism for selective bilateral hippocampal damage. For example, although rupture or blockage of the posterior communicating artery often results

**Figure 12-3.** Patient R.B.’s performance on the Rey-Osterreith figure-drawing task demonstrated intact ability to copy the drawing when it was placed in front of him but clearly impaired ability to copy the drawing from memory 10 to 20 minutes later (healthy controls typically indicate the figure with only very minor distortions at

this delay). Postmortem histological analyses revealed his anoxic episode resulted in severe cell loss limited to the CA1 fields of the left and right hippocampus (left shown). Location and extent of damage are indicated by the asterisk and arrows. (Source: Zola-Morgan et al., 1986, with permission. © 1986 by the Society for Neuroscience.)

in MTL damage (and amnesia), the damage is not restricted to the hippocampus and is unilateral. Thus, although stroke or aneurysm can lead to memory impairment, it does not give us the most powerful means of assessing hippocampal function.

Similarly, although physical infarct can lead to amnesia (e.g., the case of N.A. who suffered mammillary body damage following an accident involving a miniature fencing foil), it is hard to imagine how a physical infarct would selectively lesion the hippocampus bilaterally given the physical location of the hippocampus buried within the MTL. Alzheimer’s disease does result in bilateral damage to the hippocampus, but it also results in damage to the entorhinal cortex and damage outside the MTL (particularly as it progresses). The thiamine deficiency associated with chronic alcohol abuse and Korsakoff’s disease results in diencephalic damage and amnesia. Many highly informative and influential studies of amnesia have been conducted with patients suffering from Korsakoff’s disease (e.g., the seminal work of Warrington and Weiskrantz, 1968). However, as with patient N.A., it is clear that the damage suffered in such patients does not allow us to isolate the function of the hippocampus itself.

In contrast, anoxia (reduction in oxygen) and ischemia (reduction in blood flow) have the potential to damage the hippocampal region selectively and bilaterally. Such cases, even if quite rare, can prove to be highly informative. Several

patients have been reported to show quantifiable bilateral damage to the hippocampal region, little or no damage outside the hippocampal region, and behavior consistent with the amnesic syndrome after anoxic or ischemic episodes (Cummings et al., 1984; Zola-Morgan et al., 1986; Rempel-Clower et al., 1996; Spiers et al., 2001; Hopkins et al., 2004). In one such case, that of R.B. (Zola-Morgan et al., 1986) (Fig. 12-3), postmortem histological analysis confirmed that the damage was almost entirely limited to the CA1 field of the hippocampus with only minor damage observed elsewhere (and located outside the MTL).

The presence of these cases does not indicate that anoxia or ischemia necessarily result in selective damage to the hippocampus. Although histological analyses such as R.B.’s are rarely available (and only postmortem), even relatively basic MRI techniques have been shown to correlate with postmortem analyses of hippocampal damage, albeit at a coarser resolution and potentially with less sensitivity (Rempel-Clower et al., 1996). Using current quantitative MRI techniques, a study of anoxia resulting from carbon monoxide poisoning and obstructive sleep apnea (Gale and Hopkins, 2004) reported that only 30% to 36% of the patients were observed to have hippocampal damage. Cortical atrophy (in the form of the ventricle/brain ratio) was present in 35% of the patients with damage resulting from carbon monoxide

poisoning. Furthermore, in a review of 43 patients with damage following anoxia (Caine and Watson, 2000), 32 showed evidence of cortical damage and 31 showed evidence of damage to the pallidum or striatum. The hippocampal region was only the third most common site of damage (30 cases). Damage was also reported commonly in the basal ganglia and the thalamus. Most strikingly, in only 18% of these anoxic cases (8/43) was the damage present in and limited to the hippocampal region.

Thus, it should be quite clear that the study of patients with damage resulting from anoxia or ischemia does not necessarily imply the study of selective hippocampal damage or even hippocampal damage at all. To use anoxic patients as a route to studying the consequences of hippocampal damage, detailed structural neuroimaging assessment of the damage (whenever possible) and detailed neuropsychological assessment of their behavior is certainly required. Improved techniques for quantifying damage and for addressing the possibility of "covert" damage not resolved by current techniques are certainly warranted as well. In particular, detailed comparison of postmortem histological analyses and premorbid neuroimaging analyses are required to improve and further validate the neuroimaging analyses. However, even if current neuroimaging techniques do not provide a definitive assessment of the damage, they are infinitely better than assessing damage merely by etiology, as the above review has shown. Unfortunately, although assessments to the best of current standards have been done for some of studies of memory, they have certainly not been done for all.

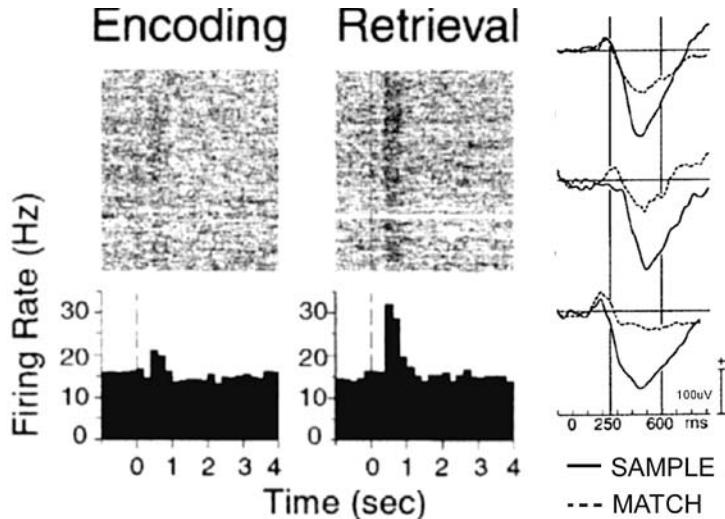

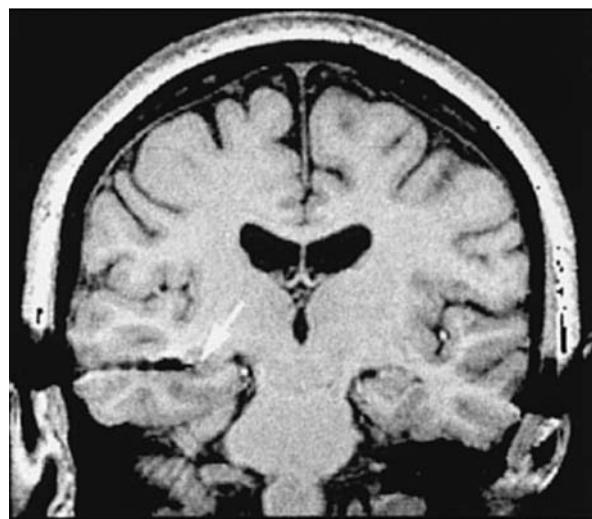

### 12.3.4 Depth Electrode Recordings

Implanting electrodes and recording from neurons in the hippocampal region and adjacent cortical structures has been a common technique for studying rodents and nonhuman primates (see Chapter 13), but electrophysiology has not been used extensively to study the human hippocampal region for obvious reasons. There have been a number of cases, however, in which depth electrodes have been placed in the human MTL to help identify the topography of epileptic seizures when other techniques for neurosurgical planning have not proved sufficient. In a limited number of these cases, single-unit recordings from the depth electrodes have been made during various explicit memory tasks (Heit et al., 1988, 1990; Fried et al., 1997, 2002; Fernandez et al., 1999b, 2002; Kreiman et al., 2000; Cameron et al., 2001; Paller and McCarthy, 2002; Fell et al., 2003) (Fig. 12–4).

Such data are certainly highly important, but they are also scarce. Unfortunately, the scarcity of the data extends not only to the small number of studies but to the small number of recordings per participant in these studies. In electrophysiological studies of the monkey hippocampus, one can expect to see data collected from 50 to 100 hippocampal neurons in each monkey (e.g., Wirth et al., 2003). In depth electrode recordings on humans, one may see data from this same number of neurons (e.g., Fried et al., 2002), but they are spread across a large number of participants, yielding single-digit numbers per participant. This is a limitation of the methodology, not of the experimenters, as multiple electrode drops and

**Figure 12–4.** Electrophysiological data in the human. *Left panel.* Trajectory of a depth electrode with microwires placed in the hippocampus (arrow indicates where wires protrude from electrode). Both peri-event spike-train histograms (middle) and field potentials (right) can be collected from such electrodes. *Middle panel.* A hippocampal neuron recorded from the electrode indicated on the left demonstrates an increase in activity at retrieval upon presentation of

the cue item in a paired-associate task. (Source: Left and middle panels: Cameron et al., 2001, with permission. © 2001 Elsevier. Right panel: Paller and McCarthy, 2002, with permission. © 2002 Wiley-Liss, a subsidiary of John Wiley & Sons.) *Right panel.* Field potentials from electrodes in the posterior portion of the hippocampus are shown for three patients demonstrating differences in activity for the sample and match phases of a delayed match-to-sample task.

continual adjustment of the electrode location or even initial placement of the electrode to isolate as many hippocampal neurons as possible is not an option. The electrode placement must be motivated by the neurosurgical planning of which these data are a by-product.

Furthermore, we must remember that the recordings are coming from brains that are decidedly not normal. The recordings are being made from patients with epilepsy severe enough to warrant neurosurgical intervention that is most likely going to target the medial temporal lobes. Whether and how this affects the data cannot be known at present. To address this concern, data are often analyzed only from sites in the unoperated hemisphere or otherwise distant from the epileptic foci.

### 12.3.5 Neuroimaging

The initial set of neuroimaging studies exploring memory and the medial temporal lobe using either PET or fMRI presented a mixed set of results. There were a number of initial PET studies with positive reports of MTL activity during memory tasks (e.g., Squire et al., 1992; Grasby et al., 1993; Nyberg et al., 1995; Schacter et al., 1995). However, at the time there were also a sizable number of studies that observed memory-related activity outside the MTL but no memory-related activity in the MTL itself (e.g., Kapur et al., 1994; Shallice et al., 1994; Tulving et al., 1994; Buckner et al., 1995). For example, Shallice et al. (1994) contrasted activity during word-pair encoding and cued recall with activity during a low-level baseline control task (e.g., hearing the pair “one thousand, two thousand” repeatedly). Although the contrasts revealed numerous regions of brain activity (e.g., prefrontal cortex), no MTL activity was present. As both contrast activity during what are clearly mnemonic tasks that are impaired in amnesic patients with activity during tasks that have no mnemonic demands and that are not impaired in amnesic patients, the negative results were unsettling. Many hypotheses for the unreliability of findings were put forth, such as the idea that the MTL might always be active (thus reducing the contrast between states) or that MTL signals may be too weak to resolve (resulting from either poor imaging signals from the MTL or inherently weak activity). It was even suggested that the MTL might not be involved in long-term memory after all.

Developments in neuroimaging techniques and further studies have now led to many positive results, supporting the former two hypotheses (and several new ones as well) but not the latter. In fact, as of this writing, more than 1300 articles indexed by PubMed during the last 5 years contained the key words “fMRI” and “hippocampus” or “medial temporal lobe.” The numbers would certainly be significantly higher if other neuroimaging techniques were included. The popularity of neuroimaging attests to the fact that it can provide useful data to further our understanding of the neural mechanisms that underlie memory.

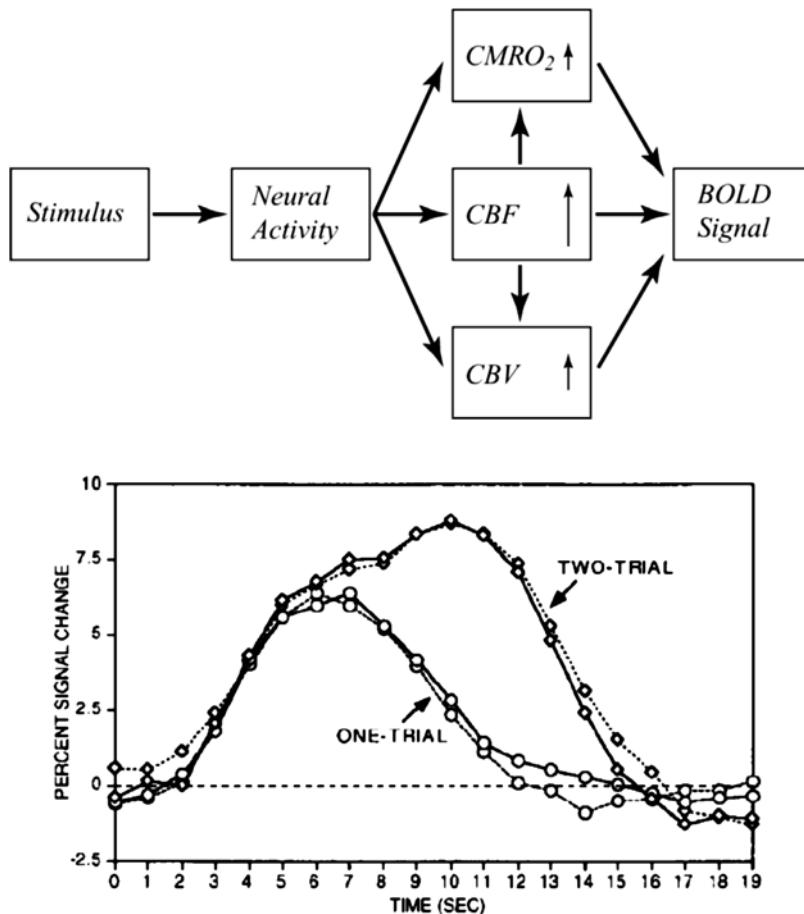

However, although useful and compelling data can be obtained using neuroimaging techniques, these techniques

have constraints and challenges that place limits on what one can conclude from their results. If the challenges are well met and experiments designed and interpreted with the constraints clearly kept in mind, neuroimaging studies can be highly informative (Henson, 2005). If they are not, they can present a confusing or conflicting state of affairs (much as was present at the time of the early studies).

The first constraint is that, on the whole, neuroimaging and electrical recording techniques provide correlational data and cannot provide evidence as to the necessity (or even actual use of) a structure in a particular function. For example, although single-unit recording shows strong hippocampal activity during delay eyeblink conditioning in the rabbit (e.g., Berger et al., 1980) and activity has similarly been observed in humans using PET (e.g., Blaxton et al., 1996), complete bilateral lesions of the hippocampus do not impair acquisition or expression of the response (e.g., Mauk and Thompson, 1987; Clark and Squire, 1998). Therefore, the activity observed in a region may be incidental to the task at hand or may be the result of processing in another region that has projections into the observed area. Whereas the use of parametric designs or other clever experimental manipulations that attempt to link imaging data to specific components of behavior (e.g., the recent attempts to link MTL activity to aspects of implicit tasks reported by Rose et al., 2002 and Schendan et al., 2003) can provide stronger evidence for a causal link than the use of simpler designs, neuroimaging data cannot be resolute in this regard.

A second problem faced by neuroimaging techniques is the lack of a baseline. Although particularly problematic for BOLD (blood oxygenation level-dependent) fMRI (Fig. 12–5), which has a signal with an arbitrary offset and arbitrary units of measurement, the lack of a clearly defined level of activity associated with a region not being involved in a task is endemic to all neuroimaging techniques. (How many spikes per second constitute “no activity” in the neuron, and what is an animal actually doing when this is assessed?) Neuroimaging techniques are contrastive in nature. Our data take the form of a higher BOLD fMRI signal, greater regional cerebral blood flow (rCBF), more spikes per second, a steeper excitatory postsynaptic potential (EPSP) slope, or a sharper tuning function during task A than during task B. These numbers can often be quantified and varied parametrically, but it is frequently difficult to interpret a result “zero activity.” This contrasts with behavioral data. For example, in two alternative forced choice recognition, scores necessarily vary between chance and 100%; and for free recall, performance necessarily varies between 0% and 100%. Where there may be floor and ceiling effects to consider, one can, in principle, identify both perfect memory and absent memory.

As noted, this lack of a standard of comparison may be especially problematic for BOLD fMRI with its arbitrary units and its complete lack of an estimate of what measurement “zero activity” in a region should be. For example, Stark and Squire (2001b) have shown that when randomly interspersed 3-second periods of rest were used as a baseline to assess “zero

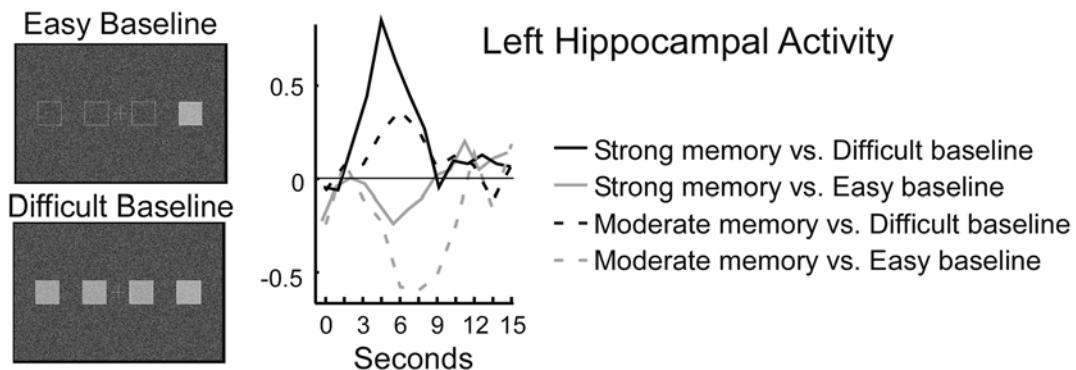

**Figure 12-5.** *Left.* A current model of the chain of events that leads to the blood oxygenation level-dependent (BOLD) effect measured on functional MRI (fMRI). Underlying neural activity results in local increases in the cerebral metabolic rate of oxygen extraction ( $\text{CMRO}_2$ ), cerebral blood flow (CBF), and cerebral blood volume (CBV). Local increases in CBF affect the other two, and all combine to change the ratio of oxygenated relative to deoxygenated hemoglobin in a local area that is measured on fMRI. This signal is called the BOLD effect. *Right.* Typical BOLD effects. Here, visual activity was recorded in response to either a single 1-second visual stimulus (flickering checkerboard) or to two 1-second trials, spaced 5 seconds apart. In both cases, the percent change from a baseline

of signals during no visual stimulation is plotted. Note how the BOLD effect is a temporally low-pass filtered response of the underlying neural activity. One second of neural activity was recorded as a protracted response that peaked approximately 6 seconds after onset and did not return to baseline until approximately 12 seconds after offset of the stimulus. Note also, though, that the response to two trials is a roughly linear summation of the response to two individual trials. (Sources: Left: Buxton, 2001, p. 419, with permission of Cambridge University Press. Right: Dale and Buckner, 1997, with permission. © 2002, Wiley-Liss, a subsidiary of John Wiley & Sons.)

activity," viewing novel or familiar pictures failed to elicit any apparent activity in the hippocampal region. However, when an active but menial task was used as a baseline (deciding whether digits were odd or even), robust activity was observed.

Similarly, Law et al. (2005) collected fMRI images as participants learned a concurrent set of arbitrarily paired associates gradually over multiple trials (Fig. 12-6). Each trial contained both encoding and cued-recall components as participants learned through trial and error which abstract geometric shapes were associated with which response options. Notably, a number of MTL regions exhibited activity that increased in conjunction with the strength of the participant's memory for a particular region. Equally notable, however, was

the observation that the choice of baseline task determined whether activity during the mnemonic trials was above or below "zero." When a trivially easy nonmnemonic perceptual task was used, activity increased with memory strength but was all "negative." When a more difficult version of the same task was used as the baseline, activity again increased with memory strength but was now all "positive." Contrasting the two baseline tasks revealed substantially greater activity in the MTL for the easy task than for the difficult task, presumably the result of participants' minds wandering during the trivially easy trials. Such mind wandering is likely to include incidental encoding and retrieval of information, the hallmark of MTL function. This result draws into sharp focus the difficulty of not having an estimate of zero activity in a region.

**Figure 12-6.** Activity in a region of the left hippocampus during a paired associate task is shown for both strong, highly accurate memories and for memories that are above chance levels of performance but still only moderately accurate. Two perceptual tasks were used to estimate “zero” activity, neither of which was overtly mnemonic. In both, the task was to identify the brightest square. The task was trivial in the Easy condition (98% correct) and challenging in the Difficult condition (54% correct). When the Easy condition was used as an estimate of “zero,” strong memories yielded small “negative” activity, and moderate strength memories yielded large “negative” activity. When the Difficult condition was used as an estimate of zero, the same exact memory task trials yielded large and small “positive” activities, respectively.

fMRI (and most other imaging techniques) yield purely relative measures, and no claims can be made about a region’s absolute level of activity in any task. The only measures available are relative measures between tasks or conditions. Furthermore, simply because a task does not require a cognitive component (memory, in this case) does not mean the component is not actually being used and that the region is not active during the task.

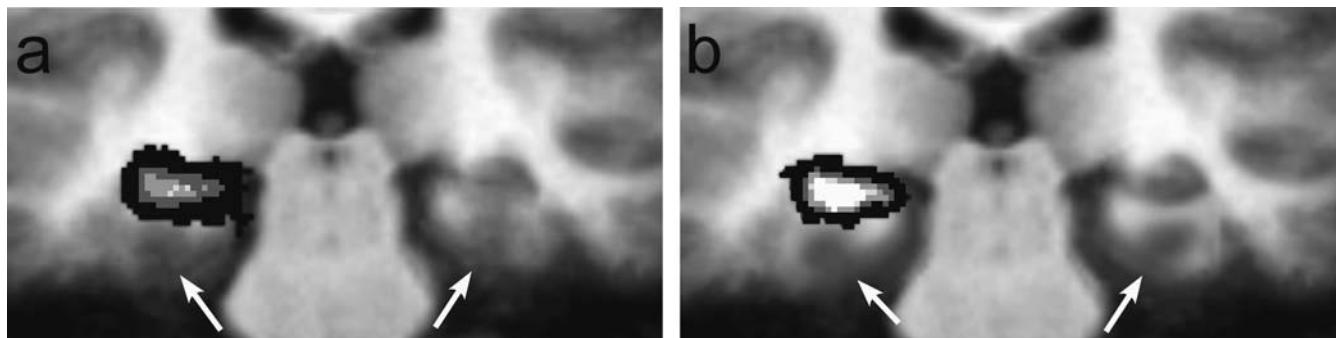

Finally, if one considers BOLD fMRI, the most popular neuroimaging technique used in humans, we still have limited temporal (~1 second) and spatial (~3 mm<sup>3</sup> or ~10,000 neurons) resolution; and we still do not have a complete understanding of the relation between neural events and the BOLD fMRI signal (or the measured by PET). Progress along these dimensions is being made, with some evidence from experiments that BOLD is more closely linked to synaptic activity than to spiking activity (Logothetis et al., 2001). One consequence of this is that inhibitory inputs may paradoxically serve to increase the BOLD effect rather than decrease it. Strong inhibition in a region results in substantial synaptic activity (and metabolic activity), even if spiking is reduced. Direct tests of this hypothesis in the rat have yielded increases in the CBF, a precursor of the BOLD effect (Caesar et al., 2003), indicating that inhibition would result in an increase rather than a decrease in BOLD. Thus, our current understanding of how to relate electrophysiological findings to neuroimaging findings is certainly incomplete, although it does appear that BOLD fMRI measures offer a relatively linear assessment of neural activity (Boynton et al., 1996; Rees et al., 2000; Logothetis et al., 2001).

These data demonstrate the effect of activity during the baseline task. Substantial activity in the hippocampus during the Easy baseline task (presumably resulting from incidental encoding and retrieval unrelated to this rather boring task) served to deflect activity during the memory task “below zero.” Note, however, that the relative differences between the curves are maintained, irrespective of baseline choice. fMRI has no baseline, and all data must be interpreted in a relative manner. All we actually know from these data is that Difficult baseline > Strong memories > Moderate memories > Easy baseline. This property is often ignored yet is a clear source of several failures to observe activity. (Source: Data are from Law et al., 2005, with permission. © Society for Neuroscience.)

### 12.3.6 Technical Challenge: Alignment of MTL Regions Across Participants

Even if the above challenges are met and the constraints respected, one significant challenge remains if neuroimaging techniques are to be able to help answer questions concerning the functional role played by the various structures in the MTL. For neuroimaging to do so, it must be possible to localize signals of the specific subregions of the MTL. Therefore, the data must be of sufficient resolution to allow confidence in localization; and if group analyses are desired, it must be possible to transform the data from multiple participants in such a way that cross-participant tests respect anatomical divisions in the MTL. Techniques such as PET and magnetoencephalography (MEG) have clear strengths. PET can directly quantify CBF and can be used to tag specific chemicals (e.g., neurotransmitters) in ways no other technique can; and MEG has millisecond temporal resolution. The spatial resolution and localization accuracy of both techniques have improved over recent years, but they still cannot approach the resolution possible with fMRI. The resolution in typical fMRI studies is typically 3 to 4 mm<sup>3</sup> but can be pushed into the cubic millimeter range (Hyde et al., 2001; Kirwan et al., in press), making fMRI a leading candidate for imaging the small structures of the MTL.

However, even if the spatial resolution is theoretically sufficient to have some confidence in localization, it is still vital that any cross-participant analyses respect the structural boundaries in the MTL. It would be pointless to attempt to discern what factors affect activity in the perirhinal cortex if

**Figure 12-7.** Coronal structural MRI sections through the hippocampus of 20 participants, averaged following Talairach alignment (*a*) and region of interest alignment (ROI-AL) (*b*). White arrows indicate the location of the collateral sulcus used to identify the parahippocampal gyrus. Overlay on the left hippocampus indicates the amount of cross-participant overlap of manual segmentations of each participant's left hippocampus when brains were aligned using each technique. The left hippocampus of each partici-

pant was initially manually segmented and then transformed along with the structural image using both techniques. In this group overlay, white is ideal (no voxels in *a* and 23 voxels in *b*) and indicates that all 20 participants' aligned segmentations identified the voxel as part of the left hippocampus. Black indicates 1 to 10 aligned segmentations identified the voxel as part of the left hippocampus. Light, medium, and dark gray indicate that 19, 18, and 16 segmentations overlap, respectively.

our alignment techniques normalized brains in such a way that a given voxel in a group analysis was located in the perirhinal cortex of one participant, the entorhinal cortex of another, the hippocampal region of a third, and outside, in the ambient cistern, of a fourth. Unfortunately, human brains are sufficiently dissimilar from each other that alignment with popular techniques (e.g., alignment to the atlas of Talairach and Tournoux, 1988) often leaves us in this situation.

An example of this problem is shown in Figure 12-7a. Here, 20 structural MRI scans were first individually aligned to the Talairach atlas before an average of the 20 scans was created (shown as a coronal image cropped around the MTL). The white arrows indicate where the collateral sulcus (a defining structure for the parahippocampal gyrus) is most likely to be. As one can see, it is far from clearly defined, indicating that the averaging across participants blurred this feature (which is plainly visible in each individual scan) into an undifferentiated mass. This poor level of cross-participant alignment arises from both global variability across participants (overall shifts in the location, orientation, and size of structures) and from differences in the shape of structures (Preussner et al., 2002).

In addition to averaging the structural MRI images, Figure 12-7a shows the result of averaging segmentations of the left hippocampal region. Each participant's left hippocampal region was manually segmented, and the same Talairach transformation was applied to each segmentation prior to averaging the segmentations across participants. The result of this averaging is a grayscale overlay that indicates how well the Talairach transformation was able to align all 20 hippocampi. In this slice, there are no voxels in which there was overlap across all 20 manual segmentations of the left hippocampal region, and there are only three voxels in which 19 of the 20 segmentations overlap. Even if our only goal is to assess activity in the hippocampal region overall (not in subregions of the hippocampus), this level of alignment is insufficient as signals

from one hippocampal region are combined with another participant's entorhinal cortex and a third participant's ventricle. If one extends this analysis to segmentations of all subregions of the MTL, the picture is worse still. Between any two participant's MTLs, only about half of the voxels are typically identified as belonging to the same structure in both participants (Stark and Okado, 2003; Kirwan et al., *in press*).

Imperfect cross-participant alignment results in a blur of the data that has two detrimental effects. First, the blur reduces the localization accuracy for any observed activity, as signals from multiple regions may be combined. Second, the blur reduces statistical power. If separate regions (or subregions) are behaving differently, the spatial blur smears activity across regions, introducing noise that prevents a consistent pattern of activity from being observed. For example, the main result of a study by Stark and Okado (2003) demonstrating activity associated with encoding during a retrieval task was not observed when the data were aligned with traditional Talairach techniques but was observed when the data were aligned using more sophisticated techniques.

Recently, there have been three approaches taken to address this issue: simple anatomical region of interest (ROI) analyses, cortical unfolding applied to the MTL, and ROI-AL (region of interest alignment). All three approaches can address the issue of improving cross-participant alignment and, in so doing, open up the possibility of using fMRI to help differentiate the role of individual structures in the MTL. Figure 12-7b shows the result of aligning the medial temporal lobe structures from the same 20 participants from Figure 12-7a but using one of these approaches (the ROI-AL method of Stark and Okado, 2003). Here, one can clearly resolve the collateral sulcus (white arrow) and differentiate it from the hippocampal region immediately above. The 20 segmentations aligned with this technique have perfect overlap in 23 voxels; and if one extends this to near-perfect (19/20) levels, the count rises to 34

voxels (versus 0 and 3 in the case of Talairach alignment). These three approaches give us hope that fMRI may be able to isolate hippocampal function from that of adjacent regions and perhaps even differentiate contributions of hippocampal subfields.

With the most straightforward technique, several articles have collapsed activity across all voxels within a set of anatomically defined ROIs (e.g., Stark and Squire, 2000a; Small et al., 2001; Reber et al., 2002, 2003). Thus, there may be a single measure that represents activity for each participant's anterior left hippocampal region in a given condition. Although this technique has the potential for perfect alignment across participants, it suffers from two drawbacks. First, by combining all voxels in an anatomically defined region into a single measure (a single, large, irregularly shaped voxel), any functional variability in that region is lost. For example, if all data from the right hippocampal region were treated as if it were one large voxel, and if two opposing patterns of activity were present in different subregions of the right hippocampal region, this functional variability would be lost. A second, related drawback is that if only a small subregion in the anatomically defined ROI is active, noise from other included voxels distort the observed activity.

A second approach has been to adapt cortical unfolding techniques to the problem of unfolding the cortical MTL structures and the spiral structure of the hippocampal region (Zeineh et al., 2000, 2003). With this approach, anatomically localized boundaries are defined and used to map the three-dimensional data onto a common two-dimensional "flat map" and to align individual participant's flat maps. Unlike collapsing all voxels in the anatomically defined ROIs, this technique has the advantage of preserving the topography in each region. In addition, because of the requirement for very high resolution of the functional data ( $1.6 \times 1.6 \times 4$  mm) and the technique's ability potentially to unfold the spiral structure of the hippocampal region, this technique holds the promise of differentiating signal from regions in the hippocampus itself. However, the unwarping process is not entirely invertible, as functional voxels that lie within a fold can be associated with two different regions of the unfolded map.

A third approach has been to use anatomically defined ROIs to guide alignment directly (Stark and Squire, 2001a; Stark and Okado, 2003; Miller et al., 2005; Kirwan et al., in press). This technique (dubbed "ROI-AL" by Stark and Okado, 2003) shares with the unfolding technique the advantage of preserving topography in regions with the unfolding technique but does not require very high-resolution functional voxels. ROI-AL takes a direct approach to aligning regions across participants. Instead of using structural MRI to align gray matter, white matter, and cerebrospinal fluid (CSF) across participants, ROI-AL attempts to align anatomically defined regions of interest based on rough segmentations of the regions. Furthermore, instead of attempting to arrive at the best fitting alignment across the entire brain, ROI-AL focuses only on alignment of a particular structure (or set of structures). Thus, all of the transformation parameters used

to align two brains with typical techniques (e.g., rotation, translation, scaling, shearing) are focused on aligning a single region (e.g., left hippocampal region). The net result is vastly improved cross-participant alignment, bringing with it improved statistical power. Furthermore, by using anatomically defined regions, ROI-AL (and unfolding) can localize results from cross-participant analyses to specific anatomically defined regions of interest (e.g., perirhinal versus parahippocampal cortices). The exact location of any region of activity in a group analysis can be compared with the segmentations from each participant (or with a composite anatomical model based on the individual participants' anatomically defined regions of interest). Thus, one can project backward from the group result to the individual participants' anatomy and determine with some precision where a signal was generated.

## 12.4 Dissociating Hippocampal Function

In the following sections, five aspects or potential divisions in long-term memory are discussed with particular attention paid to isolating the function of the hippocampus. For each of these aspects, the relevant data from patients with bilateral damage limited to the hippocampal region, from depth electrode recordings, and from neuroimaging studies are discussed.

### 12.4.1 Explicit Versus Implicit

Perhaps the clearest example of functional dissociation in long-term memory is that between *explicit*, or *declarative*, memory and *implicit*, or *nondeclarative*, memory. Explicit memory refers to "intentional or conscious recollection of prior experiences, as assessed in the laboratory by traditional tests of recall or recognition," whereas implicit memory refers to "changes in performance or behavior, produced by prior experiences, on tests that do not require any intentional or conscious recollection of those experiences" (Schacter, 1999, p. 233). These descriptive terms relate to specific task demands rather than distinctions between memory systems or specific brain structures. Yet, a wealth of data shown has shown that this descriptive distinction is strongly correlated with hippocampal function. The terms declarative and nondeclarative are defined in similar terms when applied to the human. The declarative/nondeclarative distinction goes a bit further, however, to embrace the apparent functional dissociation between multiple memory systems. Declarative memory "identifies a biologically real category of memory abilities" (Squire, 1992, p. 232) that require structures in the medial temporal lobes, whereas nondeclarative memory identifies a heterogeneous collection of memory systems that bear resemblance to each other behaviorally (all are observed with implicit memory tasks) but appear to rely on many brain structures.

Despite obvious memory impairments, it may come as a surprise to some that patients with damage limited to the hippocampal region and those with extensive damage to the medial temporal lobes demonstrate normal levels of performance on a wide range of long-term memory tasks. In an early report (Milner, 1962), H.M. was found to acquire a perceptual motor skill (learning to trace the outline of a shape when viewed in a mirror) over several days at normal rates despite not remembering the prior day's training (see Fig. 12–2). Subsequent studies have shown that even severely amnesic patients exhibit normal rates of delay eyeblink conditioning (e.g., Weiskrantz and Warrington, 1979; Clark and Squire, 1998). Furthermore, the phenomenon of categorization appears to be intact. In one task, a random dot pattern (resembling an imaginary constellation of stars) is created, and numerous distorted versions of this "prototype" are created as well by moving the dots by random amounts (Posner and Keele, 1968). After studying only highly distorted versions, even severely amnesic patients such as E.P. incidentally learn to abstract features of the prototype (or the category) so they can later correctly classify new patterns as either members or nonmembers of the studied category (e.g., Knowlton and Squire, 1993; Squire and Knowlton, 1995). They do so, however, without any knowledge that they have ever performed the task and without any ability consciously to recognize any of the previously studied dot patterns (even if the study phase consisted of seeing the same dot pattern 40 times). Thus, there appears to be a dissociation between the ability to learn in these implicit tasks gradually and the ability to remember the study episodes or contents of those episodes consciously or explicitly.

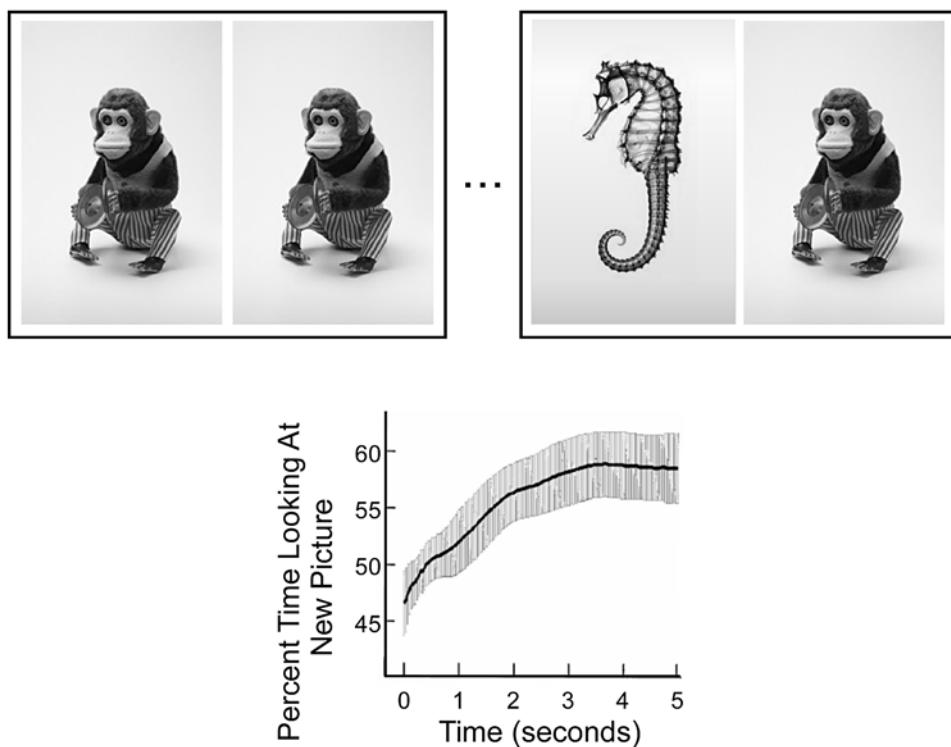

The term "priming" refers to another class of implicit memory tasks that are not affected by MTL damage. In perceptual priming tasks, exposure to a word or a picture (often incidentally, with no instruction to study the item) improves the ability to perceive the item later, usually taking the form of increased accuracy or decreased reaction time during degraded presentation. There is a long history in cognitive psychology dissociating perceptual priming and recognition memory in healthy individuals (for review see Schacter, 1994). This behavioral dissociation is relevant here in that long-term memory for an item in the form of a repetition priming effect is normal following hippocampal damage, whereas explicit memory for the same item is clearly impaired.

Warrington and Weiskrantz (1968, 1974) were the first to show that despite poor recognition memory after studying lists of words or pictures, amnesic patients had an intact form of perceptual memory for these items. When tested with a fragmented or degraded version of either type of stimulus and asked to complete this partial cue, studied items were completed more accurately or at greater levels of degradation than nonstudied items. This perceptual priming effect was normal in the amnesic patients. Likewise, if words are presented rapidly at a test so correct identification is below ceiling levels, previously studied words are identified more accurately than nonstudied words (e.g., Jacoby and Dallas, 1981). This per-

ceptual identification priming is normal even in the case of E.P., who performs at chance when given a recognition memory test under similar circumstances (Hamann and Squire, 1997).

In perhaps the most extreme example of this dissociation between intact priming and impaired recognition (Stark and Squire, 2000b), E.P. studied a list of words (e.g., "window") and after a 10-minute delay was presented with a test of repetition priming ("What is the first word that comes to mind that begins *win*\_\_\_\_") and a test of recognition memory ("Which word did you see on the list 10 minutes ago: *window* or *winter*?") on each trial. E.P. showed a normal priming effect in the form of a 26% increased likelihood of generating the studied word (relative to baseline completion rates of generating this word). However, his recognition memory performance was at chance, averaging 48% correct. Therefore, within seconds of each other, E.P. showed intact implicit memory for a word (in the form of stem completion priming) and no detectable explicit memory for that same word. Given E.P.'s complete hippocampal loss (Stefanacci et al., 2000), it is clear that the hippocampus cannot be vital for this form of implicit memory.

We should note that when comparing an amnesic patient's level of performance on repetition priming tasks (or indeed on many implicit memory tasks) relative to healthy controls, there is always the possibility that the amnesic patient's performance may be impaired relative to that of the healthy controls because the latter group may make use of covert explicit memory. Although not the case in the above-mentioned studies overall, the repetition priming task is susceptible to "explicit contamination"—the use of explicit memory on an implicit memory task. For example, if at this point in the chapter the reader were asked to complete the word stem *win*\_\_\_\_ with the first word that comes to mind, you might follow these instructions faithfully and respond with the first word that simply pops into your mind. However, you might also realize that in the preceding paragraph the word *window* was used as a sample study item (especially if this were done in the context of not one implicit probe but an entire list of them). Therefore, you might respond with "window" not because it was the first word that freely popped into your mind, but because you tried to remember what study word began with the letters *win*\_\_\_\_. Thus, despite the task instructions, participants may treat an implicit task as a thinly disguised explicit task and show enhanced levels of performance. For example, in the above-mentioned study with E.P. that combined a repetition priming task with a forced-choice recognition memory task during each trial (Stark and Squire, 2000b, experiment 4), all but one of the controls had priming effects ranging from 0.21 to 0.29. The other control had a priming effect of 0.53, approximately 8 standard deviations (SD) away from the mean priming effect. Although we do not know for certain that this particular control adopted an explicit strategy, it almost perfectly matches the mean hit rate in the recognition task, leaving this as the most reasonable hypothesis. Therefore, simply knowing

**Figure 12–8.** Visual-paired comparison task. Participants view two copies of the same image and after a variable delay are shown a new image and the old image. A bias exists to spend more time looking at the new image. This is an implicit memory task, yet the bias to look at the novel picture is dependent on the medial temporal lobes. (Source: Data are from Manns et al., 2000.)

that the task requires no more than implicit memory does not guarantee that the participants will treat it as an implicit task when there are multiple routes to solve the problem. Where implicit tasks or any other tasks are impaired in persons with amnesia, this possibility must certainly be considered.

A second form of priming, known as conceptual priming, is also apparently intact in amnesia. Here, the test presents an item or a category that is semantically or conceptually related to the studied item. For example, if the word *peach* had been presented at study (again, the study task is often incidental), participants might be asked to generate exemplars of a category (e.g., generate examples of fruits), verify category membership (e.g., how long it takes to verify that *peach* is a fruit), or perform a free-association task (e.g., free-associate to the word *pear*). In each of these, amnesic patients with damage including but not limited to the hippocampus have shown normal levels of conceptual priming (Graf et al., 1984; Shimamura and Squire, 1984; Vaidya et al., 1995; Keane et al., 1997; Levy et al., 2004) while being impaired in explicit tests for the same type of information.

A task called visual-paired comparison appears to be the one exception to the rule that implicit memory tasks are non-declarative in nature and are not impaired by damage to the hippocampal region. In this task, two copies of an object or a scene are presented to the participant for several seconds (Fig.

12–8). During this time, the participant is free to examine either copy of the object at will, and no task instructions are given. After some delay (in which intervening items may be presented), a copy of the previously exposed object or scene is presented along with a novel object or scene; and again the participant is free to examine either stimulus at will. The task, is quite implicit in instruction and behavior. Participants have a tendency to spend a greater amount of time looking at the novel stimulus than the familiar stimulus. A small bias or change is made in behavior as a result of experience on a task that makes no reference to the prior study episode—hallmarks of implicit memory tasks. In fact, the task is commonly used to assess memory in infants who would certainly not understand any explicit instructions even if given (Fagan, 1970). Yet, the task is dependent on the hippocampus in that no such bias is seen following hippocampal damage in humans (McKee and Squire, 1993; Manns et al., 2000; Pascalis et al., 2004), the monkey (Bachevalier et al., 1993; Pascalis and Bachevalier, 1999; Zola et al., 2000), or the rat (Clark et al., 2000). Furthermore, the degree of bias shown in the visual paired comparison task is predictive of subsequent recognition memory for the items shown, whereas the amount of repetition priming exhibited is not (Manns et al., 2000). Thus, even though the task requirements are implicit in nature (no reference is made to the study episode) and even though the memory is observed in the form of a change in a behavioral

bias, the task relies on the same underlying mechanisms that are responsible for declarative memory.

One final task deserves consideration when discussing the role of the hippocampus in relation to explicit and implicit memory. Chun and Phelps (1999) embedded an implicit memory task within a visual search task (locate a rotated T among numerous rotated L distractors). Although the displays appeared to be random, a set of 12 displays were repeatedly intermixed with random displays throughout the experiment. As one might expect, the reaction time to locate the target item in the random displays gradually decreased over the course of the task. This basic practice effect or increased skill in performing the task was similar in a control group and an amnesic group (two anoxic patients and two patients with encephalitic damage that included, but extended beyond, the hippocampal region), consistent with other implicit or non-declarative tasks. Furthermore, although approximately half of the healthy controls reported noticing repetition of several displays when later asked, not even they could identify which they were (54% correct). Critically, however, the controls' reaction times to the repeated items were faster than their reaction times to the random items in the later epochs of training. Although they lacked explicit knowledge of the repeated items, they had implicit knowledge of this repetition, evidenced by their reaction time. In marked contrast, the amnesic patients did not show this effect. The amnesic patients exhibited identical reductions in reaction time for repeated and random displays.

Thus, a second task exists in which the task demands and memory are implicit in nature, yet performance requires structures in the medial temporal lobes. This said, performance may not require the hippocampus itself. A follow-up study by Manns and Squire (2001) solidly replicated the basic findings of Chun and Phelps (1999). Here, however, the amnesic patient group was large enough to separate into two groups based on size and extent of the lesion. Five patients had damage limited to the hippocampal region or only mildly extending into the parahippocampal gyrus. A separate group of three were encephalitic patients who had extensive, near-complete damage to the MTL and mild damage that extended into the lateral temporal cortex (consistent with this etiology). Notably, the only group that did not show reduced reaction times specific to repeated displays was the group with extensive MTL damage. These patients performed similarly to the mixed etiology group in Chun and Phelps' (1999) study. In contrast, the patients with damage more restricted to the hippocampal region performed much like the healthy control volunteers in both studies, demonstrating improved reaction times for repeated displays. Therefore, our best understanding of this task is that implicit memory for the repeated displays is not derived from the hippocampal region itself but, rather, is derived from some other temporal lobe structure.

In summary, we can conclude that although the hippocampus plays a role in explicit or declarative memory tasks, it does not play a role in implicit or nondeclarative memory

tasks (at least when the task is solved in an implicit way). The visual-paired comparison task is the one apparent exception to this rule, highlighting the importance of extending or refining the descriptive distinctions created to understand human behavior (e.g., implicit/explicit) to more fully encompass data from other sources. The simple description of the task requirements does an admirable job of dissociating two classes of tasks, yet there is clearly something about the visual-paired comparison task that, despite its "implicit" nature, makes it dependent on the hippocampal region and the adjacent medial temporal lobe cortices.

#### **12.4.2 Encoding Versus Retrieval**

Whereas studies of patients with damage to the hippocampal region have been able to demonstrate a dissociation between declarative memory tasks that involve the hippocampus and nondeclarative memory tasks that do not, studies of patients are not particularly well suited to isolating the role of the hippocampus in encoding (or storage) versus retrieval processes. The inability to make accurate judgments in a recognition memory task or to recall items from a study list could be the result of failure to encode the items initially or failure to retrieve a well encoded item. The observation that amnesic patients can retrieve fact or event-type memory that was learned well prior to the onset of their amnesia (see Section 12.4.3) can be taken as evidence that the hippocampus is not continually required for declarative memory retrieval; however, it still leaves open the possibility that when anterograde and retrograde amnesia are observed the central impairment is one of retrieval rather than encoding or storage (e.g., Warrington and Weiskrantz, 1970).

Thus, in humans, determining whether the hippocampus plays a differential role in encoding or retrieval relies heavily on electrophysiological and neuroimaging data. Complementing this, studies of animals offer the opportunity of employing reversible lesions, blockade of long-term potentiation (LTP), and other manipulations (discussed in Chapters 8 and 13). One of the challenges that faces all such attempts is the observation that during memory retrieval tasks participants unwittingly encode the test items and can often accurately remember whether an item was present during the test (for review see Glover, 1989). fMRI activity associated with this incidental encoding has been observed in numerous frontal and parietal regions (Buckner et al., 2001) and bilaterally in the hippocampal region, perirhinal cortex, and parahippocampal cortex (Stark and Okado, 2003).

This challenge aside, hippocampal activity has been observed relating to both encoding and retrieval success. A number of fMRI studies (Small et al., 2001; Davachi and Wagner, 2002; Reber et al., 2002; Strange et al., 2002; Davachi et al., 2003; Stark and Okado, 2003; Kirwan and Stark, 2004) have observed hippocampal activity correlated with encoding success. In this so-called *Dm* (differences due to memory) effect (Paller and Wagner, 2002), there is greater activity dur-

ing the successful encoding of items that are later remembered than during the unsuccessful encoding of items that are later not remembered. Similar *Dm* effects have been observed in several studies employing recording from the hippocampal region using depth electrodes as well (Fernandez et al., 1999b; Cameron et al., 2001; Fernandez et al., 2002; Fell et al., 2003). We should note that these *Dm* effects have been frequently observed in the parahippocampal cortex (e.g., Brewer et al., 1998; Wagner et al., 1998; Fernandez et al., 1999b; Otten et al., 2001; Davachi and Wagner, 2002; Fernandez et al., 2002; Strange et al., 2002; Davachi et al., 2003) and the entorhinal or perirhinal cortices (Fernandez et al., 1999b; Cameron et al., 2001; Davachi and Wagner, 2002; Fernandez et al., 2002; Strange et al., 2002; Davachi et al., 2003; Fell et al., 2003; Kirwan and Stark, 2004) as well.

Similarly, a number of fMRI studies have demonstrated activity in the hippocampal region related to retrieval success (e.g., Gabrieli et al., 1997; Eldridge et al., 2000; Stark and Squire, 2000a, 2000c, 2001a; Stark and Okado, 2003; Kirwan and Stark, 2004). Here, successful retrieval (e.g., responding “old” to previously studied targets) usually elicits greater activity than unsuccessful retrieval (e.g., responding “new” to unstudied foil items). Similar effects have been observed using depth electrode recordings (Paller and McCarthy, 2002) and magnetic source imaging (Papanicolaou et al., 2002).

Although apparently engaged in both successful encoding and retrieval processes, a dissociation between the two is still possible; and several studies have observed differences in the hippocampal region between memory encoding processes and retrieval processes. For example, Zeineh et al. (2003) used the above-mentioned unfolding techniques to isolate encoding and retrieval-related activity for face-name pairs. They reported above-baseline (visual fixation on a cross) activity during encoding but not retrieval in CA2, CA3, and the dentate gyrus, with this activity decreasing across repeated presentations (evidence of encoding-related activity was seen in the parahippocampal cortex as well). In contrast, retrieval (and to some degree encoding) was associated with activity in the subiculum, also showing a decrease in activity with repeated presentations. Thus, some differentiation between encoding and retrieval was observed in components of the hippocampus.

In addition to differentiating encoding from retrieval across these subregions (see Chapter 3), several attempts have been made to differentiate activity along the anterior-posterior (or longitudinal) axis (Gabrieli et al., 1997; LePage et al., 1998; Fernandez et al., 1999a). However, it appears as if the initial support for this hypothesis has not been confirmed in the further analysis of these and subsequent studies (Schacter and Wagner, 1999). For example Small et al. (2001) used an anatomical ROI analysis to examine encoding- and retrieval-related activity along the longitudinal axis of the hippocampal region (eight ROIs for each participant along this axis). Here, they observed activity in different locations along the longitudinal axis for encoding faces and for encoding names. They

also observed a combination of these locations (and several others) during the encoding of face-name pairs. At retrieval, when participants were cued with a face and asked to recall the name, the pattern of activity in the hippocampal region was quite similar to the pattern of activity observed when encoding the face-name pair. Similarly, using an anatomical ROI analysis, Reber et al. (2002) observed encoding effects for both words and pictures throughout the longitudinal axis of the hippocampal region and the adjacent cortical structures (differences were observed between picture and word encoding, however).

Furthermore, in a study that attempted to reduce the effects of incidental encoding during retrieval (Stark and Okado, 2003), encoding and retrieval each resulted in activity in the hippocampal region and in the perirhinal and parahippocampal cortices. It should be noted, however, that in this study the exact voxels associated with intentional encoding, incidental encoding, and retrieval were not always the same. Likewise, Pihlajamaki et al. (2003) found evidence for greater activity during retrieval than encoding and greater activity during encoding than retrieval in areas of the perirhinal and parahippocampal cortices and the hippocampal region. Thus, it is apparent that although there may be differentiation between encoding- and retrieval-related functions on a fine scale, encoding and retrieval processes appear to be present throughout the MTL.

#### 12.4.3 Time-limited Role in Declarative Memory

At the beginning of the chapter, we noted Milner’s observation that patient H.M.’s remote memory appeared to be intact in the face of both his profoundly impaired ability to learn new information and a profound loss of information that he had been exposed to for some amount of time prior to his operation. Given his intact childhood memories, she concluded that the medial temporal lobes were not the ultimate storage site for what we now refer to as declarative memory. Therefore, some form of systems-level “consolidation” occurs by which memories that initially rely on structures in the medial temporal lobe become independent of the medial temporal lobe over time. (This is not to be confused with an alternative use of the term “consolidation” to refer to the fixation of a memory over the course of seconds to hours.) This phenomenon, termed “temporally graded retrograde amnesia,” has been observed frequently in amnesic patients since first being described by Ribot more than 100 years ago (Ribot, 1887).

This observation has been frequent but not entirely consistent. Although some have described it as temporally graded (e.g., Squire and Alvarez, 1995), others have described it as constant (e.g., Warrington and McCarthy, 1988). Some have found evidence that memory for both facts (semantic memory) and events (episodic memory) acquired before the onset of amnesia are similarly impaired (e.g., Verfaellie et al., 1995; Reed and Squire, 1998), whereas others have found more

selective (and constant) impairment in episodic memory (e.g., Nadel and Moscovitch, 1997). One potential source of variability in the data stems from the fact that all studies of retrograde memory in human amnesic patients are retrospective and quasi-experimental in nature. When testing a patient's memory for knowledge acquired before the experiment (and potentially years or decades before the experiment), we cannot know how well the information had been learned prior to the onset of amnesia or even if it had been learned at all. Furthermore, we cannot know whether the information had been retrieved, and therefore reencoded, at some time following the initial learning. Such retrieval-induced encoding could easily affect the presence or absence of a temporal gradient. Likewise, it is a matter of debate whether such retrospective tests should employ information that shows a forgetting gradient in healthy controls or they should employ information that can be retrieved at a constant level of performance across the supposed delay.

Additionally, the exact location and extent of the hippocampal lesion is often not known nor whether it extends beyond the medial temporal lobes. There are a relatively small number of cases in which damage appears to be limited to the hippocampal region and retrograde amnesia has been assessed (Zola-Morgan et al., 1986; Reed and Squire, 1998; Kapur and Brooks, 1999; Holdstock et al., 2002a). In all but one patient (Y.R. in Holdstock et al., 2002a), a temporally graded retrograde amnesia spanning several years was observed for both episodic and semantic memory. In the case of Y.R., no retrograde amnesia was detected at all in this study. However, follow-up testing on Y.R. has revealed evidence for at least some retrograde amnesia. Its precise nature with respect to temporal gradients and with respect to selectivity for any kind of information or task is currently not known, however (unpublished data, Andrew Mayes, personal communication, February 22, 2005).

Using neuroimaging to study the time-limited nature of hippocampal function is also associated with a number of challenges. One clear challenge is the problem of activity associated with incidental encoding. It is quite plausible, for example, that if memories have been consolidated and no longer require structures in the MTL the retrieval of such a memory (e.g., a childhood memory that has not been thought about for some time) induces encoding in the MTL. If participants can tell you what memories they had retrieved while inside the scanner, activity associated with this incidental encoding could mask (or even reverse) any retrograde gradient (Stark and Okado, 2003).

A second challenge that perhaps faces studies of consolidation more strongly than most is the difficulty posed by the choice of baseline tasks. Several studies have shown that there is significant activity throughout the brain (including the MTL) during rest or other baseline tasks that do not actively engage the participant (Binder et al., 1999; Gusnard et al., 2001; Gusnard and Raichle, 2001; Newman et al., 2001; Stark and Squire, 2001b). One explanation for such activity is that during rest and other low-level baseline tasks participants are

actually engaged in an undetermined and uncontrolled task (e.g., reflecting upon the experiment). When activity during episodic recollection (e.g., "Reflect upon your visit to Paris as a child") is contrasted with rest, it is quite plausible that this reflection is carried into the rest periods. Such activity during rest could reduce the magnitude of an effect such that it might not be observed or, if the amount of reflection during rest or the actual "task" performed during rest varied with condition (e.g., participants might be more likely to reminisce or attempt to further elaborate a memory following retrieval of a very old than a recent memory), one could create or even invert a gradient purely as an artifact (Stark and Squire, unpublished data).

Given these challenges, it is not entirely surprising that in neuroimaging studies of consolidation the results have been mixed. For example, Ryan et al. (2001) asked participants to generate very remote (> 20 years) and relatively recent (< 4 years) episodic memories while outside the scanner. Inside the scanner, they were asked to recall these memories for 20 seconds. In bilateral hippocampal regions that showed an overall difference in activity between recollection and rest, there was no difference in activity between activity for very remote and relatively recent memories (an alternate baseline of sentence completion was also used and did not differ from rest, but as this task required one sentence completion in 5 seconds it may be open to the same difficulties as explicit rest). Furthermore, no significant activity was observed in any of the subjects in a remote-versus-recent contrast.

Similarly, Maguire et al. (2001) collected data as participants performed a verification task on both public event information and autobiographical information from periods ranging from several weeks to more than 20 years prior to scanning (e.g., "Yes or no: You were at Tim's wedding in London"). Although hippocampal activity during both tasks was greater than baseline (listening to a set of function words), and it was greater for autobiographical than public-event verification, it did not vary parametrically with memory age. However, the participant's knowledge of this information had been assessed several weeks prior to scanning, raising the possibility that they were retrieving the information from the recent reencoded episode.

Finally, Stark and Squire (2000a) attempted a prospective study of consolidation by having participants study pictures of nameable objects at varying delays prior to scanning. At test, the names of the objects were presented. In so doing, much of the incidental encoding-related activity appears to be confined to the left hemisphere, leaving retrieval-related activity for the nameable objects relatively uncontaminated in the right hemisphere (Stark and Squire, 2001a). Activity in anatomically defined ROIs in the MTL did not differ as a function of study-test interval. It should be noted, however, that the delays employed were all relatively short, ranging from an hour to a week.

In contrast to these negative findings, there have been several studies that have shown gradients in MTL activity as a function of memory age. In the first such study, Haist et al.

(2001) used the “famous faces” task (Marslen-Wilson and Teuber, 1975) in which participants were presented with photographs of faces from various decades (of both famous and nonfamous people) and attempted to recall the names of each. An analysis identifying regions whose activity varied linearly by decade (activity determined by a contrast between famous faces from each decade and rest) isolated activity in a region that appeared to be the right entorhinal cortex. Here, activity was greatest when participants attempted to recall names from the 1990s and 1980s and lowest when participants attempted to recall names from the 1940s. No other region showed this linear trend.

In a second study, Niki and Luo (2002) used a version of the episodic reflection task in which participants attempted mentally to revisit places they had visited either recently or more than 7 years prior to scanning. In the direct comparison between recent and remote memories, activity in the left parahippocampal gyrus was observed, with greater activity for recent than remote memories. Although a number of other regions throughout the brain also showed this pattern, a substantial number showed the reverse, with greater activity for remote than recent memories.

Finally, Maguire and Frith (2003) again examined autobiographical and public event knowledge as a function of remoteness using a task similar to that in their previous work, described above (Maguire et al., 2001). Although they again observed greater hippocampal activity for autobiographical than public event memory, they did observe a gradient in right hippocampal activity as a function of remoteness of the autobiographical memory (no gradient was observed in the left hippocampal region).

Thus, with respect to the expectation that a time-limited role of the MTL in declarative memories produces a gradient in the BOLD fMRI signal, the current state of affairs is mixed. There are several null results in which no gradient was observed. There are, however, several positive results as well. None of the studies has been able to address fully the issue of incidental encoding (and how it might vary with remoteness), and many suffer from the difficulty that it is unclear whether participants are recalling events from several decades ago or from their retrieval during prescreening sessions. Furthermore, all studies have ignored the possibility that over the course of decades the representation of the memory may change in such a way that the BOLD fMRI signal is affected without altering the functional role of a particular region (e.g., recently consolidated memories may have qualitatively different representations in the tens of thousands of neurons in a typical fMRI voxel than very long-standing memories). One might consider this a clear criticism of the current studies, and the solution to these problems is not clear; nor is it clear how this question can be better approached with neuroimaging. The study of retrograde memory in humans has always been exceedingly difficult with most tasks being retrospective rather than prospective in nature. When combined with the above-mentioned difficulties presented by the limitations of current neuroimaging techniques, it seems obvious

that our best evidence for any time-limited role of MTL structures will be gained from animal models of amnesia. Controlled prospective studies have been conducted in that arena that, by and large, reveal temporal gradients following hippocampal damage (for review see Squire et al., 2001).

#### 12.4.4 Spatial Memory

The notion of a hippocampal “place cell” whose activity codes for the current location in a spatial environment is covered extensively in Chapter 11. The hypothesis that the hippocampus is primarily or even uniquely involved in spatial processing and spatial storage is laid out there, drawing extensively on electrophysiological data from the rat. This hypothesis is considered again in Chapter 13, where a wide array of data from rats, monkeys, and humans are considered. Before this more comprehensive treatment, the data concerning the role of the human hippocampus in spatial memory and spatial processing are considered. In so doing, the principal question is not whether damage to the hippocampus impairs performance on spatial memory tasks or whether place cells are observed in the human hippocampus. In fact, neuropsychological (e.g., Holdstock et al., 2000) and electrophysiological data (Ekstrom et al., 2003) have demonstrated both, implicating the human hippocampus in spatial memory tasks.

For example, Ekstrom et al. (2003) recorded data from depth electrodes implanted in the hippocampal region, parahippocampal gyrus, amygdala, and several frontal sites as participants navigated in a virtual town. Their task was to pretend to be a taxi driver, picking up and dropping off passengers. Several codes were observed in the data. In particular, 11% of the cells (31/279) could be confidently classified as place cells, with their distribution skewed toward being found in the hippocampal region. Approximately 24% of hippocampal neurons could be confidently classified as place cells, whereas significantly fewer neurons in the parahippocampal gyrus, approximately 8% of those sampled, could be confidently classified as place cells. A second code was observed primarily in the parahippocampal gyrus. These cells, termed “location-independent view cells,” were observed to code for particular objects or landmarks irrespective of their location. A total of 14 of the 279 neurons (5%) were classified as such and were observed largely in the parahippocampal gyrus. Approximately 15% of neurons in the parahippocampal gyrus were location-independent view cells (7 total) whereas only 1 of 55 neurons in the hippocampal region coded for this information. Although this dissociation was observed, one should note that the numbers of cells and their proportion to the total number sampled is quite small. For example, of the 55 hippocampal cells recorded, 43 (78%) showed main effects of factors other than place or coded for combinations of several factors.

Thus, the question at hand is not whether the hippocampus plays a role in spatial memory. Rather, the question is whether the function of the human hippocampus can be tied strongly to spatial processing or the human hippocampus is

better viewed as playing a mnemonic role, with spatial memory being only one example of hippocampal function.

One approach to this question that has been explored extensively in the rodent (see Chapter 11) (Eichenbaum et al., 1999) is to ask whether damage limited to the hippocampal region impairs memory on nonspatial tasks. If such impairment exists and if spatial contributions to the task can be eliminated, one could posit a role for the human hippocampus outside of spatial memory or processing. Although there are many reports of such impairment (see Spiers et al., 2001 for review), it is almost impossible to rule out the option that healthy human control participants engage in a spatial strategy on such nonspatial tasks. For example, even on tests of verbal recognition memory, control participants might imagine the stimuli, imagine relations between stimuli, or use other mnemonic techniques such as the method of loci to improve their performance. Were such spatial strategies not available to patients with hippocampal lesions, their performance might be impaired for spatial, rather than mnemonic, reasons. As tests of recognition memory in humans have not aimed to address the spatial hypothesis directly, they have not controlled for these potential spatial aspects of the tests as carefully as in much of the work in the rodent literature.

An alternative approach to addressing the question is to assess the spatial abilities of patients who have lesions that include the entirety of the hippocampus bilaterally. If spatial processing appears normal despite a complete hippocampal lesion, it would be difficult to conclude that the hippocampus is required for spatial processing in humans. The case of patient E.P. has provided compelling evidence that spatial memory and processing may be intact despite hippocampal loss (Teng and Squire, 1999). Unlike patient H.M., patient E.P. has what is most likely complete loss of the hippocampal region bilaterally (Stefanacci et al., 2000), with only a small “tag” of tissue (~ 10% of the volume) remaining. With the complete lack of entorhinal cortex in E.P., it is doubtful (even if this tissue contains healthy neurons, which it may well not) that it would be functional in any way. Yet, despite this complete loss of the hippocampal region, E.P. can perform a number of complex spatial tasks at normal levels. When asked to navigate in the town in which he grew up, E.P. not only can mentally navigate along familiar routes (from his childhood house to other local landmarks), he can mentally navigate along novel routes (paths between randomly chosen landmarks) and along novel routes with key paths blocked (e.g., imagine that a main road is closed). He also can perform a dead reckoning task (imagine being at one landmark and point in the direction of another landmark) at a level indistinguishable from that of healthy control volunteers who grew up with E.P. and who also left during their young adulthood (Teng and Squire, 1999). The matched control volunteers had an easier time mentally navigating in their current environments, scoring at the ceiling (100% correct). E.P., however, emphatically did not have an easier time navigating in the area he had moved into 6 years prior to testing (and 1 year after he

became amnesic). His performance dropped from 83% correct in his childhood environment to 0% correct in his current environment on the navigation tasks. Despite living on a hill that overlooks the Pacific Ocean a mere 2 miles away, E.P. was not even able to point in its direction. Thus, E.P. can retrieve spatial information and navigate in a spatial environment learned long before the onset of his amnesia but apparently has not learned any spatial information about his environment after the onset of his amnesia. With complete hippocampal loss, spatial *processing* therefore appears normal despite complete inability to acquire new spatial *information*.

Neuroimaging studies have also begun to provide useful data on the role of MTL structures in spatial processing and, consistent with lesion evidence (e.g., Epstein et al., 2001), have clearly implicated the posterior portions of the parahippocampal gyrus in topographical memory tasks. For example, in an early study, Aguirre et al. (1996) observed MTL activity that was confined to the posterior parahippocampal gyrus (likely parahippocampal cortex) as participants learned to navigate in a three-dimensional maze viewed from a first-person perspective (activity relative to a low-level control task). Using a similar task, Maguire et al. (1998) also reported parahippocampal gyrus activity associated with exploring and learning the topography of a virtual three-dimensional environment (at least when the environment contained objects that could serve as landmarks). Whether the activity is specifically related to topographical processing or is representative of more general mnemonic function cannot be determined from these data. However, it is of interest that they implicate the posterior portions of the parahippocampal gyrus and not the hippocampal region in these topographical learning tasks.

Consistent with these findings, Shelton and Gabrieli (2002) also observed activity in the posterior parahippocampal gyrus (with this region of activity extending into the posterior hippocampal region) as participants encoded a virtual three-dimensional environment when viewed from a first-person, or “route,” perspective. Of interest, the pattern clearly differed when participants encoded environments from an aerial, or “survey,” perspective. Despite similar subsequent memory for environments learned from the two perspectives, activity in the posterior parahippocampal gyrus was greater when participants encoded the environment from a route perspective than from a survey perspective. The authors suggest that this difference may be the result of qualitatively different mnemonic demands placed on participants in the two conditions. For route encoding, participants must continually bind together a representation of their present position to their past and future positions to create a layout of the entire environment. Although still spatial in nature, encoding the environment from a survey perspective did not place this same sort of demand on participants. In a subsequent task that asked participants to draw maps of the environment, the sequential order of presentation was preserved following route learning and was not preserved following survey learning, further suggesting a difference in the way the two environments were

encoded that may have led to the observed difference in activity in the parahippocampal gyrus.

Hartley et al. (2003) contrasted activity associated with navigating in a large-scale virtual environment either by way-finding (via route-based spatial knowledge gained by free exploration) or by route-following (traversing the same route that had been well learned during study). Unlike the simple route-following task, which required only recapitulation of a well learned route, the way-finding task required knowledge of the global spatial relations in the environment and navigation along a novel path. Within the MTL, Hartley et al. (2003) reported greater activity in the posterior parahippocampal gyrus overall during the way-finding task than during the route-following task. Perhaps of more interest, with the way-finding condition, activity in the hippocampal region was correlated with accuracy of performance (ceiling effects made this test impossible with the route-following task). Furthermore, in an individual differences analysis that examined correlations between the participant's overall performance in way-finding and neural activity differences between way-finding and route-finding, Hartley et al. (2003) reported a significant positive correlation in what is likely the perirhinal cortex and a significant negative correlation in the head of the right caudate. A positive correlation in the hippocampal region fell just short of significance. Thus, participants who were better at navigation showed greater MTL recruitment during the way-finding task relative to the route-finding task than participants who performed more poorly. Conversely, these same good navigators showed greater caudate recruitment during the route-finding task relative to the way-finding task than participants who performed more poorly.

One logical interpretation of these data (although not the only one, given the contrastive, or relative, nature of fMRI) is that the better navigators recruited structures in the MTL more for the way-finding task and that they recruited the caudate more for the route-finding task. Furthermore, these results make the tantalizing suggestion that this differential recruitment might be causally related to their better performance. Hartley et al. (2003) interpreted their results as being supportive of a role of the hippocampus in the use of a cognitive map, but McNamara and Shelton (2003) suggested that the correlations observed in the hippocampal region are also consistent with the view that the hippocampus processes memory in a way that allows for its flexible use in guiding behavior (e.g., Eichenbaum, 2000). Moreover, in the study of Hartley et al. (2003), the most reliable positive correlation in the individual differences analysis was observed in the perirhinal cortex, not the hippocampal region. (One reliable correlation was observed in the left hippocampal region, but this was using a mnemonically laden contrast.) That the contrast between way-finding and route-finding in the perirhinal cortex would strongly correlate with navigation skill provides a novel datapoint to help us understand the differentiation of function across structures in the MTL.

Thus, the evidence from humans suggests that the hip-

pocampus is involved in spatial memory tasks but that its function is more generally mnemonic and not limited to spatial memory. In humans, spatial memory is an excellent example of complex, declarative memory.

#### 12.4.5 Associations, Recollections, Episodes, or Sources

A large amount of the research on the human hippocampus has been aimed at functionally dissociating the role of the hippocampus from the role of adjacent cortical structures. As noted at the beginning of the chapter, a popular idea draws on the anatomy to suggest that the hippocampus integrates information from and combines the processing of the adjacent cortical structures that feed into the hippocampus. Two fundamental hypotheses that share this basic idea and that are both driven by data from human and nonhuman studies have been proposed and explored. One hypothesis states that there is a clear dissociation of function between the hippocampus and the adjacent structures. For example, the hippocampus has been described as being involved in memory that is associational, multi-item, spatial, episodic, and recollective, whereas the perirhinal cortex (and by extension at times the parahippocampal cortex) is involved in memory that is automatic, noneffortful, single-item, and familiarity, or recency-based (in contrast to recollective), with this distinction being qualitative rather than quantitative (Brown and Aggleton, 2001).

The other hypothesis states that the dissociation of function is more quantitative than qualitative in nature and that the hippocampus and the adjacent structures in the parahippocampal gyrus are all broadly involved in declarative memory. This is not to say that the medial temporal lobe is equipotential in nature. By virtue of being farther up in the hierarchical structure of the medial temporal lobe (see Chapter 3), the hippocampus is proposed to "combine and extend" the processing carried out by the entorhinal, perirhinal, and parahippocampal cortices (Squire and Zola-Morgan, 1991). By virtue of receiving input from both perirhinal and parahippocampal cortices (via the entorhinal cortex), the hippocampus is in a position to be able to integrate information across these structures and sources of information. Thus, "associative," or "conjunctive," processing can be attributed to the hippocampus. However, the structures in the parahippocampal gyrus also receive input from a wide range of sources, putting them in a position to perform "associative" or "conjunctive" processing as well. As the input to the hippocampus consists of more refined and further processed information (its major input arrives from the entorhinal cortex, which receives approximately two-thirds of its input from the perirhinal and parahippocampal cortices), the hippocampus is in a position to perform different, potentially more abstract or complex associative or conjunctive processing. This is not to say, however, that there is binary dissociation of function between the hippocampus and the adjacent cortical

structures according to associative or conjunctive versus single-item, episodic versus semantic, recollection versus familiarity, and so on.

The hypothesis that the hippocampus combines and extends the processing of the adjacent cortex is underspecified, as the current theories that take this view do not detail how this process takes place (nor, often, do the theories that propose a more binary dissociation). Data from amnesic patients with damage limited to the hippocampus and data from neuroimaging studies are presented in the following two sections. Overall, the data are not consistent with a clean, binary division of labor between the hippocampus and the cortical components of the medial temporal lobes. They are more consistent with either the graded division of labor implied by the concept of “combine and extend” or with a division of labor along lines that have yet to be explored significantly using these two techniques.

### **Amnesic Patients**

The data available from amnesic patients with bilateral damage thought to be limited to the hippocampal region are far from allowing consensus in support of either hypothesis. For example, Yonelinas et al. (2002) reported data from 56 hypoxic patients with presumed (although not confirmed—see Section 12.3.3) bilateral damage to the hippocampal region. When compared to a similar-sized group of healthy controls, the patients were impaired on both recall and recognition memory tasks. When transformed into z-scores (so the patients’ performance is expressed relative to the mean and standard deviation of the controls’ performance—see Section 12.3.2), the impairment in recall was larger than the impairment in recognition. Thus, if recall tasks place greater demands on episodic or recollective processing than recognition memory tasks, these data point to a differential role for the hippocampus in this kind of memory.

In the same study, four of the hypoxic patients were tested using the Remember-Know procedure to assess recollective and familiarity components of recognition (Tulving, 1985). In this task, participants indicate at the time of retrieval whether their memory is best described as recollective, containing episodic components and clear knowledge of the source of the memory (a “Remember” response), or best described as a feeling of familiarity (a “Know” response). Whereas patients with MTL damage known to extend beyond the hippocampal region were impaired in both recollective and familiarity components, the hypoxic patients were significantly impaired only in the recollective component. Thus, barring any concern about the lesion locations in the hypoxic patients, these data appear to support the conclusion that the hippocampus plays a key role in recall and in recollective processing, and that these processes may not be able to be supported by the adjacent cortex. Conversely, if the lack of familiarity impairment is true (in the four participants the 23% impairment was unreliable, but this may be the result of insufficient statistical power), the hippocampal region may not provide any famil-

arity signal to be used during recognition. Thus, we would have clear functional dissociation between the hippocampal region and the adjacent cortex.

The difficulty is that this pattern is not consistently observed. For example, Manns et al. (2003) tested a group of seven patients with bilateral damage limited to the hippocampal region (as determined by MRI) using the same tasks employed by Yonelinas et al. (2002). Consistent with the results of Yonelinas et al. (2002), the patients were impaired on both tests of recognition and recall. However, there was no evidence of disproportional impairment. When recall performance was measured against recognition performance, the patients’ recall score was in the 30.5th percentile of their recognition distribution and the controls’ recall score was in the 30.6th percentile of their recognition distribution. When the same z-score analysis was performed, the amnesics’ recognition performance was *worse* than their recall performance, indicating greater impairment in recognition than recall. Furthermore, the amnesics’ performance on the Remember-Know task showed similar impairments for both Remember (60% reduction) and Know (60–71% reduction, depending on the scoring method) responses. Thus, although a null result, the data of Manns et al. (2003) leave little room to support a clear functional dissociation between the hippocampal region and the adjacent MTL structures with respect to recollective processes.

Unfortunately, neither finding is entirely atypical of the results found in the literature. With regard to a specialized role for the hippocampus in this form of memory, the results are decidedly mixed, indicating a critical gap in our theories of hippocampal function or a critical methodological problem (such as the often-suggested possibility that our assessment of the damage in these patients is incomplete—see Section 12.3.3). In the particular case of these two studies, there is a potential solution to the disparity in the findings in the methodology. The potential solution serves to highlight how difficult this research can be and how tenuous the observations of differential impairments often are.

In a detailed reanalysis of the individual participant data from both data sets, Wixted and Squire (2004) noted that a single control participant of the 55 tested in the Yonelinas et al. (2002) study had a recognition score that was a marked outlier in the distribution of scores. The effect of this data-point was sufficient to skew the z-score analysis (see Section 12.3.2) and mask the apparent recognition memory impairment.

Results such as these led to a confused state of affairs in the literature, as it was often unclear what to make of the conflicting data and what factors have influenced the differing results. Looking at the effects on recall versus recognition, recollection versus familiarity, associations versus single-items, or episodic versus semantic memory, conflicting results abound. For example, Jon, a developmental-amnesic patient (neonatal hypoxia) with damage limited to the hippocampal region (as assessed by MRI), has been shown to exhibit clearly impaired episodic memory but has done relatively well in school and

obtained a solid vocabulary despite his amnesia (Vargha-Khadem et al., 1997). Jon has also been shown to demonstrate relatively normal levels of recognition memory (except on cross-modal tasks), relatively intact familiarity, and impaired recollection (Baddeley et al., 2001; Vargha-Khadem et al., 2001). Although Jon's amnesia was neonatal, it appears that this is not the source of the dissociation. While examining early-onset (perinatal to 3 months) versus late-onset (6–14 years) amnesia in children with MRI-confirmed hippocampal damage, Vargha-Khadem et al. (2003) noted substantial impairments on several standardized tests of episodic memory in both groups. In contrast, semantic memory, as assessed by measures of vocabulary acquired outside the laboratory, was in the low-average range in both groups, perhaps indicating only mild impairment (unfortunately, it is difficult to know if the amount of vocabulary training in the school or at home was similar to that of normals in these patients. (See Vargha-Khadem et al., 2001 for a similar finding.)

Furthermore, Y.R., an adult-onset amnesic patient (Holdstock et al., 2002a,b; Mayes et al., 2002) showed a similar impairment pattern. Across a series of 34 recall tests, Y.R. was substantially impaired relative to a group of healthy controls, obtaining an average z-score of -3.6. However, across a series of 43 recognition memory tests, Y.R. was only mildly impaired, averaging a z-score of -0.5 (Mayes et al., 2002). (Interestingly, by not showing a bias to view the novel item, Y.R. exhibits impaired performance in the visual paired comparison task at 5- to 10-second delays). Thus, even in a case of adult-onset amnesia, selective impairment in recall relative to recognition has been observed following hippocampal damage.

In contrast with the reports on Y.R. and the developmental amnesic patients, several studies other than that of Manns et al. (2003) have shown substantial impairments in item-recognition memory tasks in patients with hippocampal damage (Hopkins et al., 1995; Reed and Squire, 1997; Stark and Squire, 2000b, 2003; Stark et al., 2002). Thus, in some patients, hippocampal damage leads to substantial recognition memory impairments that are similar to their recall impairments. Furthermore, in two of these studies (Stark et al., 2002; Stark and Squire, 2003), single-item recognition (e.g., "Did you see this object before?") was compared with associative recognition (e.g., "You've seen both these objects before, but were they paired together?") in patients with damage limited to the hippocampal region. In both, single-item and associative recognition patients with hippocampal damage were impaired—and to the same degree (e.g., 15% impairment in single-item recognition and 13% impairment in associative recognition in Stark et al., 2002, experiment 1).

Thus, we have a number of studies that report a dissociation showing selective impairment in recall, recollection, or associative memory following hippocampal damage and a number of studies that clearly show no such dissociation. Currently, there is no clear means of explaining the varying patterns of results. Whether this is due to differences in undetected extrahippocampal damage, damage in the hippocampal

region (location or extent), the stimuli, the tasks, or the manner in which the patients approach the tasks is currently unknown. Perhaps most critically, the disparate results could arise from attempting to find evidence for the wrong dissociation. If the functional role of the hippocampus is correlated with episodic, recollective, and recall aspects of declarative memory, but in fact none of these aspects best describes its role, we could be left with a pattern of positive and negative results such as we currently face. For each positive result, some aspect of the task or stimuli correlated better with the unknown true functional role of the hippocampus than for each negative result.

### Neuroimaging

A significant number of recent neuroimaging studies have sought to complement the amnesic patient data on the functional dissociation between the hippocampal region and the adjacent cortical structures with respect to the associative, recollective, or source components of declarative memory. Although several patterns are beginning to emerge, the recent neuroimaging data also do not support a clean distinction between the role of the hippocampal region and the role of the adjacent cortical structures along these lines. Clearly, most studies to date have observed activity in the hippocampal region associated with associative, recollective, or source components of memory. However, in almost all of these studies, activity in the (presumed) parahippocampal cortex mirrors that in the hippocampal region. Furthermore, several have reported associative, recollective, or source components in (presumed) perirhinal or entorhinal cortices. In contrast, activity correlated with single-item memory or familiarity may not be limited to the parahippocampal gyrus, or even the perirhinal cortex specifically (see Section 12.4.5). For example, Henson and colleagues (2003) reported activity associated with familiarity in several studies within anterior portions of the MTL that appear to include entorhinal/perirhinal cortices and the hippocampal region as well. Thus, the conclusion best drawn from the following review is that the existing data are certainly not supportive of a clean functional distinction between the hippocampal region and the adjacent structures according to the recollective, associative, or source components of declarative memory.

Several studies (e.g., Henson et al., 1999; Eldridge et al., 2000) have examined the dissociation between recollection and familiarity using the Remember-Know (Tulving, 1985) task. In this task, Remember responses are used to index recollective memory, and Know responses are used to index recognition based on familiarity. Thus, a contrast between the two might be used to assess whether a region such as the hippocampus is particularly involved in recollective forms of memory retrieval. Henson and colleagues (1999) reported little differentiation between Remember and Know responses in the MTL, with no differences observed at the time of the test and only a small region in the parahippocampal gyrus showing less activity for subsequent Remember responses

than Know responses at the time of the study (significant differences were observed in frontal and parietal regions).

In contrast, Eldridge and colleagues (2000) observed greater activity for Remember judgments than Know judgments, correct rejections, and misses in the hippocampal region. These data are consistent with a greater role for the hippocampal region in Remember responses than in Know responses. However, there are some limitations to the Remember-Know task. First, it is difficult to perform in the fMRI scanner because it requires two steps to avoid becoming a simple confidence rating (Hicks and Marsh, 1999). If two steps are used (as was done in Eldridge et al., 2000), two cognitive processes are being engaged (first deciding yes/no recognition and then classifying the retrieval as Remember or Know), and it is impossible in fMRI data to separate activity from two events that always immediately follow each other (see Section 12.3.5). Additionally, it is difficult to ascribe the enhanced activity for Remember responses entirely to a functional dissociation favoring the recollective component of recognition. It is quite plausible that any more detail-rich retrieval would result in more activity than a detail-poor retrieval. As such, Remember responses might yield more activity than Know responses in a region not particularly involved in the recollective component itself. Finally, even if one reasonably assumes that some portion of the enhanced activity for Remember responses over Know responses can be attributed to recollective or associative aspects of processing, Eldridge et al. (2000) observed greater activity for Remember than Know responses not only in the hippocampal region but also in the parahippocampal gyrus (likely to be in the parahippocampal cortex). Thus, this recollective signal was not limited to the hippocampal region.

Activity tied to familiarity must be considered as well. Henson and colleagues (2003) reported activity associated with familiarity in several studies in anterior portions of the MTL that appear to include entorhinal/perirhinal cortices and the hippocampal region as well. Likewise, Stark and Squire (2000c, 2001a) reported activity in the hippocampal region during simple recognition memory tasks that can rely purely on familiarity, with no apparent increase in activity when the task became more associative or recollective (Stark and Squire, 2001a). Thus, the data do not support a clean functional dissociation between recollective processing in the hippocampal region and familiarity processing in the structures of the parahippocampal gyrus.

Several other studies have examined activity during the formation or retrieval of paired associates that may be used to determine whether the hippocampal region might be more involved in associative components of declarative memory than in nonassociative or single-item components. In one case (Sperling et al., 2001), associative encoding-related activity was observed in the hippocampal formation (defined as the hippocampus proper, subiculum, and entorhinal cortex) without observing significant activity elsewhere in the parahippocampal gyrus, supporting the notion that the hippocampus is particularly involved in associative aspects of memory. However, in a similarly designed study, but one that

restricted its analysis to the hippocampal region (Small et al., 2001), activity was observed not only for the encoding and retrieval of face-name associations but also for the encoding and retrieval of individual faces and names (although hippocampal activity for face-name associations was more widespread than the combination of activity for faces and activity for names alone). In both, a blocked design was used to contrast activity associated with viewing novel face-name pairs with activity associated with viewing repeated face-name pairs. Unfortunately, the blocked nature of the design impeded the ability to isolate individual encoding trials based on the quality or amount of information subsequently retrieved. Thus, in this study, it is difficult to know whether the greater activity associated with viewing novel face-name pairs was the result of encoding the face, the name, or the association or whether the activity resulted from a novelty detection (e.g., Strange et al., 1999).

Other studies contrasting associative and nonassociative memory have observed more widespread activity. For example Henke and colleagues (1997) used PET to measure activity during the encoding and retrieval of face-house pairs. More recently, Henke et al. (1999) used fMRI to measure activity during the encoding of semantic associations between words. In both studies, greater activity for associative relative to nonassociative memory was observed in both the hippocampal region and the parahippocampal gyrus. Similarly, in an fMRI study of recognition memory, Yonelinas et al. (2001) reported greater activity during associative than nonassociative recognition in both the hippocampal region and the posterior parahippocampal gyrus. Likewise, Pihlajamaki et al. (2003) observed their most consistent activity during the encoding of picture pairs not in the hippocampal region itself (where there was some evidence) but in the perirhinal cortex; and Sperling et al. (2003) reported activity associated with high-confidence encoding of face-name pairs in anterior portions of the MTL that covered the hippocampal region and the parahippocampal gyrus bilaterally (but whose most active voxels were in the hippocampal region bilaterally and in the right entorhinal cortex).

In addition to studying arbitrary associations, a number of attempts have been made to examine the automatic associations that are formed between memory for an item itself and the “source memory” or episodic knowledge of when and where that item was encountered (e.g., Did you see this item? If so, which study task was it in?). In an elegant example that looked at encoding activity that predicted subsequent memory for an item along with the source relative to encoding activity that predicted memory for the item alone, Davachi et al. (2003) reported a functional dissociation. Activity predicting subsequent source memory was somewhat widespread, with this associative activity observed bilaterally in the hippocampal region and in the left parahippocampal cortex. In contrast, item-only activity was observed solely in the left perirhinal cortex. Here, activity at encoding predicted subsequent memory in general (using as contrast greater activity at the time of encoding for items subsequently remembered relative to items subsequently forgotten), but the activity did

not differ as a function of whether the source aspect was subsequently remembered. Thus, the hippocampal region and the parahippocampal cortex appeared to play a role in encoding the source component, whereas the perirhinal cortex appeared to play a role only in encoding the item component of the memory (see Ranganath et al., 2003 for a similar finding).

In a related study, Kirwan and Stark (2004) examined activity during both the encoding and the retrieval of face-name pairs. Like Davachi et al. (2003), greater activity during the successful encoding of associations relative to their unsuccessful encoding (an “associative” pattern) was observed in the hippocampal region and the parahippocampal cortex (right unilateral in this case). Also like Davachi et al. (2003), a portion of perirhinal cortex showed a general subsequent memory effect that did not vary with the associative component (a “single item” pattern). Thus, associative signals were observed in the hippocampal region and the parahippocampal cortex whereas single-item signals were observed in the perirhinal cortex.

However, unlike Davachi et al. (2003), reliable signals that ran counter to this simple dissociation were observed as well. First, the associative pattern was observed in one portion of the right parahippocampal cortex during encoding, whereas the single-item signal was observed in a different portion of the right parahippocampal cortex. Thus, at the time of encoding, there was no clear differentiation observed between an associative hippocampal region and parahippocampal cortex and a nonassociative perirhinal cortex (nor, of course, was there clear differentiation between the hippocampal region and the parahippocampal gyrus as a whole). Furthermore, when examining activity during recognition memory testing, the left perirhinal cortex, right entorhinal cortex, right hippocampal region, and right parahippocampal cortex all showed an associative pattern of activity (greater activity during retrieval of the face/name pair and their association relative to the retrieval of the face and name without their association). Thus, at time of retrieval, greater activity in the associative than in the nonassociative condition was observed throughout the regions of the MTL, with similar amounts of associative activity (contrast between associative and nonassociative retrieval) across MTL structures.

Dobbins et al. (2002) reported a similar dissociation during retrieval of source information (what task was performed at the study?) and recency information (which word appeared more recently on the study list?). When examining activity in the source retrieval task, activity in the hippocampal region, the posterior parahippocampal gyrus (likely the parahippocampal cortex), and activity in the entorhinal/perirhinal cortex all were associated with greater activity during correct source retrieval than incorrect source retrieval. In the hippocampal region and the posterior parahippocampal gyrus, an overall task effect was observed, with both regions showing greater overall activity during source than recency judgments. In contrast, although activity in the entorhinal/perirhinal cortex indexed accuracy in the source retrieval task (it was affected by accuracy of source judgments), its activity was similar for source and recency judgments overall. Therefore,

whereas the hippocampal and posterior parahippocampal gyrus activity could be easily explained as indexing source retrieval, the entorhinal/perirhinal activity was a more complex combination of source and recency-related activity.

Thus, the current neuroimaging evidence has clearly implicated both the hippocampal region (Henke et al., 1997, 1999; Eldridge et al., 2000; Small et al., 2001; Sperling et al., 2001, 2003; Stark and Squire, 2001a; Yonelinas et al., 2001; Dobbins et al., 2002; Davachi et al., 2003; Ranganath et al., 2003; Kirwan and Stark, 2004) and the parahippocampal cortex (Henke et al., 1997, 1999; Eldridge et al., 2000; Yonelinas et al., 2001; Dobbins et al., 2002; Davachi et al., 2003; Ranganath et al., 2003; Kirwan and Stark, 2004) in recollective and associative memory encoding and retrieval. Furthermore, there has been some support for the perirhinal cortex and the entorhinal cortex in this regard as well (Dobbins et al., 2002; Pihlajamaki et al., 2003; Sperling et al., 2003; Kirwan and Stark, 2004) (see also the discussion of Hartley et al., 2003, in Section 12.4.4). Thus, it would be an oversimplification of the data to conclude that the fMRI data support a specific or unique role for the hippocampal region in associative or recollective aspects of declarative memory, as the same patterns of activity clearly extend into the adjacent cortical structures (most often the parahippocampal cortex). Likewise, it would be an oversimplification to conclude that the fMRI data support a specific or unique role for any of the adjacent cortical structures in nonassociative forms of declarative memory. Although there is evidence for nonassociative or familiarity-based activity in the entorhinal and perirhinal cortices (Dobbins et al., 2002; Davachi et al., 2003; Henson et al., 2003; Ranganath et al., 2003; Kirwan and Stark, 2004), there is evidence for such activity in the parahippocampal cortex (Kirwan and Stark, 2004) and in the hippocampal region (Stark and Squire, 2000c; Small et al., 2001; Stark and Squire, 2001a; Henson et al., 2003). In addition, each of these structures has been shown to respond according to the associative or recollective nature of the task as well. Accordingly, although these neuroimaging data cannot be resolute with respect to function (all are correlational data sets), they certainly do not support clean dissociation of function in the MTL according to recollective, associative, or source components of declarative memory.

## 12.5 Conclusions

We began this chapter by asking the question, *What does the human hippocampus do?* The significant amount of research that has followed Milner’s initial hypotheses has allowed us to reach a number of clear conclusions. First, along with the adjacent cortical structures in the parahippocampal gyrus, the human hippocampal region is critically involved in memory for facts and events (explicit or declarative memory). Second, this involvement is time-limited. Third, the hippocampal region and the adjacent cortex are not involved in immediate or working memory process and are not involved in a wide

range of implicit or nondeclarative long-term memory process (although they may be used in working memory or implicit tasks that evoke declarative processes). Fourth, the hippocampal region is not involved in nonmnemonic aspects of cognition including spatial processing (although spatial memory is a clear example of its time-limited mnemonic role).

However, despite these strides, the differentiation of function between the hippocampal region and the adjacent cortical structures of the parahippocampal gyrus is not currently apparent. That the hippocampus is involved in associative, recollective, or source components of declarative memory is quite clear. Lesions to the hippocampal region yield deficits on tasks that assess these forms of memory, and neuroimaging studies have observed activity correlated with them as well. However, it is equally clear that the hippocampus can be involved in single-item, nonassociative, and familiarity-based components of declarative memory as well. Hippocampal lesions have resulted in deficits on these tasks, and hippocampal activity has been observed during them. Furthermore, the adjacent cortical structures (most notably the parahippocampal cortex) may also serve to support associative, recollective, or source components of declarative memory. Thus, the available data do not support a clean division of labor along any of the lines proposed.

Some differentiation exists. Not only does the anatomy suggest functional differentiation, the research to date has often yielded solid evidence of functional dissociations. However, pushing our interpretations of these dissociations and the theories that fall out of them has often led to clear disconnects between the theoretical predictions and additional data.

There is a difficulty faced when one tries to assign function to a region based on the impairment observed following damage or based on a set of signals recorded from the region. If a hippocampal lesion impairs task X, does it mean that the hippocampus *does* task X? Difficulties with dissociations aside (which are also discussed in Chapter 13), even if we are certain that the ability to perform task X critically depends on processing that occurs in the hippocampus, it is still a large leap to the conclusion that the purpose of the hippocampus is to give us the processing required by task X. Yet, this is the kind of conclusion the dissociation approach can easily encourage unless one is extremely cautious about the interpretation of the data.

A more concrete example might make this problem clear. Suppose there is a task that requires one-trial learning of associative, complex, cross-modal, relational, novel, arbitrary information. Further suppose that a complete bilateral lesion to the hippocampus entirely removes the ability to perform this task at above-chance levels. One might conclude quite reasonably that the hippocampus allows us to, or is necessary to, perform one-trial learning of associative, complex, cross-modal, relational, novel, and arbitrary information. However, it would not be reasonable to conclude that this is the only thing the hippocampus does. The hippocampus might well be involved in one-trial associative, complex, cross-modal, and relational memories between pieces of information that are

not entirely novel or arbitrary. If it were not, we'd have a hippocampus that is rarely doing anything at all, as few experiences would satisfy the extreme end points of the dimensions laid out here.

Furthermore, it might well be that if one or more of these constraints were dropped or weakened, adjacent cortical regions might be able to perform the task to some degree. With the bias toward visual information found in perirhinal cortex, perhaps associative, complex, relational, novel, and arbitrary information could be learned to at least some degree if it were not heavily multimodal and if the test were not all-or-none but sensitive to somewhat more gradual learning. By still being somewhat multimodal, perirhinal cortex may support learning of multimodal information but only when other constraints are weakened.

In this situation (which parallels the data at least in spirit), what would we claim to be the function of the hippocampus? Are there tasks that only the hippocampus can perform? Yes, but, is that all that the hippocampus does? No. Is there a single feature of a task that allows us to determine that the hippocampus and only the hippocampus can perform the task? Not really. There is a combination of features, each of which points toward strengths of the hippocampus that, when taken together, isolate it as the only structure capable of performing the required task. By virtue of the anatomy, the hippocampus receives the most highly processed, multimodal information and is well designed to learn new arbitrary information rapidly. Structures such as the perirhinal cortex receive less processed, more modal-specific information and are less well designed to learn new arbitrary information rapidly.

Therefore, despite finding what might be a task clearly to isolate the hippocampus, we may very well be right back in the opposite class of theory. Even with a task that dissociates the hippocampus from the rest of the brain, the hippocampus may be combining and extending the processing of the adjacent cortex in the medial temporal lobe. It is not that the hippocampus is doing anything all that different from the adjacent cortex, it is merely that it has access to more complete, more refined information and can learn a bit more rapidly. Thus, what initially appears as a clear qualitative dissociation may, in truth, be far more quantitative in nature.

This is not meant to discourage the quest for dissociations. By finding such dissociations, we get to know in what tasks the hippocampus (or any other structure) plays a critical role. In so doing, and when looking across data sets, we can attempt to discern just what aspects make a task fully dependent on the hippocampus and what aspects make a task partially dependent on the hippocampus; we therefore can then define just what the hippocampus may be doing for us. What this is meant to argue against is the simple extension from dissociation to functional interpretation. The shorthand of labeling a structure such as the hippocampus as "performing task X memory" or "being responsible for" a particular kind of memory implies that it does not perform task Y memory, and other structures cannot be responsible for this kind of memory. It is not the dissociation in the data that is problematical but its

interpretation as a binary functional dissociation that does injustice to the data and oversimplifies the operation of a complex, highly interconnected and dynamic system.

What we are then currently left with is incomplete understanding of the medial temporal lobe and the role the hippocampus plays in its function. As several have suggested, the division of labor is likely to be graded rather than absolute (e.g., Lavenex and Amaral, 2000; Suzuki and Eichenbaum, 2000; Stark et al., 2002; Norman and O'Reilly, 2003). Although it may best be thought of currently in terms of combining and extending the processing of the adjacent cortex, this is still an unsatisfying definition of the role of the hippocampus. We still do not know the exact nature of this division of labor, what exactly can be combined and extended, how it is done, and how the collection of structures interact to perform this mnemonic function. We also do not know the role of the perirhinal, entorhinal, and parahippocampal cortices; and we do not know how they all interact as a dynamic system. These issues represent currently active areas of experimentation and theoretical development, and all can benefit from the recent methodological advances laid out earlier in the chapter. In short, although our present understanding of human hippocampal function is far from complete, we have certainly made great strides. This is an exciting time for human hippocampal research.

In conclusion, one final point needs to be addressed. Throughout this chapter, the hippocampus and the rest of the medial temporal lobes have been discussed as providing a critical role in declarative or explicit long-term memory. The reader should not take this to mean that the structures of the medial temporal lobe are the only ones responsible for long-term memory performance. Their role is essential, as they appear to act as a repository for this kind of information or at least for some compressed version of this information (i.e., a "pointer") for some period of time. However, encoding and retrieval tasks engage structures well beyond the medial temporal lobes. For example, in cued recall, the cue must be assembled in some format suitable for probing memory's contents, and the results of the retrieval must be interpreted and evaluated. Quite likely, the results of the initial retrieval attempt leads to an extended or revised cue that is again used in a retrieval attempt. Much of this appears to be the purview of structures outside the medial temporal lobe (of frontal structures in particular), making memory, and even long-term declarative memory, the operation of a large system of structures. The medial temporal lobe and the hippocampus in particular are but one component, albeit a vital component, of this larger system.

## ACKNOWLEDGMENTS

The author thanks Shauna Stark, Brock Kirwan, Yoko Okado, Marci Flanery, and Richard Morris for their comments on drafts of the chapter; Susan Corkin for providing previously unpublished data on H.M.; and the National Science Foundation for support.

# Theories of Hippocampal Function

## 13.1 Overview

What does the hippocampal formation do? Does it have one function or many? Can we understand its functions in isolation from that of other areas of the brain? The theories we review in this chapter all focus on the idea that it is a special kind of “memory machine.” The link between the hippocampus and memory is an old idea, having its roots in clinical and experimental observations on patients who sustained brain damage that included the hippocampus but all too often extended into other areas of the medial temporal lobe or midbrain (see Chapter 2). Careful study of the small number of patients with more selective damage (see Chapter 12) and that of animals given experimental lesions or other interventions (see later in this chapter) has provided further grounds for believing that the integrity of the hippocampal formation is causally involved in implementing some but not all types of memory. Given that multiple “types” of memory have now been proposed—such as declarative, spatial, and episodic memory—the focus of this chapter is on identifying which of these or other putative types of memory are mediated by the hippocampal formation. Success in this task requires that we recognize that the hippocampus operates in conjunction with other networks and brain structures, including neuromodulatory afferent systems emanating from the midbrain and diverse regions of the neocortex. Any claim that the integrity of the hippocampus is required for one or another type of memory does not, therefore, mean that other brain areas are not involved as well. Discussion of types of memory and their anatomical substrate carries us forward to consider the logically distinct issue of the various “phases” of memory processing in which the hippocampus may be engaged—the encoding of information into memory, the storage of memory traces as biochemical and structural changes in the nervous system, the consolidation processes responsible for their

stability over time, and the subsequent retrieval and reactivation of hippocampus-dependent memories during recall. Newer research techniques, such as functional magnetic resonance imaging (fMRI) in humans and invasive techniques with animals such as ensemble single-cell recording and selective neuropharmacological perturbations, all point to a role for specific aspects of hippocampal neural activity in successive phases of memory processing.

Two theories have dominated research on hippocampal function over the past quarter century. The first, discussed in Section 13.3, is that it is involved in the formation of memories for everyday facts and events that can be consciously recalled—collectively called *declarative memory* (Squire, 1992; Squire et al., 2004). Complementing the human studies of the preceding chapter, a particular focus has been the development of a primate model of amnesia built largely on studies of recognition memory. Other behavioral tasks have also been examined, but they have been secondary to testing a key issue: whether the hippocampus is involved in recognizing stimuli that have been presented before. The other major theory (see Section 13.4), emerging from observations first made during the recording of single-cell activity in freely moving rodents (see Chapter 11), is the idea that it is involved in *spatial memory* and, more specifically, the formation of cognitive maps and their use in navigation through space (O’Keefe and Nadel, 1978; Burgess et al., 2002). This theory makes testable predictions about the cell activity that occurs during spatial navigation and the impact of hippocampal dysfunction on spatial memory. Although enormously influential, and often at loggerheads with each other, it will become clear that neither of these two major theories offers a fully satisfactory account of the available data.

Section 13.5 discusses a range of alternative theories, particularly those built around how memory systems handle ambiguity, associative-relations, and context. In 1984, Schmajuk identified more than 20 psychological theories of hippocampal function (Schmajuk, 1984). There have been yet

others since. Here we focus on certain particularly influential ideas of the past 25 years, namely that the hippocampus implements a learning process involving the formation of *stimulus configurations* (Sutherland and Rudy, 1989a; O'Reilly and Rudy, 2001), that it is involved in the *relational processing* of stimuli in a manner that enables flexible retrieval (Cohen and Eichenbaum, 1993; Eichenbaum and Cohen, 2001), or that it provides the substrate for encoding and retrieval of information in relation to the *spatiotemporal context* in which that information occurs. Contexts, relations, and configurations may each help disambiguate conflicting associative relations in which a specific stimulus occurs (Hirsh, 1974; Good and Honey, 1991). Although perhaps less prominent than the two major theories, these ideas have been important in expanding our concepts of what memory is all about and its mediation by diverse structures in the brain.

The present focus on memory is, arguably, too exclusive. The hippocampus has also been implicated in a range of other brain functions, including behavioural inhibition and anxiety (Kimble, 1968; Gray, 1982; Davidson and Jarrard, 2004), sensorimotor function (Vanderwolf and Cain, 1994), and acting as a comparator to detect novelty (Gray, 2000). The presence in the hippocampus of a high density of receptors for adrenocortical hormones such as cortisol and corticosterone has also implicated the hippocampus in the cognitive regulation of stress and the hypothalamic-pituitary axis (Sapolsky, 1985; McEwen and Sapolsky, 1995; de Kloet et al., 1999). For clarity, these issues are considered separately in Chapter 15.

Certain concepts relevant to identifying hippocampal function in relation to memory are excluded from detailed discussion in this chapter because it seemed most appropriate to outline them elsewhere. They include the widely discussed idea that activity-dependent synaptic plasticity, such as long-term potentiation (LTP) and long-term depression (LTD), might play a role in learning and memory (Martin et al., 2000; Bliss et al., 2004). This important topic is discussed at the end of Chapter 10. Hebb's concepts of the "cell assembly" and "phase sequence" (Hebb, 1949) and Marr's proposal that distributed associative memories could be implemented by hippocampal local circuitry (Marr, 1971) were both touched on in our historical overview (see Chapter 2) and are developed more fully in Chapter 14. Neural network modeling is a field in its own right that has matured to a level of conceptual and mathematical precision that is beyond the scope of this chapter (Willshaw and Buckingham, 1990; O'Reilly, 1998; Rolls and Treves, 1998; Lisman and Zhabotinsky, 2001; O'Reilly and Norman, 2002).

The chapter concludes by zeroing in on the idea that neural activity in the hippocampal formation contributes to episodic memory (Tulving, 1983; Aggleton and Brown, 1999; Redish, 1999). This contribution has been variously characterized as remembering the "scenes" in which events take place (Gaffan, 1994a), or as processing the "automatic" components of recording and recalling experience that are downstream of neocortical attentional systems (Morris and Frey, 1997). In animals, where the phenomenological aspects of memory are

so difficult to capture (Hampton and Schwartz, 2004), this is now often referred to as "episodic-like" memory (Clayton and Dickinson, 1998). Although also applied elsewhere, it is in this section that we see the greatest implementation of new research technologies, such as novel behavioral tasks, reversible pharmacological manipulations, and region-specific gene targeting. This new way of thinking about hippocampal function also draws more explicitly on the anatomical, physiological, and cell biological ideas discussed in earlier chapters of this book.

In each section, the main concepts of each theory are outlined followed by an examination of exemplar experimental work that supports or conflicts with it and then a general critique. Given the scale of the literature, no attempt has been made to be definitively inclusive, and the choice of studies cited is inevitably subjective. When possible, an attempt is made to refer to ideas about hippocampal function that have emerged from the principles discussed in earlier chapters. Understanding the hippocampal memory machine is an ambitious exercise that requires integrating "top-down" psychological concepts about the distinct types and processing phases of memory with "bottom-up" physiological and cell biological ideas about the local networks, cells, and signal transduction pathways that constitute this beautiful brain structure.

## 13.2 Cognitive and Behavioral Neuroscience, Interventional Techniques, and the Hippocampus

### 13.2.1 Value of Interventional Studies to Identify Function

If you want to learn how a machine works, it is a good idea to watch it working. An appropriate next step is to look at selective interventions that disrupt one part of the machine or another and study the various changes in the machine's operation that then occur. In the case of a modular organ such as the brain, it is essential to complement studies that involve its cells being cut up, put under microscopes, poked with electrodes, or bathed in drugs (see Chapters 3–11) with studies of selective interventions that may affect its behavior. This is part of what cognitive and behavioral neuroscientists do to try to understand the functions of the distinct but interacting regions of the brain. Lesion studies in animals, on which we largely focus in this chapter, have been the classic "interventionist" technique for testing theories of function. They have their methodological and interpretative problems, as do pharmacological and genetic techniques. Intervention is, however, the only way to secure definitive information about whether the integrity of a particular anatomical region of the brain or specific physiological and cell biological processes in it is *necessary* for a particular function.

In humans, damage to the brain may arise because of a tumor, a stroke, or a viral infection, or it may be incurred

through neurosurgery undertaken to prevent further brain damage (e.g., the surgical management of epilepsy). A few striking and analytically valuable exceptions aside, lesions that arise from these causes are rarely restricted to anatomically circumscribed areas of the brain; nor when they are is the damage incurred ever complete (see Chapter 12). In animal studies, in contrast, specific brain regions can be subject to selective lesions to evaluate whether one or more functions can still be carried out normally. Postmortem histological techniques complement the behavioral observations, providing a vital, relatively immediate check on an experimentalist's intentions with respect to the site and size of the lesion. It is also now possible to use histologically calibrated structural MRI techniques *in vivo* to establish the accuracy and extent of damage before extensive behavioral testing is undertaken (Malkova et al., 2001).

The lesion method is, of course, used widely in biology, the modern variants of it being pharmacological techniques directed at specific receptors or targeted molecular engineering to investigate gene function ("gene knockouts"). The common analytical principle underlying such approaches is that the study of dysfunction offers insights into normal function. Creating dysfunction does not necessarily require invasive interventions—the study of visual illusions being a case in point—but the neurological approach, as twentieth century neurologist Sir Henry Head put it so well, is one in which "it should not be the injury that captures our attention but how, through injury or disease, normal function is laid bare."

There are, however, problems strewn along the path of laying things bare. In some cases it is the pitfalls of the approach that lead an investigator astray. First, a brain reacts to permanent damage with repair mechanisms—cerebrovascular, neural, glial—that collectively result in dynamic changes from the moment the damage occurs. It may be some while before brain function restabilizes after surgically induced diaschisis (Stein et al., 1983; Finger et al., 2004). Second, even when it does restabilize, we should not assume that adjacent undamaged brain areas necessarily function normally, as the neural activity carried on input pathways may have been affected by the nearby damage. Lesions can also induce structural changes, such as axonal growth and synaptogenesis (see Chapter 9). This "sprouting" can be compensatory and thus homeostatic, or it may give rise to abnormal circuitry not usually seen in the normal brain (Lynch et al., 1973; Steward et al., 1974). Third, even if postlesion reorganization achieves relatively little in the way of compensation for lost tissue, the person or animal may still alter his behavior in a manner that enables him to compensate for lost function through the use of undamaged systems. Behavioral compensation can help mask a neurological deficit. With respect to damage to the medial temporal lobe and the ensuing amnesia, for example, the use of memory aids such as electronic devices to remind people to do things is one example of such "compensatory" behavior (Wilson, 1999). Desirable as these aids are therapeutically, the possibility that behavioral compensation occurs naturally over the course of time adds difficulties

to the neuroscientist's efforts to interpret lesion effects in relation to the functional theories they are intended to test. Notwithstanding these obstacles along the path, interventionist techniques can be used successfully, provided a number of conceptual issues are also considered.

### 13.2.2 Lesions, Functional Hypotheses, and Behavioral Tasks

#### Dissociations, Double Dissociations, and Hypotheses

Experimental lesions are widely used to establish functional dissociations between tasks that are thought to depend on distinct forms of information processing. Thus, if behavior A is *impaired* by a lesion made in area X and, simultaneously, behavior B is *unaffected* by lesion X, there are grounds for suspecting that behaviors A and B may, at least in part, depend on different brain circuits. The confidence in such assertions grows when a so-called double dissociation is obtained—when a different lesion Y impairs behavior B but not behavior A (Teuber, 1955). However, discovering a list of behaviors that are affected or unaffected by a particular set of lesions (or other intervention) is only the first step toward such a theory.

An essential parallel step is the development of hypotheses about information processing in the brain (Shallice, 1988). Numerous hypotheses have been developed by cognitive neuroscientists to account for the cerebral organization of perceptual processes, attention, language processing, executive function, and memory (Shallice, 1988; McCarthy and Warrington, 1990; Gazzaniga, 2002). With respect to the hippocampal formation, numerous hypotheses have been developed and are discussed in this chapter. As we saw in the overview, these theories differ in their claims about the character and timing of the information processing that is taking place in the hippocampal formation during learning and memory.

#### Learning, Performance, and Hippocampus-dependent Learning and Memory Tasks

One important theme in studies of learning and memory is the distinction between *learning* and *performance*. In a behaving animal, performance is what we can see and measure, whereas learning reflects a variety of covert processes that we presume are taking place in the brain. It is these covert processes that are responsible for the acquisition of knowledge. Performance is the expression of this knowledge. Of course, performance may also itself be learned, as occurs with sensorimotor skills, but it is often a reflection of learning rather than being a participant in such a process. Obstructing performance in some way (e.g., by putting a barrier in a maze that an animal has been trained to run through) may prevent the usual expression of learned performance, but it does not affect what the animal "knows." The animal generally tries to find an alternative way in which to express this knowledge,

such as its memory of where some desired food is located (Tolman, 1948).

The concept of learning itself must also be fractionated as the brain has evolved to have a number of qualitatively distinct forms of learning. Most theories of hippocampal function are statements about the type (or types) of learning and memory in which this group of structures is engaged. There is passionate debate about how to characterize them. Over the years, a range of learning tasks have been developed that are now widely used in studies with rodents, primates, and birds to try to identify which of them involve hippocampus-dependent processes. Widely used tasks for rats and mice include alternation protocols in T mazes and cross mazes, foraging for food in radial mazes, and other spatial tasks such as finding the way home in an open arena or swimming to safety in a watermaze. Recognition memory can be studied by presenting novel and familiar objects or by taking advantage of rats' superb olfactory sense and then "asking" which object or smell is familiar. One widely used protocol is the conditioning of fear to the context where testing takes place, and another examines the social transmission of food preferences. Certain protocols of some of these tasks seem to be "hippocampus-dependent" (i.e., affected by hippocampal lesions), whereas others are not. The community that conducts research on temporal lobe function in primates has its family of tried and trusted tasks for investigating memory ranging from manual protocols with three-dimensional objects to automated touch-screen technology, some of which has now seen application as neuropsychological tests for humans (Robbins et al., 1994). Birds are also used extensively, with due consideration to their natural behavioral ecology. Innovation has gone into the design and development of rigorous laboratory-based tasks such as food caching and recovery (Suzuki and Clayton, 2000). In using this range of tasks, there is ongoing debate about the relative value of standardization on a subset of tasks that are then used in a common way within and across laboratories and of innovation with respect to procedure in the search for better ways of characterizing hippocampus-dependent learning and memory.

One complication is that there is rarely, if ever, a simple one-to-one mapping between a specific task and a single putative type of learning. All of them rely on effective sensory/perceptual processing in "upstream" brain structures and on effective motor processing "downstream." Researchers have then to be careful that any alteration in task performance caused by interventions is really due to an interruption of a neural process mediated by the hippocampus or to some secondary effect on upstream or downstream processes. The conceptual boundary between input, cognition, and output is hazy, particularly as it becomes ever more apparent that "bottom-up" processes can be modulated by "top-down" mechanisms. Indeed some researchers of a behaviorist persuasion even question whether the conceptual boundary between learning and performance exists, in part because an animal may appear to be unable to learn when, in practice, a treatment has been given that has affected only its ability to sense

afferent stimuli or to move around effectively (Vanderwolf and Cain, 1994).

### **What, How, and When: Different Aspects of Hippocampus-dependent Memory**

The overall aim of the functional enterprise is to find out what the hippocampus does and how it does it. Identifying which tasks are hippocampus-dependent and which are not is an important part of this endeavor, particularly when they shed analytical light on the relative merits of different theories.

There are, however, a number of ways in which learning and memory tasks can be theoretically ambiguous. The first has to do with *what* an animal learns. In a simple T maze, a rat might be taught to run from a start box in the stem and then turn left to find food at the end of the arm—but has it learned the motor response of turning left? Or that food is to be found near landmarks positioned on the left? One way to find out is to rotate the maze through 180° and now start the animal from the stem of the L maze. If it has learned the motor response of turning left, it should move toward what had been the right-hand side of the maze during training. Conversely, if it has learned to approach landmarks on the left-hand side of the room, it should now turn right at the choice point. This manipulation nicely dissociates control and hippocampus-lesioned rats early in training; but, interestingly, if training continues too long, normal rats develop a "turning habit" that is inflexible to manipulations of the starting location (Packard and McGaugh, 1996). Another example of ambiguity about what has been learned concerns recognition memory. Recognition can be defined as the memory of past occurrence (Brown and Xiang, 1998), but there are several ways it can be achieved. For example, recognition of a past stimulus by a monkey may be mediated by a feeling of familiarity evoked by the stimulus itself. Alternatively, the stimulus may evoke a covert mental recollection of past experience. The monkey cannot tell us about either of these possibilities in the way that a person would through language, but its sense of familiarity or its sense of recollection is expressed as appropriate choice behavior in a memory test (performance). A current challenge is trying to find a way of distinguishing these two possibilities of what the animal has learned.

The second kind of ambiguity arises if two or more theories offer different accounts of *how* an animal has learned a particular task. In this case, there is agreement about what the mouse, monkey, or human has learned but not how it has been achieved. Allocentric spatial learning is a relevant case in point, as there is widespread agreement that animals can learn where things are and that the hippocampus is involved but disagreement about how it is done. Questions include whether there is anything special about spatial learning that might require specialized neural circuitry, or is it just an instance of a more general form of declarative memory? Are different learning rules involved for spatial learning than other types of learning? Do different brain areas have to interact for spatial learning than for other forms of declarative or relational learning?

A third ambiguity arises from the distinction between *types* of learning and memory *processes*. The classic concept of a hippocampus-dependent learning task is one that is impaired by permanent hippocampal lesions. An unambiguous hippocampus-dependent learning task is one that is affected by such lesions but unaffected by others. However, this categorization does not capture the subtlety that neural activity in the hippocampus may be required at one stage of learning but not at another. It might, for example, be required at encoding but not at retrieval or during the initial stages of memory storage but not during consolidation. The logically orthogonal concept of a memory “process” refers to important distinctions that must be made between the distinct memory processes associated with encoding, storage, consolidation, and retrieval. It is orthogonal, as each of these processes applies to many types of learning and memory. They are distinguished experimentally through the various hemodynamic, physiological, or cell biological correlates that are seen in association with these various phases, by the impact of lesions made at different stages of training, and by the effects of reversible interventions (such as drugs) used to inactivate brain areas temporarily or to disrupt specific neural mechanisms.

Thus, the overarching task of dissociating theories of regional brain function involves zeroing in on *what*, *how*, and *when*. Many subtle variations in behavioral protocol are designed to explore the hypotheses. These variations of protocol are guided by predictions, better still by the counterintuitive predictions, of functional hypotheses about structure–function relations (Crabbe and Morris, 2004). The declarative memory, cognitive mapping, and predictive ambiguity theories outlined below often make common predictions about standardized versions of specific tasks but distinct predictions about their variants.

### Cerebral Localization or Dissociation Between Mental Processes?

A frequent non sequitur in the interpretation of an interventional study is the assertion, following a positive experimental finding, that a function can somehow be “localized” to the targeted brain structure or pathway. A classic and amusing critique of this “localizational” way of thinking was presented by Gregory (1961), who pointed out that if removing a part of an old valve radio causes the radio to howl it need not mean that the “function” of this bit is to suppress howling. This overly “symptomatic” way of thinking pervaded the hippocampal field early on and indeed much of the brain sciences since the early days of experimental neurology. One early claim about hippocampal function was that it is involved in “behavioral inhibition” (Kimble, 1968). This claim rested, in part, on the observation that hippocampus-lesioned animals are very inflexible in their behavior; they often persist much longer in carrying out well learned habits in inappropriate situations than do control subjects. Analysis of behavior in runways, mazes, and operant tasks has revealed, however, a number of

reasons why behavioral inflexibility could arise from other than excision of neural machinery that had (somehow) evolved to inhibit inflexibility. For example, if the lesioned animal has a deficit in spatial memory and so cannot learn or remember that one end of a runway (A) is in a different “place” than the other end of a runway (B), it cannot acquire knowledge about their relative location. It learns only to run. Changing a spatial performance strategy is much easier for normal animals than the “slamming on the brakes” to constrain a habitual running response (Nadel et al., 1975). The debate about the relative merits of these specific views has largely subsided, although the inhibitory view still has its followers (Chan et al., 2001; Davidson and Jarrard, 2004), but the logical point remains that the overt phenotype of response stereotypy need not imply the existence of an inhibition module localized in the hippocampus or, indeed, anywhere else in the brain.

Gregory’s (1961) critique should, however, not be overstated. If one were to lesion a car’s exhaust system, it would be right to infer that its function is to make the engine quieter. Damaging the earphones of an iPOD limits its ability make a sound. By the same token, in a modular structure such as the brain, inferences about localization may often be correct. If the overarching aim of the enterprise is to develop a theory of what different parts of the brain do and how they do it, we must also consider how brain areas interact to realize the seamless control of all aspects of behavior. It is an article of faith in the field that different brain areas or neuromodulatory transmitter systems must have different and therefore, at least in principle, dissociable functions.

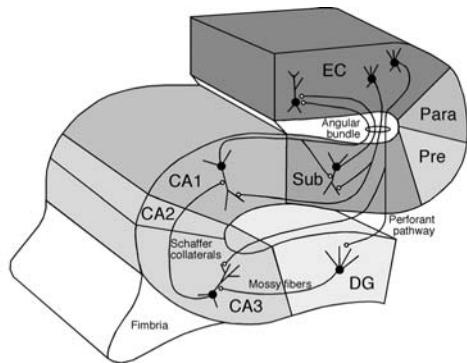

Equally, however, it is also understood that no brain area is an island; different brain areas work together in networks. In recent years, there has been growing interest in the issue of how memory systems interact—when they compete, when they complement each other, when the interruption of one enables another to learn faster or slower, and so on (White and McDonald, 2002; McDonald et al., 2004; Voermans et al., 2004). This change of emphasis is refreshing, as it counterbalances the near-exclusive stress on “dissociations” of earlier years. A desire to understand how these systems interact is taking its place as the brain sciences mature. In any event, whether the immediate aim is functional dissociation or the understanding of competition and/or complementarity, data secured using lesions and other interventions are a powerful way of testing theories.

### 13.2.3 Contemporary Lesion Techniques: Pharmacological and Genetic Interventions

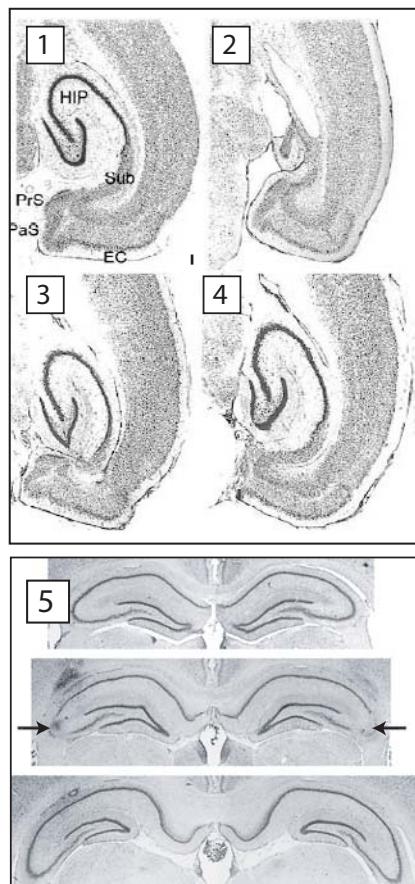

#### Neurotoxic Lesions

The technique by which a lesion is made can be important because certain techniques, such as the use of excitotoxins, first introduced to study hippocampal function by Jarrard (1989), have the effect of damaging cells while leaving fibers of passage intact (Fig. 13–1). Thus, if a brain function critically

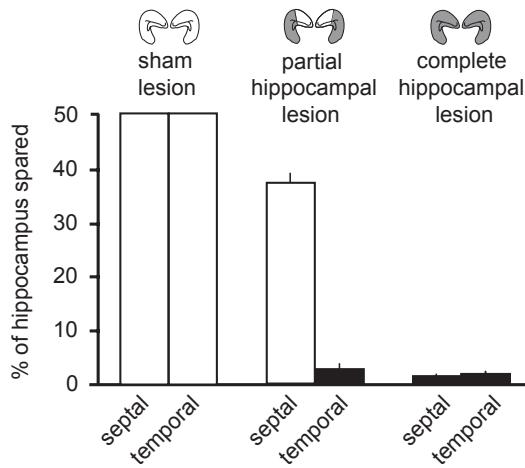

### A. Topological arrangement of HPC Formation

### B. Selective neurotoxic and knife-cut lesions in rats

### C. Quantitative assessment of partial lesion volume

**Figure 13-1.** Excitotoxic and knife-cut lesions of the hippocampal formation in rats. A. Topological arrangement of the structures comprising the hippocampal formation (from Chapter 3, Figure 3-1). B. Photomicrographs of horizontal sections from a representative control rat (B1) and rats with neurotoxin lesions of hippocampus (2), subiculum (3), and presubiculum/parsubiculum (4). EC, entorhinal cortex; HIP, hippocampus; PaS, parasubiculum; PrS, presubiculum; Sub, subiculum. (Source: Courtesy of Len Jarrard.) C. Use of three-dimensional volumetric techniques to

establish the quantitative extent of the cell loss associated with partial lesions placed at different points along the septotemporal axis. (Source: Courtesy of Livia de Hoz.) D. Use of a knife cut through the longitudinal-association pathway in area CA3. This cuts fibers (not shown) and damages a small number of cells in CA3 at one particular point along the axis. Animals to which the same amount of neurotoxic damage was deliberately applied without damaging the longitudinal fibers are used as controls in such a study. (Source: Courtesy of Hill-Aina Steffenach.)

depends on communication from area X to area Z, with fibers passing through area Y, old-fashioned lesions might lead to the false conclusion that area Y is essential for this function whereas the modern approach would not. By the same token, a positive outcome of a lesion study using an excitotoxin gives comfort to the notion that it is the targeted neurons that are functionally significant for the task under examination. Conversely, lesions that cut fibers while leaving cells intact can also be valuable, especially when the axons of a population of neurons have axon collaterals. Neurotoxic lesions can be highly localized (e.g., to distinct components of the hippocampal formation such as the dentate gyrus, subiculum, or entorhinal cortex). They may even extend to killing specific cell types in the region to which the toxin is delivered, such as the use of immunoglobulin G (IgG) saporin to ablate cholin-

ergic cells afferent to the hippocampus while leaving nearby  $\gamma$ -aminobutyric acid (GABA)ergic neurons intact (Gallagher and Rapp, 1997). It has been claimed that lesions restricted to area CA1 but not CA3, or vice versa, can be achieved with precise stereotaxic techniques (Lee and Kesner, 2004). This precision can certainly be achieved along a small length of the longitudinal axis of the hippocampus, but it remains unclear how complete and yet still selective such lesions can be. Lesions that cut fibers while leaving cells intact can also be valuable, especially when the axons of a population of neurons have axon collaterals, but it is extremely difficult to do this in a manner that interferes with one and only one fiber pathway.

Techniques for making permanent lesions are accompanied, when testing is complete, by histological analysis of the

damage caused. Was the target brain area damaged as expected? Was the lesion complete? Did it encroach on other brain areas? Did it damage cells and fibers or only cells? If the latter, was confirmation obtained through tract tracing techniques that the apparently intact fibers are capable of axonal transport? Doing this is part of the point of using animals rather than just studying people. Nissl stains, silver stains that reveal degenerating fibers, and other histochemical techniques can all be used to good effect. More ambitiously, one might enquire whether an apparently intact fiber tract at or near to a lesion site is electrophysiologically functional. Likewise, the check might be on whether the lesion has selectively affected one but not another neuromodulatory system by using *in vivo* neurochemistry to monitor changes of particular neurotransmitters. The use of all of these techniques for postexperiment histology is the “gold standard” to which most laboratories aspire, but a difficulty shared by all is that it is not always practical to dot every “i” and cross every “t” in every experiment. Much has to be taken on trust so research can proceed at a reasonable pace—but this trust is sometimes misplaced, which sows seeds of confusion. As will become clear, the size of a lesion can be a major factor to consider when interpreting experiments on hippocampal function in relation to recognition memory or spatial memory.

Permanent lesions are often used to realize network “disconnections” (Aggleton and Pearce, 2001). Most lesion studies in animals involve bilateral damage to a brain structure, but, in an ingenious twist, a unilateral lesion of one structure can be made in conjunction with contralateral damage to another. In right-handed people language is largely mediated by structures in the left hemisphere such that a stroke in the left brain can interfere with speech, whereas one on the right does so rarely (McCarthy and Warrington, 1990). Conversely, right-hemisphere damage to the parietal cortex is associated with the fascinating syndrome of spatial neglect (Behrmann et al., 2004; Farah, 2004). Laterality is barely present in animals (one exception being song birds), such that unilateral lesions in animals are often behaviorally benign. Thinking is shifting from a focus on localization toward a “crossed-lesion” approach to reveal the importance of functional connectivity. For example, a unilateral lesion might be made to the entorhinal cortex (on the left) and a second unilateral lesion to the fimbria-fornix (on the right) with, perhaps, section of the hippocampal commissures to prevent cross-talk of information within the hippocampus via residual interhemispheric connectivity. Such a lesion might produce a syndrome similar to that of an entire hippocampal lesion (even though the hippocampus and dentate gyrus are actually intact, and neither brain area that is lesioned has a bilateral lesion) because it has successfully disconnected cortical and subcortical structures that normally interact via the hippocampus. The “disconnection” approach is increasingly popular (Warburton et al., 2001; Gaffan, 2002; Miyashita, 2004). Disconnection of the hippocampus need not always be achieved by damaging afferent or efferent structures in opposite hemispheres. It can also be done by sectioning major interconnecting pathways, such

as the fimbria-fornix, or by selective knife cuts of intrinsic circuitry such as the longitudinal-associational pathway of area CA3 (Steffenach et al., 2002).

### Pharmacological and Genetic Manipulations

Drugs and genetic manipulations are alternative ways of intervening in brain function. The turn of the twenty-first century is something of a methodological “tipping point” (Gladwell, 2002) as the major behavioral neuroscience laboratories move on from deploying classic lesions on their own to using them in conjunction with single-unit recording and tract-tracing techniques, together with reversible pharmacological and cell biological manipulations. With respect to the opportunities afforded by targeted molecular engineering Wulff and Wisden quoted Francis Crick’s view that “the lesion approach needs new methods, especially as the usual ways of ablating the parts of the brain are so crude. For example, it would be useful to inactivate, preferably reversibly, a single type of neuron in a single area of the brain” (Wulff and Wisden, 2005, p. 44). As it happens, this would not be very useful for behavioral studies, as a certain minimum amount of tissue must be affected, but the point is taken nonetheless.

The use of drugs in conjunction with behavioral studies has a long scientific history (McGaugh, 2000). One aspect of this approach has been the analytical use of intracerebral infusions of microliter and nanoliter quantities of active compounds targeted to specific regions, often (although not always) given with posttraining to avoid the impact of known side effects. In relation to hippocampal function, typical drugs used include excitatory amino acid antagonists acting at  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), *N*-methyl-D-aspartate (NMDA), and metabotropic glutamate (mGluR) receptors, and ligands at inhibitory synapses such as GABAergic agonists (as described in Chapter 6). These compounds interfere with (or potentiate) normal excitatory or inhibitory neurotransmission for as long as the drug remains present and active at its site of administration. Drugs interacting with the synthesis, transport, or degradation of neuromodulatory transmitters—acetylcholine (ACh), norepinephrine (NE), dopamine (DA), and serotonin (5-HT), for example—or antagonists of their target receptors are also analytically powerful. There is growing interest in drugs acting intracellularly on signal-transduction pathways downstream of postsynaptic receptors, such as CAMKII and MAPkinase (see Chapters 6, 7, and 10). Their use requires compounds capable of penetrating cell membranes to reach their site of action rather than acting extracellularly at membrane-bound receptors (Sweatt, 2003).

The exploitation of drug actions in the hippocampal formation as a tool to study learning and memory function is a relatively new departure. One aspect capitalizes on the developments in our understanding of synaptic function discussed earlier in the book. An AMPA receptor antagonist, such as CNQX, shuts down normal fast synaptic transmission for a period of time (see Chapter 6). In principle, its effects should

be similar to that of a neurotoxic lesion that spares fibers of passage—with the analytical advantage of reversibility. In contrast, an NMDA antagonist such as D-AP5 has the distinct effect of blocking NMDA receptor-dependent mechanisms, such as activity-dependent synaptic plasticity (LTP and LTD), while leaving fast synaptic transmission intact. This should and does have very different effects on cognition than any permanent lesion could have, allowing previously acquired spatial memory to be displayed in performance but preventing new learning (Morris et al., 1986b). Interestingly, the effects of an NMDA antagonist such as D-AP5 are “regionally dependent” because NMDA receptors mediate different physiological functions in different brain areas. In the spinal cord, NMDA receptors help mediate suprasegmental connectivity, partly by enabling the rhythmical activation of  $\text{Ca}^{2+}$ -dependent  $\text{K}^+$  currents (Dale and Roberts, 1985; Grillner et al., 1998), whereas in the hippocampus they serve as a trigger for certain forms of neuronal plasticity (see Chapter 10).

What virtually all drugs have in common and what makes them so useful compared to lesions is that their actions are, at least in principle, reversible. Reversibility has two main ramifications. First, the intended dysfunction lasts only a short time, and thus the chances of brain damage or compensatory changes are reduced. Second, reversibility makes it possible to dissect different phases of memory—encoding, storage, consolidation, retrieval—in a more exacting way. However, no less than lesions, the impact of drugs must be studied with care. Drugs diffuse, raising questions about variation in concentration across a target brain region. This variation may itself vary with time, particularly with acute injections. Osmotic minipumps enable drugs to be infused at a steady rate over periods ranging from 1 day to 1 month. A steady-state concentration is then achieved when the rates of infusion and diffusion of a drug match precisely—a great advance on acute infusions. Last and by no means least, it is essential to establish precisely what and where a drug has had its effect. It is astonishing how rarely this is done independently of the effects on behavior that the drug may have. The use of autoradiography to establish the local spread of action of a radiolabeled version of a drug is valuable (Steele and Morris, 1999; Attwell et al., 2001), but this is a surrogate for an independent marker of its functional effect. If an AMPA antagonist is used, physiology should be undertaken to establish the extent to which synaptic transmission has been compromised. Monitoring glucose metabolism is one way of looking at this and direct physiological recording another (Riedel et al., 1999).

The last 15 years have witnessed considerable excitement regarding the introduction of transgenic and knockout mice as *in vivo* methods of genetic manipulation. Their application to study the systems-level and cellular mechanisms of learning and memory has been particularly imaginative (Tonegawa et al., 1995). Beginning with pioneering studies that targeted molecules such as  $\alpha$ CAMKII and *fyn* tyrosine kinase, which were implicated in LTP (Grant et al., 1992; Silva et al., 1992), an “industrial production line” of transgenic and mutant mice soon became available in virtually all fields of neuroscience

(Morris and Kennedy, 1992). Knockouts are now (almost) routine, with many a PhD student in well-founded molecular-genetic laboratories saying that they “would like to make a mouse” during the course of their studies. The development of these techniques has been accompanied by databases and repositories of mouse lines, such as those at the Jackson Laboratory in the United States (<http://www.jax.org/lab>), the development of testing facilities such as those at the Mary Lyon Centre in the United Kingdom (<http://www.mrc.har.mrc.ac.uk/aboutUs.html>), and meetings at which ideas and recommendations about breeding different lines of mice are debated in an open, constructive manner (Conference, 1997). Neuroinformatics expertise is having a considerable impact on the field (<http://www.neuroinf.de/Members/stefan/mbl>).

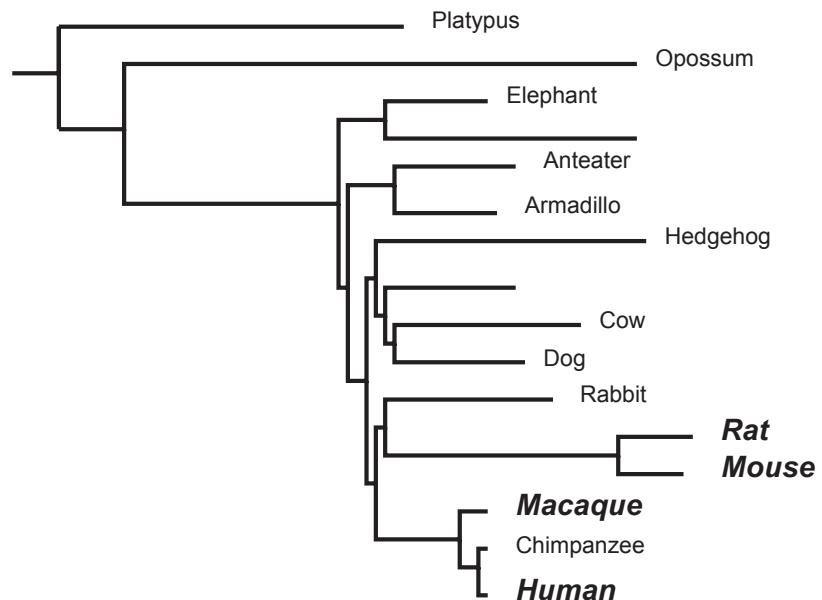

This molecular-genetic approach has now advanced from homologous recombination to regionally specific manipulations, using the cre-LOX procedure, enabling studies to focus on the role of genes in specific brain areas such as the hippocampus (Tsien et al., 1996). The introduction of inducible constructs, such as tetracycline, has taken the mouse knockout enterprise into a third phase of sophistication, potentially allowing the inactivation of specific genes at specific times in specific cells of specific regions of the hippocampal formation or other areas (Mayford et al., 1996). For all this enviable specificity, however, there remain formidable technical problems to be solved—not least the discovery of region-specific promoters and the apparent “leakiness” of inducible manipulations. Another problem is that most studies have to be conducted on mice. Many molecular behaviorists look on mice as “miniature rats,” but this is clearly absurd. Rats are different. A rarely tested assumption in the field is that hippocampus-dependent tasks for rats may be used similarly in mice. Other technical issues have to do with running appropriate controls for knockout mice made using homologous recombination (Gerlai, 1996), pleiotropic developmental abnormalities associated with deletion of a gene throughout embryogenesis and postnatal life (Tonegawa et al., 1995), and issues associated with the genetic or pharmacological rescue of a normal phenotype by transgenic expression of a gene in a mouse with a knockout background (Ohno, 2001). Others are longstanding conceptual problems such as the need, so rarely addressed, for the double dissociations that are common in conventional lesion studies. Fortunately, these problems are being recognized, and the solutions are forthcoming. The technological innovations are remarkable; they are continuing, and the molecular-genetic approach has a great deal to offer.

### **13.2.4 Biological Continuity of Hippocampal Function**

#### **Virtues of a Comparative Approach**

All mammals possess a brain with the same basic pattern of organization: spinal cord, hindbrain, midbrain, forebrain, and cerebral hemispheres (Swanson, 2000). The simplest view

## The genetic similarity of mammals

**Figure 13-2.** Genomic sequence similarity in mammals. Publication of the genomic sequence of the rat brain, following those of the mouse and of humans, provided an opportunity to assess the degree of sequence “similarity” across species. The outcome places rodents on a line less distant from primates and humans than that of many other mammalian species. (Source: Consortium, 2004.)

of this common pattern is that although there has been substantial encephalization of function in primates and humans relative to rodents the core functions of various areas of the central nervous system (CNS)—cerebellum, midbrain, neocortex—are most likely conserved across all mammalian species. Even where anatomical similarities may seem cryptic, there are striking genetic similarities that justify the use of primates and other mammals (Fig. 13–2), and there may even have been convergent evolution of certain aspects of anatomy and intelligence in avian species (Jarvis et al., 2005), as in the case of corvids (Emery and Clayton, 2004).

If this comparative assumption also applies to the hippocampus, which it surely should, the key advantage of using animals is that invasive anatomical, physiological, and behavioral studies can be carried out. Although not everyone shares the view that such work is ethically acceptable—a concern exacerbated by growing evidence of the complex emotional, cognitive, and cultural life of higher primates—most neuroscientists adopt the utilitarian perspective that such work is justified on its scientific merits and by its potential to relieve both human and animal suffering. The macaque monkey is a particularly suitable subject because Old World monkeys are closely related to humans, although the last common ancestor was about 30 million years ago (Kay et al., 1997). Its brain is remarkably similar to that of humans (see Chapter 3), and functional imaging studies are revealing striking similarities in, for example, the dynamic organization and responsiveness of the cerebral cortex (Van Essen and Drury, 1997). Rodents may seem less well justified on this account, although the topological organization of their brain is also quite similar (Whishaw, 2004b). The comparative similarity argument may

take flight with birds, but unlike rodents they are visual animals and have a number of other advantages than make them useful for certain studies.

When using animals, it is essential to be respectful of their biological needs, to use the minimum number necessary to realize the required level of statistical power, and to think carefully about how to motivate and reward them in an ethically acceptable manner. Reduction and refinement are laudable goals in animal experimentation. In general, we cannot ask animals to do something through language, but mild food deprivation creates the opportunity to “reinforce” an animal with rewards for performing a task. This is more charitable than it sounds because, as it happens, food deprivation actually lengthens the life of laboratory animals (Nelson, 1988). The use of mild electric shock to motivate animals in studies of learning and memory may seem unfortunate to some, but the neurobiological study of fear and stress is important; and there are circumstances in which the rapid learning achieved with shock cannot easily be achieved in other ways. Electric shock has the advantage of being variable and can be motivating even when quite mild, but it is artificial. It is probably no more stressful than the first day of swimming in a watermaze, although the stress of the latter habituates quickly, and escaping from water may be a more biologically meaningful form of motivation.

### Limitations in the Use of Laboratory Animals to Investigate Brain Function

Animal work does have its disadvantages. In comparison with human studies, animal studies include problems associated with what the animals may be said to “know,” with language

and communication, and the artificiality of the physical and social environments in which animals are tested.

Can we be confident that animals possess “knowledge” in the same way humans do? As certain kinds of human knowledge come to us via language (such as semantic, or “fact,” memory), some observers have questioned whether such forms of knowledge exist in animals (Macphail, 1998). An American knows that a “slam dunk” is a shot in basketball, and he can explain it to a puzzled foreigner; but how do we teach “knowledge” to animals? Do they have “semantic-like” knowledge or merely conditioned responses? Should we assume that a monkey “knows” that a particular object “means” reward simply because it has been consistently paired with reward, or that one stimulus leads to another because they are associated? The presence of pair-associate neurons in the temporal regions of the neocortex of monkeys is suggestive (Miyashita, 2004); and at a strictly behavioral level something akin to word learning has been demonstrated in dogs (Kaminski et al., 2004; Markman and Abelev, 2004). The primary reason for believing that animals “know” things is because they behave in relation to stimuli—food, water, shelter, danger—as if they know what these stimuli are. A monkey that has learned to use a rake to collect food that is beyond arm’s length probably does “know” what a rake is and what it can be used for. Receptive fields in appropriate somatosensory areas of the cortex expand in association with learning (Maravita and Iriki, 2004).

The problem is that, although the possession of knowledge does not logically require language, communication about it to others usually does. For example, episodic and autobiographical memories are about specific events (“what”) that happen in particular places (“where”) at particular times (“when”) (see Section 13.6). The memory that one person has of “what, where, and when” may be different from that of another person who experiences the same event; in fact, much discourse is concerned with debating such differences. It follows that it is difficult to investigate episodic memory in animals. The medium of communication is different and unlikely to be one that satisfactorily reflects that animal’s personal experience. Indeed, Tulving took the view that “as far as we know, members of no other species possess quite the same ability to experience again now, in a different situation and perhaps a different form, happenings from the past, and know that the experience refers to an event that occurred in another time and in another place” (Tulving, 1983, p. 1). Regardless of whether this skepticism is justified, we should recognize that distinguishing both “episodic-like” and “semantic-like” memory from mere changes in learned behavior is far from straightforward. Several studies have suggested that animals probably can remember events as events, and there is no a priori reason why language is necessary for them to be able to do so “at another time and in another place.”

The “training” (of animals) and the “asking” (of humans) may not always yield the same answer in experiments on learning and memory. The primary ways of teaching animals to perform particular behavioral tasks are, as we have seen, by

engaging their curiosity and the use of reward and punishment. Such techniques are more painstaking than merely asking a person to remember something; and they run the risk of missing important subtleties. The answers you get from humans who are doing memory tasks depend critically on the way the questions are put and thus the subject’s awareness of the problem at hand (Graf et al., 1984; Squire, 2004). This issue was discussed in detail in Chapter 12: recognizing the distinction between “explicit” and “implicit” memory processing. Although this distinction may also apply to animals—and the declarative memory theory argues that it does—it is difficult to get a handle on it analytically. It seems unlikely that we shall ever know whether animals are “conscious,” although here again experimenters have come forward with ingenious ideas to try tackle the problem.

Finally, behavioral tasks in the laboratory are clearly artificial, but then so are cyclotrons and supercolliders and, for that matter, test tubes. Science often has to be artificial to proceed. Biomedical laboratory work generally requires that animals are kept in somewhat artificial conditions, trained when they are experimentally “naïve” rather than after they have accumulated knowledge, skill, or experience, and often trained on protocols that seem to bear little relation to “normal” behavior in the wild. Many primatologists and evolutionary psychologists see this as a major problem (Tooby and Cosmides, 2000), particularly with respect to the evolution of social behavior. In contrast, others look upon ecological factors (and species differences) as somewhat tangential to the primary task of searching for general principles of brain function (Macphail, 1982; Bolhuis and Macphail, 2001). This disagreement has provoked much debate (Healy and Braithwaite, 2000; Hampton et al., 2002). What is not always appreciated is the extent to which certain laboratory tasks are either explicitly designed to be analogous to things that animals do in the wild (e.g., recognizing a previously seen stimulus) or unexpectedly turn out to be analogous to naturalistic behavior. An example is the ability of rhesus macaques to learn arbitrary “sensory-motor mappings.” These are tasks that require a monkey to perform action A to stimulus A, action B to stimulus B, and so on. In one laboratory investigation of this ability, different visual cues were presented to rhesus monkeys, with the monkeys then having to make different movements of a computer joystick (Brasted et al., 2002). Such sensorimotor mappings are learned quite slowly; and on the face of it, this may seem hardly surprising as monkey cognition did not evolve to play computer games. However, as pointed out by the authors, the different actions of vervet monkeys to different alarm calls made by troop members (Seyfarth et al., 1980) are also examples of arbitrary sensory-motor mappings. Monkeys climb trees in response to the “barking call” uttered when a leopard is nearby and look skyward followed by hiding in bushes to the “cough call” uttered when an eagle is spotted. Brasted et al. (2002) summarized evidence indicating that these different actions to distinct stimuli seem to be learned, just as the computer joystick movements have to be. An apparently abstract laboratory task may be

somewhat closer to primate “cognitive ecology” than might be appreciated.

To conclude: interventional studies in animals are a powerful way of investigating brain function. When using them in conjunction with behavioral tasks, we must accept that the way in which hippocampal function is studied in animals has to be different from the approaches described in Chapter 12 because animals cannot talk, they cannot tell us of what they are aware (if anything), and they are unlikely to have a sense of their past or their future or to have, to quote Tulving (1983) again, “quite the same ability to experience the past” that humans do. It does not follow, however, that these differences of approach mean that the hippocampal formation in animals is carrying out a different memory function than exists in humans.

The enlightened possibility, reflecting the commonalities of anatomy, physiology, and cell biology, is that it carries out essentially the same information-processing algorithms but that they might *seem* to be different because the human hippocampus and the animal hippocampus are operating on different inputs and so provide different outputs to downstream targets. A metaphor may help to explain the gist of this idea. Imagine being able to transplant the hippocampus of a monkey into the brain of a human. Suppose the neurosurgeon is the wizard we know all neurosurgeons to be, and that she successfully connects up all the nerves and blood vessels to their appropriate targets. Our perspective is that the result of such an operation is that all should be well—our monkey hippocampus should work normally inside the human brain. However, because it would now be receiving different kinds of information from its cortical and subcortical inputs, the end result would be appropriate to the *human*, not the monkey. Laterality of function in the human brain is a less fanciful illustration of the same argument because it seems unlikely that the left and right hippocampi of humans are anatomically, physiologically, or biochemically very different; yet the outcomes of their processing are clearly distinct. With this “optimistic” perspective of the enterprise at hand, we now proceed to discuss the major theories of hippocampal function.

### 13.3 Declarative Memory Theory

#### 13.3.1 Outline of the Theory

In 1980, Cohen and Squire suggested that the distinction between “declarative” and “procedural” information processing could be relevant to the pattern of memory deficits seen with amnesia. Drawing upon Gilbert Ryle’s distinction between “knowing that” and “knowing how” (Ryle, 1949), they proposed that amnesic patients are impaired in forming conscious memories of facts and events (“remembering that”) but have relatively normal learning motor and cognitive skills (“remembering how”). Following Milner’s observations of successful motor learning in patient H.M. (see Chapters 2 and 12), this

distinction was prompted by their finding that amnesic patients could acquire and retain the cognitive skill of mirror-reading novel words (in which words and all their letters were printed backward) despite showing no conscious memory of the training experience itself. Control subjects learned at an identical rate and, of course, could also recall their training on the task (Cohen and Squire, 1980). Squire went on to develop and articulate the “declarative memory” theory of amnesia, implicating the hippocampal formation and other structures of the medial-temporal lobe (Squire and Cohen, 1984; Squire and Zola-Morgan, 1991; Squire, 1992; Squire et al., 2004). Four key propositions of this theory (Box 13–1) are as follows.

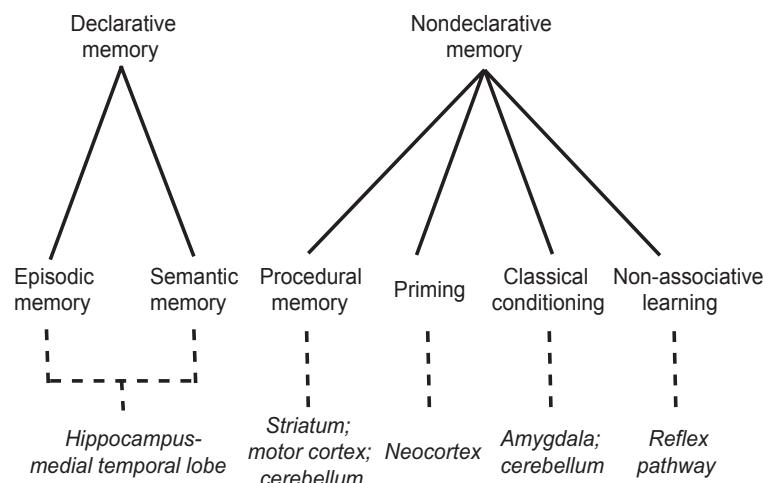

The first proposition—that *the hippocampus is primarily involved in memory*—is now relatively noncontroversial. It is strongly supported by work on amnesic patients and functional imaging studies (see Chapter 12). Observations on people have been extensively confirmed and elaborated in studies of the effects of experimental lesions in animals. In keeping with the overriding theme of this chapter, we accept this first proposition of the theory without further comment.

The second proposition defines “declarative memory” as *representing both facts and events* (Fig. 13–3). What fact (semantic memory) and events (episodic memory) have in common is that both are propositional and can be brought to conscious awareness. Information about facts and events can be “declared” (“Paris is the capital of France” or “I ate an almond croissant for breakfast”), and such declarations can be either true or false. By virtue of this shared property of fact and event memory, such memories can be combined inferentially with other information to yield new propositions (a point developed further in the “relational-processing” version of this theory—see Section 13.5). This inferential property is

#### Box 13–1 Declarative Memory Theory

- Memory:** The primary function of the hippocampal formation is in memory.
- Selectivity:** The role of the hippocampal formation in memory is selective. It mediates the memory of facts and events, called “declarative memory.” This is the type of memory that, in humans, can be consciously recalled.
- Memory systems:** The hippocampal formation is one of a number of structures that comprise a “medial temporal lobe memory system.” Although the components of this system may have distinct subfunctions, it operates collectively to mediate the formation and initial storage of declarative memories.
- Time-limited:** The role of the hippocampus in memory is time-limited. Memory is gradually reorganized as time passes after learning. The hippocampus contributes to a time-dependent systems-level consolidation process such that, once completed, long-term memory traces are stored in the cortex and neural activity in the hippocampus is no longer required for or involved in recall.

## Declarative memory theory: a taxonomy of mammalian memory systems

**Figure 13-3.** Taxonomy of mammalian memory systems. The declarative memory theory recognizes many types of “memory system” and their mediation by distinct neural brain areas. The scheme was first introduced by Squire (1987) and has been updated many times since (e.g., Squire, 2004). The relative independence and interdependence of these separate systems has not been clearly delineated.

an important point of similarity between information about facts and events, but controversy surrounds the theory’s assertion that there is a common neural substrate for the formation of both episodic and semantic types of memory.

A key psychological difference is that unique events occur only once and are specific to particular contexts and moments in time, whereas factual knowledge is often gradually accumulated and (generally) nonspecific with respect to the context of learning. Certain other neuropsychological theories of human memory argue that the nervous system encodes, stores, and retrieves episodic information in a way that is qualitatively different from that for semantic information (Shallice, 1988; McCarthy and Warrington, 1990; Schacter and Tulving, 1994; Aggleton and Brown, 1999). Such theories generally embrace or, at least, start off from the concept of episodic memory as a distinct entity (Tulving, 1983) and question whether it is helpful to subsume it with semantic memory into the unitary category of declarative memory. In contrast, declarative memory theorists see the distinction between facts and events as descriptive rather than fundamental, both being initially encoded by structures in the medial temporal lobe (MTL) that collectively comprise what they believe to be a unitary “memory system.” Anatomically, the MTL is positioned downstream of structures in the ventral “what” pathway of the visual system in primates (Ungerleider and Mishkin, 1982) and so is well placed to receive attended, perceptually processed information. Damage to this downstream system is therefore held as likely to cause a proportionate impairment in both fact and event processing, at least in the anterograde domain..

Whether viewed as a merely descriptive or fundamental distinction, these two forms of memory are not thought (by anyone) to operate in isolation. There is a dialectic here, such that our ability to form new event memories depends on both our general and our personal knowledge of the world (semantic knowledge) and on accumulating information from our experience of events in the world (episodic memory). As

Tulving has long argued, the input to episodic memory must be partly via semantic memory; equally, we add to that knowledge structure through our experience and memory of events, so the development of new semantic memories generally depends on episodic memory. The two forms of memory are “interdependent.” However, they can also act in parallel and independently with, for example, direct input of information from perceptual-representational systems to both semantic and episodic memory (Graham et al., 2000). Investigations of developmental amnesia—focusing on a set of young people referred to a neurological clinic who had grown up being very forgetful about everyday life but able to do reasonably well in school—raised the alternative possibility that the hippocampus plays an exclusive role in the formation of episodic memory (Vargha-Khadem et al., 1997). However, rigorous assessment of this idea is hampered by uncertainties about the extent of hippocampal damage in these cases and theoretical uncertainties about the relative degree of “independence” and “interdependence” of episodic and semantic memory. We discuss these cases in the critique below.

Notwithstanding this qualification, the second proposition of the declarative memory theory implies that a central focus of the theory has to do with the information processing and neural representation of what we ordinarily think of as “memory”—the things we bring to mind as conscious recollections. For some, the term “explicit” memory is preferred to describe certain types of memory task in which the subject is consciously aware of the earlier study episode—in contrast to “implicit” memory tasks, which lack the requirement for recollective awareness (Graf and Schacter, 1985). The differences between the declarative/nondeclarative and explicit/implicit distinctions are important at some levels of analysis but are arguably little more than terminological at another. In practice, the declarative memory theory treats “explicit” and “declarative” memory as interchangeable terms (see Chapter 12). In the same vein, no strong philosophical position about consciousness is implied by the

theory's supposition that declarative memories entail "awareness" or "consciousness." The theory is not tied to any particular theory of this problematic but fascinating concept (Zeman, 2004); it quite reasonably takes a "folk psychology" view of the matter.

Another issue about the second proposition of the theory is its skepticism that a categorical subdivision of memory retrieval with respect to familiarity and recollection (Yonelinas, 2001) can be mapped onto distinct MTL brain structures. Both forms of remembering involve conscious awareness, the defining attribute of declarative memory. Familiarity appears to be a phenomenological attribute that is acquired by a novel stimulus, within several sensory systems, after its first presentation. A stimulus that has been presented before may then be judged "familiar," but this can happen without the subject having any recollection of when or where that stimulus was seen, heard, or smelled previously. Recollection is more complicated, as it also involves source memory pertaining to where or when the stimulus was previously presented. Subjects may even engage in "mental time travel"—the act of moving in their mind's eye back to the time or place of prior occurrence while simultaneously remaining in the temporal present and responsive to their perceived surroundings (such as in conversations about the past with someone while simultaneously driving a car). Certain theorists look upon these two forms of memory retrieval as independent (Baddeley et al., 2002), with only recollection or "relational" memories critically dependent on processing in the hippocampal formation and diencephalon (Cohen and Eichenbaum, 1993; Aggleton and Brown, 1999; Eichenbaum and Cohen, 2001). Yonelinas (2001) has outlined quantitative techniques derived from signal detection theory to identify circumstances in which people may be using recollection rather than familiarity, arguing that recollection is a "threshold" process, whereas familiarity can be better understood in signal-detection terms; they then applied this to the analysis of selected amnesic patients (Yonelinas et al., 2002). However, this approach has been the subject of fierce criticism by Manns et al. (2003) and Wixted and Squire (2004). As some of these ideas constitute major changes to the declarative memory theory as it was originally conceived, they are presented in separate sections (see Sections 13.5 and 13.6). For the present, we accept "declarative memory" as a conceptual category on its own merits.

How are other types of long-term memory considered in the theory? Collectively called "nondeclarative memory," they are thought to reflect acquired information, habits, and learned dispositions that are expressed in behavior but cannot be "declared." Initially called "procedural" (Squire and Cohen, 1984), a term first used in the field of artificial intelligence by Winograd (1975), these types of learning are held to include the following.

- Motor skills and learned dispositions (e.g., the stimulus–stimulus associations and stimulus–response habits acquired during simple conditioning tasks) (Corkin, 1984; Cavaco et al., 2004)

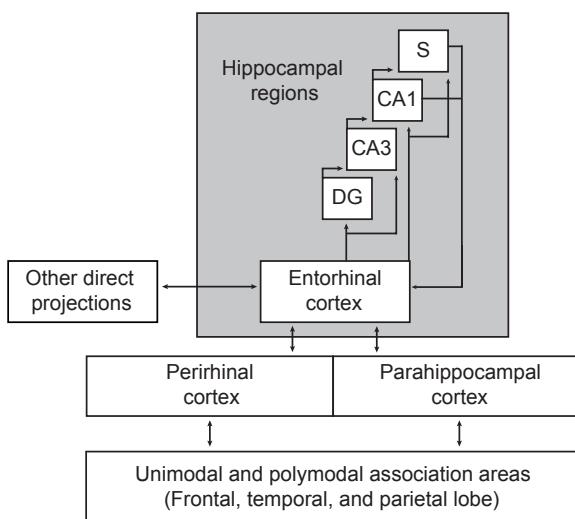

- Perceptual and cognitive skills (e.g., the mirror-reading task of Cohen and Squire, 1980); priming phenomena (e.g., word-stem completion) (Graf et al., 1984), perceptual priming (Hamann and Squire, 1997), and conceptual priming (Levy et al., 2004) (see discussion in Chapter 12)
- Simple forms of nonassociative learning such as habituation (waning of responsiveness following repetition) and sensitization (augmented responsiveness) (e.g., Kandel et al., 2000)

The collective attributes of this heterogeneous group of skills is that they are not propositional (and so can be neither true nor false), are generally learned gradually (although are sometimes rapidly acquired), do not require conscious awareness of the knowledge implicit in their execution, and are simply things that people or animals learn to do. For some (Macphail, 1998), they are the sum-total of what animals can learn to do—such as the proverbial rat that presses the lever in an operant chamber because doing so in the past he has been rewarded but not because it has any expectation of securing reward. Although not what we would ordinarily regard in everyday discourse as "remembering," nondeclarative learning is important in constituting "the dispositions, habits, attitudes, and preferences that are inaccessible to conscious recollection, yet are shaped by past events, influence our behavior and our mental life, and are a fundamental part of who we are" (Kandel et al., 2000, p. 1119).

The third proposition of the theory concerns the existence of distinct *brain systems for memory*. Systems are distinguished with respect to structure as well as function. Different forms of memory are held to depend on anatomically distinct, though partially overlapping, brain regions. Different brain systems for memory probably evolved to mediate functionally incompatible purposes (Sherry and Schacter, 1987a), although the lack of a "fossil record" for memory makes it extremely difficult to draw firm conclusions about their evolution. However, that different memory systems might be mediated by anatomically different brain substrates nicely reflects Francois Jacob's idea that evolution is a tinkerer," adding qualitatively distinct circuits rather than bringing about wholesale changes to the brain.

The putative "medial temporal lobe memory system" (Squire and Zola-Morgan, 1991) is held to be one of these brain systems for memory. It comprises the hippocampal formation (as defined in Chapter 3) and both the perirhinal and parahippocampal cortices of the medial temporal lobe (Fig. 13–4). Damage to these structures in humans and nonhuman primates causes disturbances of declarative memory without necessarily affecting other types of learning or memory. Damage to homologous structures in rats causes apparently similar dissociations. In an evocative phrase, Squire wrote of the distinction between declarative and nondeclarative memory as being "honored by the nervous system." He suggested that, in addition to the *medial temporal lobe* mediating declarative memory, the *striatum* is important for stimulus-response habits, the *neocortex* is the substrate for simple perceptual

### The medial-temporal lobe memory system

**Figure 13–4.** Medial temporal lobe memory system. Major components of Squire and Zola-Morgan's (1991) "medial-temporal lobe memory system" (structures with gray shading), which is believed to be the neural substrate for the formation of declarative memories (as updated in 2004). Information enters the system from neocortical association areas. It is projected via the adjacent perirhinal and parahippocampal cortices to the entorhinal cortex, which has the pivotal role of being both the point of entry of information into the hippocampal formation and a point of exit. Information passes within the hippocampal formation via a cascade of unidirectional projections before signals relevant to the encoding of new memories, or their consolidation, are fed back to the neocortex. CA1, CA3, and SUB represent areas CA1 and CA3 and the subiculum, as defined in Chapter 3; DG, dentate gyrus.

representations and priming (see Chapter 12), the *amygdala* for emotional and social learning, and the *cerebellum* for the learning of skeletal components of classic conditioning. This anatomically based taxonomy is seen as a crucial advance in understanding by those neuroscientists who hold a relatively "localizational" view of brain systems.

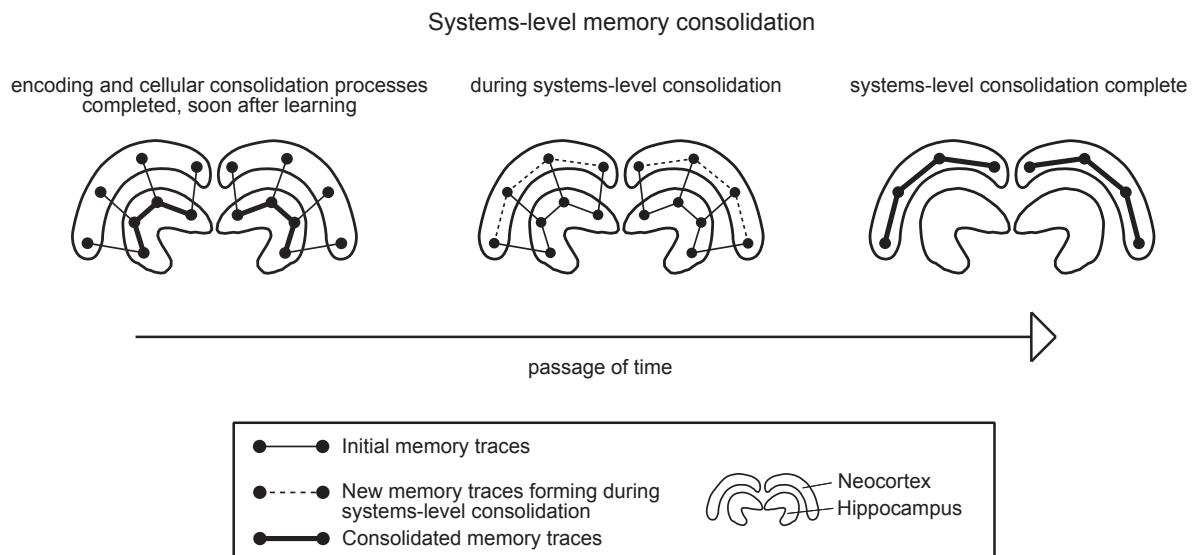

However, as outlined in Section 13.2, current ideas about information processing in the CNS refer to networks of interacting brain areas whose normal operation can be disrupted by disconnections rather than lesions of specific brain areas (McCarthy and Warrington, 1990; Aggleton and Brown, 1999; Gaffan, 2002; Murray and Wise, 2004). Human brain imaging work has also moved rapidly from a "localizationist" perspective to one that stresses the importance of "effective connectivity" between brain areas (Friston, 1995, 2004) and the dynamic interaction of medial temporal and frontal regions during intentional aspects of memory retrieval (Miyashita, 2004). Accordingly, the "one-to-one" mapping of memory type to brain area of the original statements of declarative memory theory is now somewhat dated.

Another complication associated with the mapping of types of memory onto brain areas, explicit in Figure 13–3, is that even the proponents of declarative memory theory recognize that brain areas outside the hippocampal formation, and

even outside the medial temporal lobe itself, are also involved in declarative memory. For example, Shimamura and Squire (1987) claimed that the frontal lobes contribute memory of the context in which information is acquired (i.e., "source memory") on the basis of what they observed in amnesic patients with additional frontal damage. As recalling the context where an event happened is a fact that one can declare and of which one is conscious, it must (by definition) be a type of declarative memory. Similarly, Squire has written of a "limbic/diencephalic" brain system that incorporates structures such as the "anterior thalamic nucleus, the mediodorsal nucleus and connections to and from the medial thalamus that lie within the internal medullary lamina" (Squire et al., 1993, p. 462). Squire and Zola asserted that declarative memory is dependent "on the integrity of medial temporal lobe and midline diencephalic structures" (Squire and Zola, 1998, p. 205). This anatomical liberalism wisely recognizes that medial temporal structures do not operate in isolation from the rest of the brain (hence the reference to direct projections in Fig. 13–4), but it leaves skeptics wondering where the anatomical boundaries of the medial temporal lobe memory system begin and end. In any event, the key point of this third proposition is clear: The declarative memory theory places the hippocampal formation at the apex of declarative memory processing supported by a network of other brain structures.

The fourth major postulate of the theory concerns *memory consolidation*. This is a particularly important aspect of the theory and a focus of much current research. The basic idea is that the hippocampal formation has a time-limited role in memory for an individual fact or event. Some interaction is held to take place between it and presumed long-term storage sites in the neocortex. Gradually, through some time-dependent "consolidation" process in which the hippocampus and neocortex interact, initially labile memory traces in the cortex become stabilized. This renders them resistant to later brain damage to the medial temporal lobe itself, although not, of course, to brain areas that are the eventual storage sites of lasting memory traces (Fig. 13–5). Implicit in this fourth proposition of the theory is the supposition that memory for remote events depends on the strength of memory traces (i.e., information encoded within ensembles of spatially dispersed neocortical neurons), where trace strength can be roughly thought of in reductionist terms as alterations in membrane excitability, the strength of synaptic connections, or other activity-dependent properties of cellular physiology. Memories with high trace strength can be recalled easily; those with lower trace strength cannot. Consolidation is thought to be a process that gradually, sometimes through the interleaving of new traces with existing traces, brings trace strength from low to high levels.

A key issue when thinking about consolidation is exactly what is temporarily stored in the hippocampal formation itself. There are several possibilities. One view is that detailed sensory/perceptual information is stored there for an intermediate period of time and then literally shuttled to the neocortex. At the start of the consolidation period, the memories would be "in" the hippocampus; by the end, they would be

**Figure 13-5.** Systems-level memory consolidation. Pathways between neocortical areas representing recent events or recently acquired facts are held to be weak initially, even after the protein synthesis-dependent cellular consolidation that sometimes follows immediately after initial encoding (left). Memory soon after learning relies on rapidly formed connections between these neocortical

areas and the hippocampal formation. Over time, a consolidation signal emanating in the hippocampus is thought to strengthen neocortical connections (middle) to the point where hippocampal activity is no longer necessary (right). The time this consolidation process takes may be quite long—weeks, months, or even longer (Squire and Alvarez, 1995).

“in” the cortex. No one has much confidence in this possibility—as if the brain were some kind of railway shunting yard; and it was never considered seriously by Squire. Another idea, albeit a somewhat metaphorical one, is that hippocampal storage consists of “pointers” or “indices” (Teyler and DiScenna, 1986). These representations do not contain detailed information; they are more like cartoons and are thought to do two things. First, they help activate—by pointing at them—the relevant but dispersed neocortical neurons at which traces representing detailed sensory information are located (presumably through alterations in synaptic strength between interconnecting neurons—see Chapter 10). This is a lovely metaphor—neurons pointing at each other—but exactly how such an addressing mechanism would work is unclear. How does a neuron in the hippocampus “point at” one or more neurons in the cortex or, even more difficult, a subset of their synaptic interconnections? The answer, if this metaphor is on the right lines, is likely to involve diffuse activation coupled to local signals, in much the same way that in the dark a flashlight (diffuse) lights up a prowling cat’s eyes (local). It is the conjunction of light and the cat that enables spatial specificity, it not being a property of either feature alone. More generally, “specificity” is one of the big issues of modern neuroscience at every level of analysis applying as much to intracellular synaptic stabilization mechanisms (Goelet et al., 1986; Frey and Morris, 1997) as to the systems-level memory consolidation processes that involve several brain structures (Dudai and Morris, 2001).

Given that areas in the neocortex are the likely sites of perceptual processing and the eventual sites of storage, we might reasonably wonder why the hippocampus is ever needed. Why bother with such apparent duplication? Moreover, even

though systems-level memory consolidation is a process revealed through experiments in which the hippocampus is rendered dysfunctional, it is unlikely that the evolutionary pressure to develop a consolidation mechanism was to avoid the deleterious effects on memory of brain damage. So what is the function of consolidation and why the need for a brain area with a time-limited role in memory? One answer, from McNaughton et al. (2003), is that the numerous neocortical interconnections that exist for creating an associational framework of acquired knowledge are weak, slowly formed, and/or liable to rapid decay. It is essential to protect against “everything-becoming-connected-to-everything” during the long process of learning throughout development and adult life. More generally, consolidation is held to be a gradual, selective process precisely because it has to be—ensuring that only the relevant connections are made across ensembles in and between cortical networks to represent information about facts and events accurately (O’Reilly and Norman, 2002). We revisit the issue of whether consolidation always has to be gradual in Section 13.6.

The second thing that hippocampus indices and pointers are supposed to do is guide the consolidation process over time (Squire and Alvarez, 1995). It may take place over hours, days, weeks, months, or even years—the virtue of such slow processing being that it helps avoid catastrophic interference in distributed associative memory traces stored in the cortex (McClelland et al., 1995). This is the “teenager’s bedroom” type of interference that occurs when one set of new memories (new junk) overlays earlier formed traces (old junk) in such a manner as to interfere with their subsequent retrieval (“Has anyone seen my iPOD?”). Cautious interleaving, guided by hippocampal pointers, prevents this from happening. As

this consolidation process eventually comes to an end for a particular set of information, the pointers have done their job. There is therefore no need for extensive long-term memory retention in hippocampus. Like forgotten movie stars, hippocampal pointers just fade away.

Declarative memory theory therefore asserts that after consolidation is complete damage to the hippocampus should have no effect on memory. However, as consolidation takes time, the theory makes the important prediction that temporal gradients of retrograde amnesia should be obtained in both humans and animals after damage to the medial temporal lobe. This prediction is attractively counterintuitive: It states that if the hippocampus is damaged at time  $t$  an event experienced several weeks *before* time  $t$  would be remembered *better* than an event experienced only a few days earlier because the former, despite being older, would have enjoyed a longer period of consolidation. Testing this prediction has become a cottage industry in its own right within the field.

This completes our presentation of the major features of the theory. In the discussion that follows, we first present relevant interventional studies on animals (primarily primates but with some mention of other species) and then a critique. As noted earlier, the relevant human studies have been discussed in Chapter 12, and an important extension of the declarative memory theory called the “relational processing” theory (Cohen and Eichenbaum, 1993; Eichenbaum and Cohen, 2001) is considered separately (see Section 13.5). It has inspired a body of experimentation somewhat separate from Squire’s version of declarative memory theory. Similarly, work on the consolidation of spatial memory is reserved for discussion in Section 13.4.

### **13.3.2 Development of a Primate**

#### **Model of Amnesia**

In the historical survey of Chapter 2, we noted that the initial efforts to model human amnesia in animals were largely unsuccessful. Monkeys given lesions of the medial temporal lobe showed deficits in certain tasks, but overall they were capable of learning tasks that one might not expect an “amnesic” monkey to learn. Similarly, rats given hippocampal lesions showed diminished exploration and striking inflexibility in their learned behavior but were quite capable of learning many quite complex tasks. The apparent discrepancy between the human and animal data did not go unnoticed, and various attempts were made to explain it (Iversen, 1976; Weiskrantz, 1982).

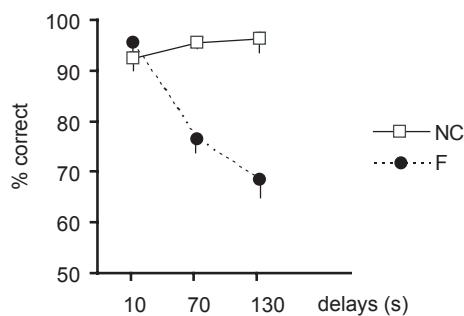

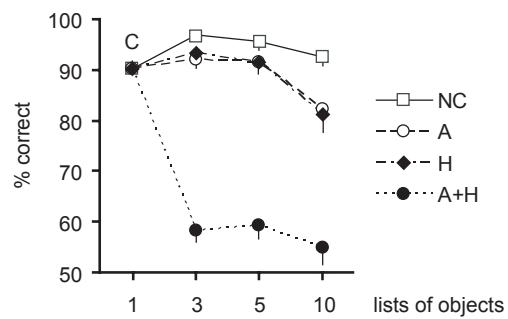

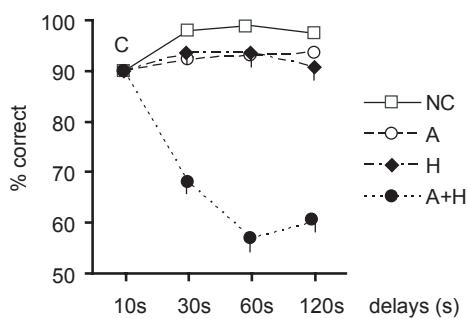

#### **Development of New Tasks for Monkeys to Parallel the Types of Memory Lost in Amnesia**

An important insight by Gaffan was that the tasks then used in animal studies were quite unlike those on which amnesics were seen to fail (Gaffan, 1974). He suggested that new tasks be developed to capture what he then saw as an important distinction between “recognition-memory” and “associative-

memory.” Recognition memory refers, at least operationally, to the ability to discriminate between stimulus items that have been seen recently and others that have not. A judgment of prior occurrence (Brown, 1996), it is generally impaired in global amnesia, as shown by a standard test such as Warrington’s Recognition Memory Test; however, it is not always severely impaired in patients with more restricted hippocampal damage (Aggleton and Shaw, 1996). Associative memory, on the other hand, refers to the ability to learn that two stimulus items go together, such as a stimulus and a reward or a response and a reward, without regard to their familiarity. This is a “habit” type of learning that Gaffan argued was preserved in the presence of amnesia.

To model recognition memory, he collected a set of 300 junk objects and presented 60 of them to the monkeys each day. Each trial consisted of a “sample” phase, during which the experimenter presented one object on its own, and a “choice” phase in which two objects were presented: the one that had just been shown as a sample together with another, novel object. These objects were presented on trays inside a Wisconsin General Testing Apparatus (WGTA) (Fig. 13–6A). To motivate the monkeys to perform the task, a “sugar puff” reward could be retrieved when they displaced the object presented during the sample phase and again when they chose that same object during the choice phase. The only way the monkeys could perform correctly was if they: (1) learned and then applied the rule that a reward was available for displacing the familiar object rather than the novel one; and (2) remembered which object was familiar during the choice phase of each trial after the memory interval following sample presentation. This technique of probing recognition memory was therefore called “delayed matching to sample with trial-unique cues,” where “matching-to-sample” refers to the rule for solution, “trial-unique” to the fact that an absolute judgment of familiarity of the objects is required, and “delayed” because of the memory interval between the sample and choice phases of each trial. It is usually abbreviated as DMTS. After learning using the short memory delay of 5 to 8 seconds (at which the monkeys performed extremely well), two performance challenges were added. One was to increase the memory delay up to several minutes; the other was to present a “list” of several sample objects, one after the other, and then do a series of choice trials. Delays and lists are widely used in modern variants of this task. Finally, to model associative memory, Gaffan used a small subset of the same junk objects but a different protocol. The monkeys had to learn which objects were consistently rewarded and which consistently unrewarded, presenting the objects time and again until they were all completely familiar. The animals indicated their knowledge of the object-reward relations correctly by reaching for rewarded objects when they were presented and toward a small brass disk placed alongside when the nonrewarded objects were presented. Correct choices were rewarded; incorrect choices were not (Box 13–2).

The monkeys given fornix lesions showed delay-dependent impairment in the recognition task (Fig. 13–6B) and list

Conjoint aspiration lesions

length-dependent impairment, but their associative learning was unimpaired. As correct performance at short delays depends on successful execution of the procedural rule learned preoperatively (matching-to-sample), the deficit caused by the fornix lesion at longer delays is unlikely to have been due to the monkeys not remembering the rule. Rather, it suggested that fornix lesions have no effect on (1) short-term

of the hippocampus and amygdala lesions, including neocortical structures of the medial temporal lobe, cause delay-dependent (left) and list-dependent (right) impairment of delayed nonmatching to sample (DNMS) after the animals reach the initial criterion of 90% correct with single-sample objects. (*Source*: After Mishkin, 1978.)

memory or (2) intellectual function (they had learned the rule preoperatively and could still execute it postoperatively), but (3) they prevent the formation of memories lasting much longer than about 2 minutes. This conjunction of three important characteristics of human amnesia in a single experiment represented the first apparently successful attempt to model key features of the syndrome in animals. Ironically, although explicitly introduced on the grounds that it would cause “the least extrahippocampal damage” (Gaffan, 1974, p. 1100), fornix lesions are associated with only modest amnesia in humans (see Chapter 12). This represented something of a puzzle but one that was soon solved.

**Emergence of Delayed Nonmatching to Sample as the Benchmark Test of Recognition Memory in Primates**

DMTS tasks had been used previously with animals, but Gaffan's innovation of trial-unique cues during each week of testing appeared to ensure that the familiarity discrimination demanded of the monkeys was effectively an absolute judgment (“Have I ever seen this object before?”) rather than, as happens with pairs of cues that are repeatedly given across trials, a judgment of relative recency (“Which of these objects have I seen most recently?”). Relative recency may still be a

factor, even with 300 junk objects, as testing requires that they be reused within a week or so (Charles et al., 2004a). In any event, this subtle procedural change successfully engaged a brain system that operated in the domain of long-term, rather than short-term, memory. Additionally, the use of lists of items appeared to make the task analogous to the list-learning tasks so widely used in human studies. It is, perhaps, a slightly unrealistic model of human list learning because the stimulus materials usually presented to people (e.g., words or word-pairs) are items with which people are already familiar. The human test is not whether the word “cat” has *ever* been seen before, but if this word appeared in the list presented by the experimenter several minutes earlier. Thus, in the human experiment, word lists are context-specific, a distinction not thought to matter at the outset but, as we shall see later, arguably critical to the anatomical mediation of different types of memory. For the monkeys, whether a judgment of absolute familiarity or relative recency is required may not matter provided a sufficiently large number of objects are used. However, it most certainly does matter if only two objects are used, as Owen and Butler (1981) were to show, because fornix lesions have no effect on remembering which of two objects has been seen most recently. This is not surprising because normal monkeys can do this well only over a few seconds, and they use short-term memory to do so; the task is impaired by a combined orbitofrontal and temporal stem lesion (Cirillo et al., 1989). Thus, fornix lesions do not interfere with short-term memory but may affect long-term memory.

Another, more important difficulty with DMTS relates to the matching rule. With such a rule, the monkey is rewarded during the sample trial for displacing a *novel* object but rewarded on the choice trial for displacing what is then the *familiar* object. This potential source of confusion can be avoided with several variants of the delayed-matching protocol, but the simplest and most influential change in procedure was the shift to tasks employing a “delayed *non*matching-to-sample” rule. With nonmatching, the monkey is rewarded for reaching for a novel object each time he reaches out: on sample trials for the single sample object and on choice trials when presented with a pair of objects. Mishkin and Delacour (1975) developed such a task and found that normal monkeys could learn nonmatching more easily than matching, probably because of their natural inquisitiveness about novelty. Being easier and being later shown to be sensitive to large lesions of the medial temporal lobe, delayed nonmatching to sample became the task of choice for many years.

In an important study, Mishkin (1978) exploited both characteristics of delayed nonmatching to sample to investigate the effects of hippocampal, amygdala, and combined hippocampal/amygdala lesions on recognition memory. He trained monkeys on the delayed nonmatching to sample task until they were performing at 90% correct or better. They were then divided into four groups, with most undergoing bilateral surgery to the medial temporal lobe; three monkeys were left as normal controls. Of the nine operated monkeys, three were

subjected to hippocampal lesioning, three to amygdala lesioning, and three to lesioning of both structures. Postoperatively, the animals that had lesions of the hippocampus (but including the caudal perirhinal cortex and parts of the parahippocampal cortex because an aspiration technique was used) and those with lesions of the amygdala (including parts of the rostral perirhinal cortex) all relearned the task quickly. Those with the combined lesion—a lesion analogous to the medial temporal lobectomy in patient H.M.—were severely impaired. Mishkin (1978) also found that once criterion levels of performance had been reached by all groups with a short memory delay the combined lesion group showed pronounced list-length and delay-dependent impairments in recognition memory (Fig. 13–6C). The other groups performed well—indistinguishably from the nonoperated controls. Thus, the group that had been subjected to lesioning similar to that applied to H.M. showed strikingly similar memory impairment. This was a great step forward, and the paper has been justly celebrated as a classic paper of twentieth-century neuroscience (Aggleton, 1999).

Both lesions involved removing cortical tissue adjacent to the target structures of the amygdala and hippocampus. At the time, this was not thought to be of particular significance by most observers (Horel, 1978), and the results were long described by Mishkin’s group and by almost everyone else in the field as lesions of the “hippocampus” and of the “amygdala,” respectively. The pattern in the findings suggested that these two structures played a parallel role in memory (which might yet be dissociated by other tasks), the “dual circuit” idea emerging as part of a theory of memory proposed a few years later (Mishkin, 1982).

Delayed nonmatching-to-sample (DNMTS) rapidly emerged as, in Zola’s phrase, the “benchmark test” of recognition memory. It was used in numerous studies, notably by the National Institutes of Health (NIH) group led by Mishkin and colleagues Bachevalier, Murray, Saunders, and others and separately by the San Diego group of Squire, Zola-Morgan (Zola), Amaral, Suzuki, and others. A distinctive and laudable feature of their work over the 20-year period from 1978 to 1998 was partial standardization of the manual testing protocols such that comparisons could be made across studies, at least within each laboratory. With the sole but important exception that the NIH experiments typically involved extensive pretraining prior to the lesion whereas the San Diego series always involved surgery prior to training (Zola-Morgan et al., 1982), this standardization was extremely valuable. In the case of the San Diego experiments, it made possible a comparison of lesion groups with first one and later a second “standardized” group of unoperated control animals. Research using primates is not undertaken lightly because of the ethical, conservation, and financial reasons referred to earlier (see Section 13.2). Thus, establishing a set of repeatable protocols for a test that models several aspects of amnesia was an important step forward. If there was a weakness of this standardization, it was that different experimenters were inevitably involved in testing the two control groups and the

various lesion groups over the years, a practice that would not ordinarily be accepted in research on rodents. The experimenter was typically not “blinded” with respect to the lesion created in the animal, whereas this also is common practice in the best laboratories working with rodents. However, the robustness of the task and the tight variability of the forgetting functions with memory delays make it unlikely that these weaknesses seriously limit its validity, even if it slightly injures their elegance.

The outcome of studies conducted throughout the 1980s and early 1990s indicate that after the combined lesion (lesions that include the underlying cortical structures of the posterior entorhinal cortex, perirhinal cortex, and parahippocampal gyrus), a DNMTS deficit is observed whose main characteristics can be summarized as follows (Box 13–3):

Working through these numbered points in turn, the following additional comments and qualifications should be noted. First, despite the use of different monkey species and different surgeons, experimenters, and WGTA designs, bilateral damage to the medial temporal lobe similar to that produced in the original study of Mishkin (1978) always causes a memory deficit in DNMTS (Squire et al., 2004). It is, however, important to stress that this does not mean that the hippocampus alone is involved in recognition memory, as the lesions that were used initially typically encompassed extrahippocampal structures. Second, performance is good at short delays but appears to decline monotonically as the time between sample and choice is lengthened (Mishkin, 1978; Zola-Morgan and Squire, 1985; Overman et al., 1990; Alvarez et al., 1994a; but see Ringo, 1991, 1993). Securing this claim involved the development of computer-automated systems for presenting stimulus material to get around the difficulty that there was always a small delay in the WGTA when the screen separating the monkey and the experimenter was raised and lowered. Notwithstanding this technological improvement in testing procedure, there was an intense if somewhat technical debate about delay-dependence, an issue we shall come to shortly. Third, a deficit occurs in the visual and tactile modalities, and by inference it is probably multimodal. For example, monkeys tested in the dark so they can only feel the sample and choice objects also show a memory deficit following medial temporal lobe lesions (Murray and Mishkin, 1983;

Suzuki et al., 1993). However, the inference about other modalities is insecure. The available data on auditory DNMTS indicates no impact of perirhinal lesions (Fritz et al., 2005), a finding also observed in dogs (Kowalska et al., 2001). The data of Fritz et al. (2005) led to the intriguing speculation that language may be unique to humans not only because it depends on speech but because it requires long-term auditory memory, although, as they pointed out, this appears to be contradicted by field studies showing their ability to recognize alarm calls that signal predators (Seyfarth et al., 1980). To our knowledge, the impact of medial temporal lesions on olfactory recognition has not been reported in primates (T. Otto and M. Munoz, personal communication), partly owing to the difficulty of making olfactory cues salient for monkeys (M. Baxter, personal communication). Fourth, the effects of distraction in DNMTS are analogous to what happens with amnesic patients. They can retain small amounts of information for extended periods when not distracted but forget more rapidly when their attention is diverted (Zola-Morgan and Squire, 1985)—although interaction between distraction and the effects of a lesion is not always present (Zola-Morgan et al., 1989). Fifth, there is no recovery of function; a deficit is still seen when memory testing is conducted up to 4 years after surgery as well as when it is carried out shortly after surgery (Zola-Morgan et al., 1986). These five characteristics of DNMTS performance after large medial temporal lobe lesions map neatly onto several features of the amnesia syndrome. It is not without reason that object recognition memory, as measured in DNMTS, was championed as an “animal model of amnesia” (Squire and Zola-Morgan, 1991) and even declared a “millennial achievement” in neuroscience (Kandel et al., 2000).

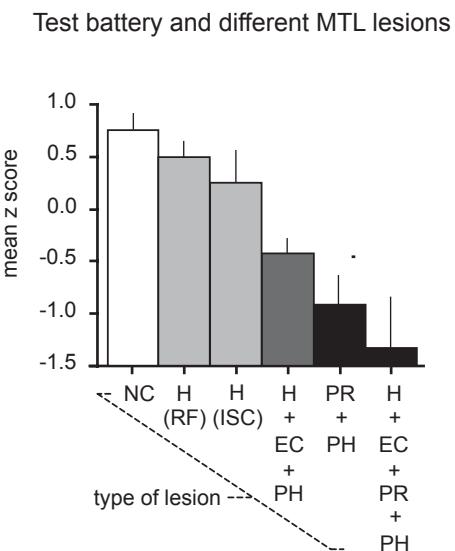

#### Other Tasks Used in a Comprehensive Test Battery to Explore Declarative Memory in Primates

Although DNMTS became the most widely used task, it was complemented by other tasks designed to probe different types of declarative memory. During the early years, Squire and Zola-Morgan often used a standardized “test battery” consisting of several of the tasks shown in Box 13–2. Large medial temporal lobe lesions cause a learning impairment in the *concurrent object discrimination task* involving the interleaved presentation of eight pairs of objects of which one member of each pair is consistently rewarded, and the *delayed retention of object discriminations* (Zola-Morgan and Squire, 1985). Deficits in the *delayed response task* are sometimes seen, but they are capricious. This is because lesioned monkeys have no deficit in short-term memory and even normal monkeys can tolerate only short memory delays before they become confused about whether they are remembering the present or a previous trial. This is never a problem for DNMTS because of the use of trial-unique cues.

Each of these and other tasks in the battery is held to be “declarative” in the sense that, with only slight suspension of disbelief, they can be seen as analogous to tasks given to

#### Box 13–3 Delayed Nonmatching to Sample Reveals an Important Role for the Medial Temporal Lobe in Recognition Memory

1. The deficit in DNMTS after large medial temporal lobe lesions is robust and repeatable.
2. The deficit is apparently delay-dependent.
3. The deficit may be independent of modality.
4. The deficit is exacerbated by distracting stimuli presented during the delay interval.
5. The deficit is enduring.

**Figure 13-7.** Pooling data across the test battery. The results of several tasks of the San Diego test battery were pooled using z-scores to reveal a graded deficit proportional to the extent of the medial temporal lobe lesion and the way it was made. EC, entorhinal cortex; H, hippocampal lesions; ISC, ischemic; NC, normal control; PH, parahippocampal cortex; PR, perirhinal cortex; RF, radiofrequency. (Source: Zola-Morgan et al., 1994.)

people. For example, the concurrent object discrimination task can be thought of as analogous to learning a list of words, the delayed retention of object discriminations to remembering a passage of prose, and so on. Moreover, when the data from all of tasks used in the San Diego test battery are combined across experiments by averaging z-scores (reflecting relative statistical variability rather than absolute values), a clear deficit is observed after lesions of the medial temporal lobe that, with some exceptions (Baxter and Murray, 2001b), is nicely graded with respect to extent of damage (Zola-Morgan et al., 1994) (Fig. 13-7). However, the test battery has gradually fallen out of favor, partly because components of it are now thought to depend on other brain structures. For example, the deficit in the concurrent object discrimination task after large medial temporal lobe lesions is probably due to damage to area TE (Buffalo et al., 1998b), and this same task involves habit learning in humans rather than declarative memory (Bayley et al., 2005a).

#### Adequacy of These Tasks as Models of Declarative Memory

One qualification of this ostensibly tidy picture was an argument first posed by Ringo to the effect that the delay dependence of the DNMTS deficit may depend on the choice of numerical scale with which performance is scored (Ringo, 1991, 1993). This is an important technical point. The outcome of a single trial in DNMTS is the monkey choosing the correct or incorrect object. It is therefore usual to plot performance on a scale from 50% (chance) to 100% (perfect perfor-

mance) using a linear scale. Ringo argued that statistical considerations require an arcsine or other transformation for such data, particularly if scores come close to 90% correct as they often do at short memory delays. His reanalysis of several published DNMTS studies using such a transformation led him to conclude that medial temporal lesions may not, in fact, cause delay-dependent forgetting. He suggested that *apparent* delay dependence in several studies could arise because lesion-induced deficits are concealed at short memory-delay intervals through use of the linear scale. For example, controls may be scoring 92% correct and lesioned monkeys 90%—performance levels that do not differ statistically when the variability is computed using the entire data set. However, an arcsine transformation (which “stretches” the scale as values approach either 0 or 100%) may show a different picture, as Ringo’s reanalysis of several data sets indicated. This is a cogent argument, although it did play down the overlap of performance by lesioned and control monkeys at short delays in some studies, as pointed out by Alvarez-Royo et al. (1992). Its importance was nevertheless taken on board. It spurred the development of, or at least the better appreciation of, automated versions of the WGTA that permit the presentation of very short sample-choice intervals. Under these conditions, no lesion-induced deficit is observed in the rate of acquisition of the DNMTS task at “zero delay,” with control and lesioned animals reaching the same performance asymptote. An unambiguous delay-dependent deficit still pops out at long delays (Overman et al., 1990; Alvarez et al., 1994). Ringo’s concern, however, should not be forgotten, as findings obtained more recently with neurotoxic lesions of structures *within* the hippocampal formation add a further note of caution. To claim a *differential* effect on memory rather than perception, it is essential to secure the statistical interaction between group and memory delay. This is because a lesion that impaired perception would be expected to have as large an effect at short memory delays as at long ones—the animals being just as poor at seeing the objects in front of them at both intervals. This is the gold standard for establishing that the performance of groups differs across the domain of long-term memory. Many studies have aspired to this standard; the truth is that few primate DNMTS studies have reached it.

A separate concern about the test battery is that the psychological justification for regarding tasks in the test battery as “declarative” is not always clear, and in some cases the argument borders on the circular. We have just noted that concurrent discrimination learning might be thought akin to a person learning a list of words. The trouble is that there are lists and there are lists. For example, Squire (1992) claimed that the concurrent discrimination task in which eight pairs of objects are presented a number of times during a single testing session (a task developed originally by Moss et al., 1981) is declarative, whereas a 20-pair concurrent task in which each pair of objects is presented only once per day is not (Malamut et al., 1984). The basis for these assertions was that the former was impaired by medial temporal lobe lesions, whereas the latter was not. Clearly this circularity, if that is all there is to it,

is unsatisfactory. In fairness, there is more to it, namely that many behavioral tasks can be learned using different strategies—even those of ostensibly the same logical structure (task ambiguity being one of the key conceptual issues discussed in Section 13.2). Varying the pattern and temporal spacing of the trials may bias animals toward or away from using a “declarative strategy”—an example of a *quantitative* change having a *qualitative* effect. In the case of concurrent object discrimination tasks, normal monkeys might be able to remember the “fact” that a particular object was paired with reward for a period of time despite the interference produced by the other eight interposed problems with different objects. Provided another trial of the first problem comes along soon enough, they could then use their fact-based declarative memory to solve the problem. However, if the intertrial interval is long, as with the 24-hour delay task, even the normal monkey may find a declarative strategy less reliable. It might then fall back on a stimulus-response strategy, by which is meant the gradual strengthening of a disposition to reach for the rewarded object and not for the nonrewarded object, rather than explicit memory of a prior object and reward episode. Because this nondeclarative strategy, according to the theory, is also available to the lesioned monkey, no difference in performance would be expected between groups. Interestingly, people generally use a declarative strategy to learn lists, irrespective of how long the list and how many trials are presented per day, although, as already noted, people also learn the concurrent object discrimination task in a habit-like manner (Bayley et al., 2005a). Debate about the interpretation of tasks first published 20 years ago may seem like a historical sideline, but it is not. For the issue of “strategy used” versus “logical structure” is a key one and, as we shall see, has reemerged as an issue with respect to the memory strategies mediating DNMTS.

The way to avoid circularity is to come up with independent psychological evidence that a particular strategy is being used or that performance on one task correlates with that on another and allow this evidence to help guide definitive predictions from the theory. In the case of concurrent object discrimination learning, one way might be to use the “reward-devaluation” procedure as originally developed in experiments on rats (Adams and Dickinson, 1981). If the association between reaching for an object and securing reward is learned as a “fact,” pairing the reward with a toxin such as lithium chloride should render it less palatable and so make the animal less inclined to reach for the object. This is because the animal would, in some sense, infer from his “propositional knowledge” that reaching for the object leads to the reward, and thus seeing the object should retrieve a memory representation of the reward and that it is now no longer worth having. However, if the animal had merely learned the habit of reaching for the object as a disposition (and learned it because it was repeatedly paired with reward during training), reward devaluation would not have any immediate effects on performance. The animal would reach for the reward because reaching for rewards is what it had been

trained to do, not because it has in any sense “remembered” that doing so actually leads to anything. Murray and her colleagues at the NIH laboratory have used this reinforcer-devaluation procedure to dissociate fact and habit learning in studies that have revealed that excitotoxic damage to the amygdala disrupts the ability of animals to change their internal representations of reinforcement value (Malkova et al., 1997). Stimulus–stimulus associations can therefore be represented in a manner that might be thought of as a “fact.” However, neither the hippocampus nor the rhinal cortex seems to be a brain structure mediating reinforcer devaluation (Thornton et al., 1998).

As an aside, exclusion of the amygdala from a revised medial temporal lobe memory system may also be mistaken because there are aspects of recognition memory that do seem to involve stimulus value. Seeing old friends again, such as colleagues at an annual scientific gathering, invokes great pleasure. We all witness and experience this on the first day of such a meeting—a curious pleasure as it is all too often followed by heated debate in the lecture theater with these self same people. Although this emotional characteristic of stimulus familiarity may be mediated by the hippocampus and/or the perirhinal cortex, it seems unlikely. It is tempting to speculate that there may be role for the amygdala as well.

### 13.3.3 Domains of Preserved Learning Following Medial Temporal Lobe Lesions in Primates

When constructing an animal model of amnesia, it is important to model *spared* memory as well as impaired memory, of which Gaffan’s (1974) use of an associative task was an early example. Historically, systematic analysis of the issue of multiple types of learning and memory and their differential sensitivity to different lesions began in the rodent literature (see Sections 13.4 and 13.5). It was, however, not long before the idea was taken up in studies with primates beginning with tasks involving motor skill. For example, Zola-Morgan and Squire (1984) found that control and medial temporal lobe (MTL)-lesioned monkeys could learn to thread a “lifesaver” candy (which contains a central hole) along and then off a thin wire. Eating the candy was the monkey’s reward. With experience, normal and lesioned monkeys got steadily faster, and they learned at an equivalent rate. Presumably, the lesioned monkeys did not remember doing the task from one day to the next or recognize the apparatus when it was shown to them again, but they threaded the “lifesaver” nonetheless. If only we could “ask” them about their mental experience in such a situation!

Perceptual skills have also been studied in monkeys using pattern discrimination tasks (Squire and Zola-Morgan, 1983). These are slowly learned discriminations in which two similar patterns (such as alpha-numeric characters) are differentially paired with reward. Learning typically takes place slowly, over hundreds of trials; and with one exception no deficit in learning is seen following even large MTL lesions or after

hippocampus-specific lesions. The interesting exception noted by Squire is that performance is sometimes poorer over the first few trials of the day. He suggested that this difference between groups is due to controls remembering the first few trials in an explicit or declarative way prior to the build-up of within-session interference and the reliance on learned habits. However, more recent experiments, discussed in the critique later on, challenge the idea that components of the MTL memory system are not involved in learning stimulus-reward associations (Murray and Wise, 2004).

With respect to cognitive skills, that lesioned monkeys can learn tasks such as DNMTS at a normal rate at zero delay (Alvarez-Royo et al., 1992) seems to imply that they are able to abstract, from the sequence of trial events, the appropriate rule for performance. This finding is inconsistent with their having any major deficit in “intelligence.” However, although the investigation of primate cognitive skills, knowledge, and “metaknowledge” (i.e., what they know they know) has been considered by those working in a more ecological context (Hauser, 2003), it has only recently been considered seriously by behavioral neuroscientists (Hampton, 2001). Monkeys have not yet been taught the subtle tasks of learning a finite grammar or to make accurate weather forecasts—tasks that have imaginatively extended the domain of preserved learning in amnesics (Knowlton and Squire, 1993), but the range of laboratory tasks of nondeclarative memory is steadily expanding.

### **13.3.4 Selective Lesions of Distinct Components of the Medial-temporal Lobe Reveal Heterogeneity of Function**

Squire and Zola-Morgan’s development of a test battery was motivated by the reasonable ambition of developing tasks that are analogues of the verbal and visual memory protocols on which MTL amnesics are impaired. Combining data from these tasks in the form of z-scores to create a single quantitative index (Fig. 13–7) revealed a monotonic effect of lesions within the MTL: the larger the lesion, the greater the deficit (Zola-Morgan et al., 1994). However, mindful of the uncertainties surrounding the classic but misleading concepts of mass action and equipotentiality (Lashley, 1950), it is not surprising that critics of declarative memory theory are wary of the notion that the entire MTL functions as a single homogeneous unit. Indeed, further research has revealed that restricted lesions of MTL structures cause little or no impairment in some declarative tasks but do affect others. This is not just a matter of graded task difficulty, as double dissociations are seen (as we shall see shortly). Particularly problematic are data suggesting that neither restricted hippocampal lesions nor damage confined to the entorhinal cortex necessarily cause an enduring deficit in DNMTS.

Absolute confidence in the “benchmark test” of DNMTS began to unravel for a number of reasons. One problem has to do with understanding what the test is really measuring psychologically; another relates to identifying the necessary and sufficient lesion that impairs it. These two issues are connected.

Mishkin’s “dual-circuit” theory relating to the putative role of the “hippocampus” and “amygdala” in recognition memory prompted the question of whether different types of information processing occurred in the two routes of his dual pathway (Mishkin, 1982). One prescient idea, based in part on theorizing by Mandler (1980) was that recognition memory could be based on either a memory of the polymodal features of an object or on memory of where the object had been seen before. We may think of this as, on the one hand, distinguishing between features that are intrinsically *part* of the object and, on the other, between features that *reflect the context* in which an object is seen. Whereas the former are part of (and so would move with) an object when it is displaced, the latter might not.

Two studies began the systematic exploration of this issue. One examined cross-modal transfer of information, and the other examined memory for the place where an object had been presented. Murray and Mishkin (1985) found that “amygdala” lesions (which included damage to the perirhinal cortex) caused impaired cross-modal transfer, whereas “hippocampal” lesions (which also damaged the parahippocampal cortex) were with without effect. Monkeys were trained to sample one of a restricted set of 40 objects in complete darkness and then make a choice between the sample and another member of the set in the light. Information acquired in the tactile modality was sufficient to guide visually directed choices accurately, but performance, at even short memory delays, was selectively impaired by the “amygdala” lesions. In contrast, Parkinson et al. (1988) found that their hippocampal lesions selectively impaired both a place task and an object-in-place task, whereas the amygdala lesions had no effect. In a concurrent “place” and “object-in-place” tasks, two objects were presented during the sample trial in two of three possible locations on the tray in front of the monkey. On the choice trial, these objects were again put in front of the monkey. In the “place” choice trials, the monkey had only to choose on the basis of the locations occupied by the objects in the sample trial; whereas for the “object-in-place” choice trials, the animals had to choose on the basis of remembering the particular places occupied by particular objects. It was later established that monkeys with “hippocampal” lesions could remember one place but not two (Angeli et al., 1993).

The sufficient lesions for seeing these deficits are now known to be purely neocortical, but the historically still important point to emerge from these studies is that recognition of novelty might be mediated by either “intrinsic” or “contextual” components that are not disambiguated in the standard DNMTS test. The distinction echoes the concept of recognition being mediated either by a sense of familiarity (intrinsic) or by recollection (contextual recall) (Mandler, 1980). Recognition by familiarity would involve the monkey making its choice because of the two objects confronting him in the choice test one evokes a sense of familiarity. It could do that even if the monkey was unable to recollect the occasion when or where it had seen it before. Recognition by contextual recall, on the other hand, would involve the monkey utilizing

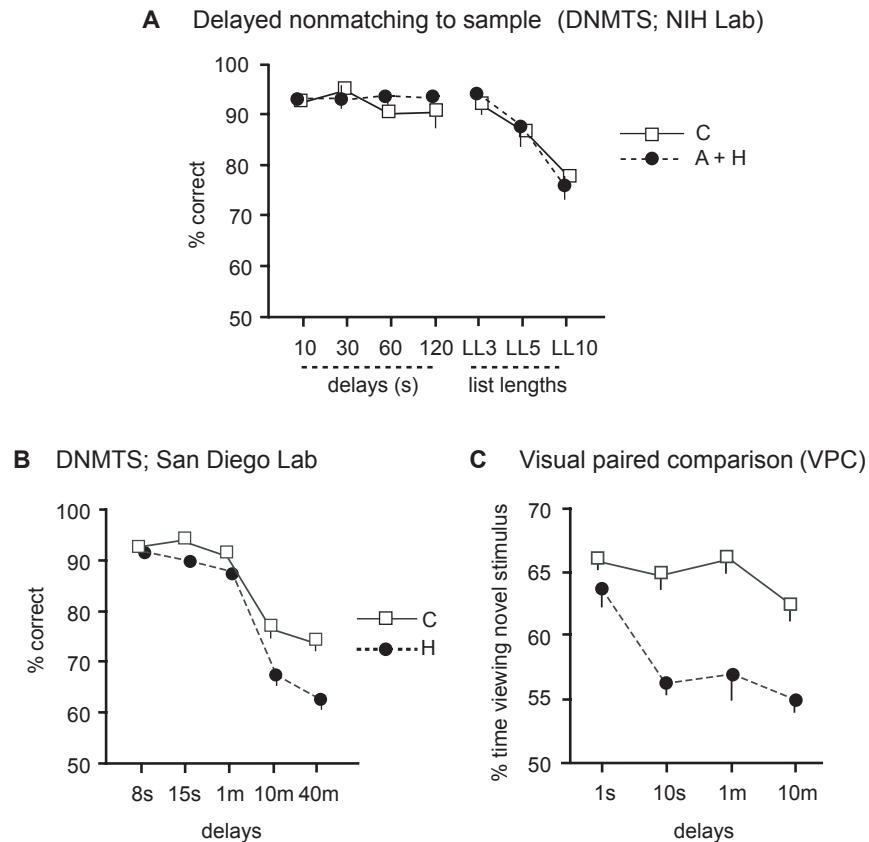

the cues of the WGTA surrounding him to “bring back to mind” that of the two objects before him one had been presented before in this context. Although we cannot talk to the monkey about it, we can nonetheless imagine the animal having a private “recollective experience” in much the same way that we would do in a similar situation.

Unfortunately, the important line of psychological thinking embedded in these ingenious studies was largely overshadowed by preoccupation with the anatomical implications of the aspiration lesion technique. Damage to tissue lying in the entorhinal, perirhinal, and/or parahippocampal cortices might have been contributing to poor performance in the “amygdala”- and “hippocampus”-lesioned animals rather than damage to these target areas. Later studies using more selective lesions have borne this out. For example, we now know that cross-modal memory is affected principally by the perirhinal but not the amygdala component of the original lesions (Murray and Bussey, 1999). Similarly, the spatial task appears to be unaffected by neurotoxic hippocampal lesions (Malkova and Mishkin, 2003).

Studies during the late 1980s revealed, somewhat surprisingly, that neurons in the perirhinal cortex were sensitive to familiarity and relative recency (Brown et al., 1987; Brown and Xiang, 1998). In parallel, careful anatomical studies began to focus on the neocortical regions neighboring the hippocampus, such as the entorhinal cortex (Amaral et al., 1987; Insausti et al., 1987a,b) and both the perirhinal and parahippocampal cortex (Suzuki and Amaral, 1994a, b). This work was accompanied by further lesion studies. With few exceptions,

Gaffan’s laboratory in Oxford being one of them, these studies remained focused on using the old warhorse DNMTS. Lesions described as being in the “rhinal cortex” (part of the anterior perirhinal cortex) were sufficient to cause severe, enduring delay-dependent impairment of DNMTS irrespective of whether the hippocampus had also been damaged (Meunier et al., 1993; Suzuki et al., 1993; Mishkin and Murray, 1994). Following these important discoveries, Murray and Mishkin (1998) reinvestigated the role of the hippocampus and amygdala using excitotoxic lesions. Not only does this type of lesion leave the surrounding cortex unaffected, excitotoxins should not damage fibers from the anterior perirhinal cortex passing through the ventral amygdalo-fugal pathway to the medial thalamus or the posterior perirhinal efferents projecting through the fimbria-fornix and posterior thalamus to the same nucleus (see Chapter 3). The key finding was that monkeys with average lesion sizes of 88% damage to the amygdala and 73% damage to the hippocampus showed no impairment in DNMTS (Fig. 13–8A). This comprehensive study included varying list lengths and memory delays and, following the protocols set by Alvarez et al. (1995), included delays of up to 40 minutes in a subset of four monkeys. As no deficit was observed, Murray and Mishkin concluded that, in the MTL, “the rhinal cortex is not only necessary but also sufficient to sustain visual recognition ability” (Murray and Mishkin, 1998, p. 6579). This conclusion is entirely compatible with the available electrophysiological and lesion data. In passing it should be noted that these findings rescue part of the memory circuit for memory originally proposed by

**Figure 13–8.** Conflicting findings in studies of selective lesions of the hippocampus upon delayed nonmatching to sample (DNMTS). A. Murray and Mishkin (1998) found that conjoint damage of both amygdala and hippocampus without major damage to surrounding perirhinal and parahippocampal cortex had no effect on DNMTS with memory delays as long as 40 minutes. B. Zola et al. (2000) reported that damage restricted to the hippocampus made using ischemia, radiofrequency heating, or excitotoxins caused a delay-dependent deficit in DNMTS over the same time delays. C. Zola et al. (2000) observed a similar deficit in another test of recognition memory—visual paired comparison.

Mishkin (1982) by showing that the critical pathway for a judgment of familiarity emanates from the perirhinal cortex to the medial nucleus of the thalamus, bypassing the hippocampus itself.

However, in contrast and over memory delays of as short as 2 and 10 minutes, Beason-Held et al. (1999) found hippocampus lesion-induced impairment. Zola et al. (2000) also reported that restricted hippocampal damage can be sufficient to cause impairments in both DNMTS and another test of recognition memory called the visual paired-comparison (VPC) task (Fig. 13–8B,C). The latter task, like certain tasks developed by Gaffan much earlier (e.g., Gaffan et al., 1984), involves no formal training—merely exposing the monkey to pairs of black and white line drawings on a computer screen (Bachevalier et al., 1993). After looking at these drawings for about 30 seconds, monkeys spontaneously direct their eye movements to a new drawing presented on the screen beside one of the old ones (a phenomenon first observed experimentally in studies of human infant perception (Fantz, 1964). Many pairs of such stimuli can be presented, one after the other, to build up a profile of the animal's ability to detect novelty spontaneously.

Drawing together data from experiments over 10 years using a variety of lesion techniques and a large number of monkeys, Zola et al. (2000) claimed that ischemic, radiofrequency, and excitotoxic lesions of the hippocampal region all cause a modest but significant deficit in recognition memory in both DNMTS and VPC. The deficit is apparent at delays as short as 15 seconds, with larger effects seen (at least on DNMS) at longer delays of 10 and 40 minutes. Consistent with the declarative memory theory, they concluded that the integrity of the hippocampal region is essential for recognition memory. The extent of hippocampal damage varied substantially among these three studies, ranging from 33% to 62% in the San Diego animals but, paradoxically, averaging 73% in Murray and Mishkin's NIH study that found no deficit. However, Nemanic et al. (2004) came to a somewhat different conclusion after a similar comparison of DNMTS and VPC. Their data point to a substantial deficit in both tasks after perirhinal lesions but no deficit in VPC in hippocampus-lesioned monkeys until longer delays are interposed and only a slight deficit in DNMTS at a memory delay interval of 10 minutes. Bachevalier raised the important qualification about her own study (Nemanic et al., 2004) that the average lesion size in her hippocampal group was only 43.5% (this being made with ibotenic acid), but this does not appear to be substantially different from the mean lesion size prevailing in the San Diego studies that also used excitotoxins.

#### **Comparison of Conflicting Studies Reveals Subtle Differences in Lesion Size and Methodology**

How is the discrepancy between these experiments to be explained? Some reports have indicated that apparently restricted hippocampal lesions did impair recognition memory and others that they did not. There were several pro-

cedural differences. One of these was the use of extensive pretraining by the NIH laboratory. Zola et al. commented that: "Training on the rule provides the monkeys with extended practice at holding novel objects in memory across short delays, which might then make it easier to hold novel objects in memory across the longer delays from which the performance scores are derived" (Zola et al., 2000, p. 459). The implication seems to be that avoiding preoperative training makes for a more sensitive behavioral assay, a view consistent with the apparently greater sensitivity to hippocampal lesions of the VPC task in which there is no formal training at all. This may be true empirically but is unsatisfying intellectually, as there is nothing in declarative memory theory to explain this dependence. Indeed, we should be wary of a logical inconsistency with respect to mission of this enterprise, namely, modeling amnesia. Amnesic patients have extensive experience recognizing things prior to becoming amnesic but, according to Squire, have a recognition deficit even if their brain damage is restricted to the hippocampus. Why should the animal model be any different? Furthermore, why did the San Diego laboratory insist on using a protocol so different from what they were doing with their patients?

A major focus of attention has been on the extent of damage to hippocampal and extrahippocampal regions. Growing awareness of the importance of the extent of lesion damage in individual animals led to the development of MRI-based evaluations of the locus and extent of damage (Malkova et al., 2001). Suitably calibrated, these evaluations offer the opportunity of providing accurate, noninvasive estimates of brain damage in advance of extensive postoperative testing (an ethically desirable development apart from anything else). The more usual postmortem histology has often—no doubt to the dismay of experimenters (after years of training an individual animal)—revealed wide variations in locus and size after lesions made by various techniques. There was, for example, an average of 18% extrahippocampal damage (to the parahippocampal cortex) in the monkeys trained by Zola et al. (2000), who claimed a specific hippocampus lesion-induced deficit in DNMS; but there was only 4% extrahippocampal damage in a study by Murray and Mishkin (1998), who claimed the opposite. To be fair, despite incursion into this neighboring brain area, there was no evidence of any within-group correlation between performance and the extent of parahippocampal damage in the Zola et al. (2000) study (damage ranged from 0% to 46%). Not much comfort should be drawn from this, however, as the study did not report any correlation between the extent of hippocampal damage and the recognition performance (ranging from 13% to 76% across all 14 animals tested). In contrast, Murray and Mishkin's findings indicated, paradoxically, a positive correlation between the extent of hippocampal damage and performance at the longer delays: the *greater* the hippocampal damage, the *better* the recognition performance.

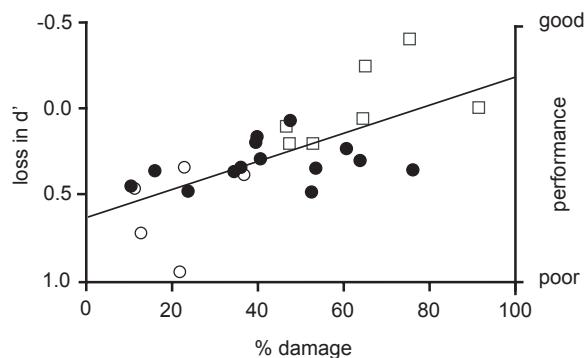

Baxter and Murray (2001b) took this curious inverse relation further with a meta-analysis of these three studies of DNMTS in monkeys with restricted hippocampal lesions.

Using an optimum  $d'$  statistic (which takes into account differences in the performance of control monkeys across studies), their analysis revealed an inverse correlation between the loss in  $d'$  and percent damage to the hippocampus (Fig. 13–9). Zola and Squire (2001) argued that this meta-analysis was invalid because it failed to partial out the potential influence of various factors that differed across studies, other than lesion size, such as whether pretraining had been given, the way the lesions were made, and the delays used to assess memory—a caution that ironically did not prevent Zola himself from generating a  $z$ -score statistic to characterize a wide range of tasks (as in Fig. 13–7, p. 600). Baxter and Murray (2001a) conceded the weakness of pooling data across studies that used slightly different training protocols but asserted that even when factors relating to lack of task identity are partialled out a nonparametric analysis of the inverse relation between loss of  $d'$  and lesion size remains significant. As in Ringo's earlier analysis of delay dependence, the use of a  $d'$  statistic was helpful, though by no means critical, as the same result pertains when raw percent correct difference scores are used (M.G. Baxter, personal communication). Moreover, each of the pooled studies secured a trend or significant inverse relation on their own.

Baxter and Murray's meta-analysis is an empirical observation, not an explanation about why there might be an inverse correlation. One possibility is that residual hippocampal tissue adjacent to the lesion produces aberrant neural activity that disrupts neighboring brain regions. There is, however, another possible reason for this paradoxical correlation that deserves careful discussion. Once again, like the debate about concurrent object discrimination learning (above), it is the old problem of task ambiguity. We saw earlier that DNMTS is amenable to two distinct strategies: a “familiarity” strategy and a “recollection” strategy. If recollection is either exclusively or

**Figure 13–9.** Meta-analysis of DNMTS. Systematic comparison of data from several laboratories reveal the paradoxical inverse relation between DNMTS performance and hippocampal lesion size (Baxter and Murray 2001). The various symbols represent data from different studies: squares, Murray and Mishkin (1998); triangles, Beason-Held et al. (1999); circles, Zola et al. (2000).

#### Paradoxical relationship between DNMTS and lesion size

monkeys (and humans) passively witnessing a new event to keep a trace (however weak it is) of the whole event, because anything can later prove to be behaviorally relevant (i.e., the stimulus, its elements, and its spatial and temporal contexts). This incidental encoding could favor the formation of conjunctive representations not only of the different elements of the sample but also of its location and contexts. (Nemanic et al., 2004, p. 2025)

We come back to this thoughtful comment in Sections 13.5 and 13.6, where the argument is presented that *incidental* encoding of stimuli does not necessarily commit an animal to being able to make only familiarity judgments about them and that the formation of conjunctive representations, even if encoded automatically, is an essential building block of recollection. Whatever the psychological basis of the VPC task, proponents of declarative memory theory do, nonetheless, like it. However, there is a lurking suspicion of circularity in this attraction; unlike DNMS, the task is reliably impaired by hippocampal lesions at reasonably short memory delays.

Again, what is needed is an information-processing analysis of specific tasks that is independent of any tests of their sensitivity to brain damage. DNMTS and VPC both suffer from the problem that there are at least two ways in which a monkey might perform the test. We need either new, less ambiguous tests of memory or new behavioral assays to establish when an animal is performing these ambiguous tasks one way or the other. Assuming that these could be developed, we could then return to the main task of mapping the cognitive process onto underlying brain systems and networks. Given that stimulus familiarity suffices to solve the DNMTS task, instances where excitotoxic hippocampal lesions have no effect (Murray and Mishkin, 1998) may be because the task has been set up to encourage no more than a judgment of familiarity (extensive pretraining?). By the same token, instances where a deficit is seen (Zola et al., 2000) may occur because the control animals enjoy the benefit, at least on some trials, of explicit recollection. In such cases, the hippocampus may provide the processing necessary for remembering the object or its image on a computer screen in its spatiotemporal context.

If this analysis is correct, a novel prediction is that context-specific recognition memory is impaired by discrete hippocampus damage in monkeys. A possible experiment might be one in which the monkey would be shown object A once in context 1 and a short while later object B in context 2. After a memory delay, it would then be presented with different types of recognition judgment. Numerous novel objects would be used across a series of trial triads. Some tests would require no more than an *absolute* familiarity judgment: Has either of the two objects been presented before? Others would involve making a *context-specific* judgment: Can the monkey indicate that object B in context 1 (or A in context 2) is a novel condition? On the analysis just presented, discrete hippocampal lesions might affect context-specific recognition memory but

not judgments of absolute familiarity. However, such a task might only work in “*incidental*” mode. Deliberate training with multiple objects in the different contexts, or objects over multiple trials, may engage conditioning processes that utilize configural cues mediated by neocortical circuitry (see Section 13.5). However, if this or another appropriate protocol could be developed, disagreement about whether the hippocampus is or is not involved in “recognition” might then move forward toward discussion about qualitatively different types of recognition memory. Such experiments would start the process of fractionating “declarative” into different kinds of propositional knowledge, just as the “visual system” has been fractionated into different streams of processing. Precisely such context-specific recognition experiments are already underway using rodents (Dix and Aggleton, 1999; Eacott and Norman, 2004). In primates, context-specific discrimination tasks have been explored (Dore et al., 1998), showing deficits after neurotoxic hippocampal lesions but not yet recognition memory.

The era of primate lesion experiments on recognition memory using DNMTS has probably drawn to a close. This is partly because of the ambiguities discussed above but also because the individuals particularly interested in these issues have moved on and a new generation of primate researchers is tackling other issues. Some primate lesion experiments are underway using new tasks, and others are focusing on single-unit and multiple single-unit recording during memory tasks (Suzuki and Eichenbaum, 2000; Squire et al., 2004). One common feature of these experiments is abandoning the notion that recognition and association are likely to be fundamentally different; both may be associative processes. Buckmaster et al. (2004) have developed tests of paired-associate learning that are more sophisticated than merely pairing an object with a reward. The animal must learn that object A goes with object B. Tests of transitive inference and delayed spatial recall are also being added to the arsenal of tests with which the multiple types of memory in the primate brain will eventually be uncovered. Similarly, Suzuki and her colleagues have examined the hippocampal single-unit correlates of paired-associate learning in monkeys, for new pairs and for well-established pairs (Wirth et al., 2003; Yanike et al., 2004). We consider the application of new behavioral tests of declarative memory later in our discussion of relational-processing theory (see Section 13.5).

### **13.3.5 Remote Memory, Retrograde Amnesia, and the Time Course of Memory Consolidation in Primates**

Given the uncertainties of testing remote memory in humans (see Chapter 12), there has been interest in examining retrograde amnesia in animals. The value of doing this is that studies can be done *prospectively*. The training experience of laboratory animals can be accurately controlled, with no ambiguity about precisely what events—and when or where—have occurred prior to a lesion. The experimenter

knows and does not have to rely on the uncertain testimony of relatives. There are, however, looming difficulties in the use of animals for such studies, one being the critical episodic/semantic distinction.

Zola-Morgan and Squire (1990) sought evidence for gradual memory consolidation by first teaching monkeys a series of 100 object discrimination problems. They were divided into five sets of 20 problems scheduled at intervals of 2, 4, 8, 12, and 16 weeks prior to creating aspiration lesions in the animals' hippocampus and surrounding parahippocampal cortex. Two weeks later they were retested on each of the 100 problems by presenting pairs of discriminanda just once (to examine retention uncontaminated by new learning). The lesioned monkeys were impaired relative to controls on the problems learned shortly before surgery, but the two groups performed at a comparable, above-chance level for problems learned 12 or 16 weeks earlier (Fig. 13–10).

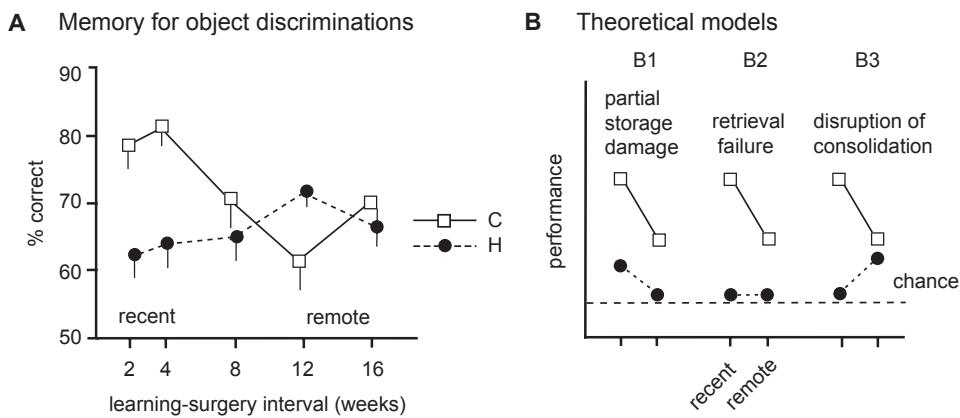

As just described, the results do not necessarily require reference to a concept such as memory consolidation – they could reflect no more than damage to a storage site and differential rates of forgetting in control and lesioned animals (Fig. 13–10, pattern in panel B1). Of greater significance are the within-subject comparisons. The controls did best on the most recent problems and worst on the problems learned initially, a pattern that reflects gradual forgetting over time. In contrast, the lesioned monkeys did not fail at both training-lesion intervals (Fig. 13–10, data pattern in panel B2), but actually did worse on problems learned 2 weeks before surgery than those learned 12 weeks earlier (Fig. 13–10, the true pattern, in panel B3). This dual pattern of performance—*forgetting* in controls but gradual *improvement* in the lesion group—is critical to the interpretation of the data. It strongly

suggests that a memory consolidation process must have been taking place in normal animals that was interrupted by the hippocampal/parahippocampal lesion.

Other primate studies failed to obtain positive evidence for consolidation (Dean and Weiskrantz, 1974; Salmon et al., 1987; Gaffan, 1993), but there are several reasons why no temporal gradient may have been observed. Inferotemporal lesions, as studied by Dean and Weiskrantz, could have damaged the actual site of memory storage in the neocortex, making it impossible to see the effect on remote memory of any putative process of consolidation orchestrated by the MTL. The study by Salmon et al. (1987), also using large MTL lesions, showed little forgetting in control animals and very poor performance in the lesioned animals—concerns about ceiling and floor effects that led directly to the design of the later experiment with more restricted lesions. Gaffan (1993) examined picture memory with various retention intervals prior to the administration of fornix lesions, but it had several curious features: First, a different number of pictures were presented in the set just before surgery than at the earlier time point; and second, a retention test was given just before surgery that could have reminded the animals of the pictures and so altered the extent to which they can be considered as exclusively belonging to the “recent” or “remote” set. Indeed, demonstrable improvement in the performance of the control group between the two retention tests strongly suggested that reminding altered the effective “age” of the memories. Although this weakens the force of Gaffan’s study, the possibility that recall can induce “re-storage” of information and so alter trace strength should not be ignored.

The study by Zola-Morgan and Squire (1990) is therefore widely considered the definitive study of gradual time-

**Figure 13–10.** Retrograde amnesia and declarative memory theory. A. Average performance during a single postsurgery probe trial for each of 100 object discrimination problems learned earlier. The data are plotted as a function of the time interval between training and the subsequent lesion. Problems learned 12 weeks before surgery are remembered better than those only 2 weeks beforehand. (Source: Zola-Morgan and Squire, 1990.) B. Data to be expected on various models of how lesions might affect storage sites or memory consolidation. B1. The lesion causes partial disruption of the site of storage.

Performance by the lesion group is always poorer than that of controls, although they may display a shallower gradient of forgetting. B2. The lesion causes disruption of retrieval. Performance is poor at all time intervals. B3. The lesion causes selective disruption of long-term consolidation. Performance shows an inverted-U shape, being better for problems when there has been time for consolidation prior to the lesion but, like normal controls, also forgetting over time. The exact form of the memory gradients is critical to the interpretation.

dependent memory consolidation in primates, although there are aspects of the results that are troubling. The use of lesions encompassing both the hippocampus and the parahippocampal cortex raises the question of whether damage restricted to the hippocampus would cause a retrograde effect. This is important given the lack of much retrograde amnesia in patients R.B. and G.D. (see Chapter 12). A study using monkeys in whom ischemic and/or neurotoxic lesions were created could offer a more exact model of the etiology and damage in these patients. To our knowledge, this has not been done. The use of a within-subjects design is a strength (with respect to mimicking the human syndrome and allowing modest use of animals), but it raises the question of whether the repeated act of “reminding” the animal of the testing situation preoperatively could influence the memory strength of earlier trained items. Putting a monkey back into the WGTa apparatus to learn a new set of problems 4 weeks after it has learned an earlier set could re-activate memory representations of the first trained problems even though the specific stimulus items are not presented again. This could happen because the training context may be sufficient to activate hippocampus-specific “pointers.” Put simply, being in a place you have been in previously reminds you of things that happened there and may make these remembered events more memorable in the future, a process that is more akin to a cyclical “reactivation and re-storage” process than an inexorable time-dependent consolidation process. Insofar as this did happen in the within-subjects design, it would particularly affect the problems learned earliest before surgery—the very ones remembered best by the lesioned animals (a different problem from that in the Gaffan study where reminding occurred just before surgery). This argument would be more convincing had there been an improvement in memory for these same “early” problems in the control group, but the controls exhibited forgetting over time. here is also the further possibility of all animals developing a “learning-set” over the succession of discrimination problems (Murray and Bussey, 2001). What is needed to settle this issue is a systematic comparison of training conditions that involve repeated reexposure to the context and of training conditions that do not. Such a study is now most unlikely to be conducted in primates, but fortunately this issue has been followed up using rodents.

Studies of retrograde amnesia in nonprimate species have been conducted using social transmission of food preferences, cue and context fear conditioning, trace-eyeblink conditioning, spatial learning, and object discrimination learning tasks (e.g., Winocur, 1990; Kim and Fanselow, 1992; Bolhuis et al., 1994; Anagnostaras et al., 1999; see Squire et al., 2001 for review). Some studies suffer from “ceiling” or “floor” effects in the data (i.e., performance being so good or so bad across a range of intervals that not all studies have both a forgetting and a consolidation gradient). However, the general pattern is of temporal gradients of retrograde amnesia consistent with a gradual process of memory consolidation, with the sole exception being certain spatial tasks that are discussed in detail later (see Section 13.4). Data showing gradual time-

dependent changes in 2-deoxyglucose utilization in the hippocampus after learning are also consistent with the idea that increases in hippocampal activity occur for a limited period time after learning (Bontempi et al., 1999; Frankland et al., 2004; Mavie et al., 2004b). These changes may constitute a physiological and molecular signature of consolidation.

There are numerous outstanding issues concerning memory consolidation as envisaged within the declarative memory theory. A key issue is what determines whether new memories are consolidated or allowed to fade. Most event memories that humans make automatically during a typical day are lost; some passive or active selection process must come into play that determines what is retained or discarded (Morris et al., 2003). Second, once set in motion, is consolidation a gradual, inexorable, largely time-dependent process? Or is it a more “quantal” process in which short consolidation episodes occur repeatedly over a longer period of time, perhaps triggered by contextual retrieval (Dudai and Morris, 2001)? Both gradual and quantal ways of thinking about consolidation could result in gradual temporal functions of retrograde amnesia when average data are considered, but the underlying mechanism by which individual traces are strengthened might be very different. Third, how does consolidated information become integrated or interleaved with information already stored in the neocortex (McClelland et al., 1995)? Fourth, should a distinction be made between “consolidation” and “semanticization”? The former would allow the persistent memory of discrete events and enable the “recovered consciousness” and mental time travel characteristic of episodic memory (Moscovitch, 1995). The latter would involve an interleaving process through which the regularities that emerge from successive similar episodes are abstracted and so be able to add to the subject’s semantic knowledge. The later recall of such information need not entail access to spatiotemporal tags (Winocur et al., 2005). Fifth, is there just one type of memory consolidation, or is there a family of distinct processes? Some have argued for a distinction between “cellular” consolidation that putatively operates rapidly within single neurons in a single brain area, and “systems-level” consolidation involving the interaction of different brain areas (Dudai and Morris, 2001). Finally, what are the indices or pointers, what do they index or point at, and how is neuronal and synaptic specificity in neocortex realized by the signals emanating from hippocampus? These and related issues constitute an important next step in the development of declarative memory theory.

### 13.3.6 Critique

The declarative memory theory of hippocampal function has been immensely influential and remains the most cited theory of memory in neuroscience textbooks (Kandel et al., 2000; Bear et al., 2001). Yet, although simplicity is desirable, one should always remember Einstein’s dictum that scientists should “keep things as simple as possible, but no simpler.” Several critics empathize with this view, two describing the theory bluntly as follows: “It is attractive, it is parsimonious, it

is extraordinarily popular, and it is wrong" (Murray and Wise, 2004, p. 194). Others, notably Gaffan (2002), go further in opposing the whole concept of memory systems, particularly that of a unitary declarative memory system encapsulated entirely within the MTL. Whether these and other critiques are well founded or merely idiosyncratic is a matter of opinion.

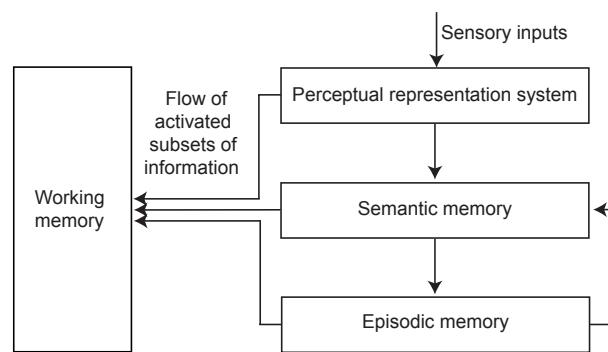

What is clear is that several problems with declarative memory theory are now widely recognized. They range from empirical issues to do with how well the data really do fit the theory, many of which have already been discussed, to conceptual issues such as the status of the taxonomy of memory systems, the role of conscious awareness in the encoding and retrieval of declarative information in humans and animals, and problems surrounding the concept and time scale of systems-level memory consolidation.

### What Is the Status of the Memory Taxonomy?

The taxonomy depicted in Figure 13–3 is easy to grasp and easy to remember. It is a joy to teach, and many a lecture in research seminars begins with this diagram—but what does it really mean? Is it meant to be an accurate depiction of evolutionary or logical distinctions between different forms of learning and their mapping onto specific structures in the human brain? Or is it actually no more than an *aide memoire*?

Taking issue with the taxonomy may seem no more than a semantic side show; but if the taxonomy is conceptually confused, it is important to reflect on this. The term "taxonomy" is used in evolutionary biology to denote "relatedness," such as between species, orders, and groups. Clearly, the use of the term here is not intended to imply that the evolution of memory proceeded first through some ancient differentiation between short-term and long-term memory and then on through all the binary divisions of the hierarchy. To the contrary, it is generally assumed that nondeclarative memory evolved earliest (Sherry and Schacter, 1987). The term "taxonomy" is being used in a different sense—one expressing ostensibly qualitative distinctions between types of memory. Nonetheless, some critics of declarative memory theory feel the need to move beyond mere taxonomy to more precise, noncircular statements of what is different (in information-processing terms) about the identified forms of memory depicted within the framework. Do the distinct nodes of the taxonomy have different "inputs" such that they operate on different types of information? Schacter and Tulving (1994), for example, argued for the flow of information into memory occurring in a serial, parallel, independent manner—the information passing first via perceptual representational systems, then through semantic memory, and on into episodic memory (Fig. 13–11). Activated subsets of semantic and episodic memory constitute the inputs to working memory, thereby creating a set of input-output relations between memory systems quite different from those envisaged in the declarative memory theory. Continuing in this vein, we may ask of the standard taxonomy (and of Schacter and Tulving's alternative), whether the memory systems in it use different learn-

Tulving's alternative SPI framework for propositional memory

**Figure 13–11.** Tulving's SPI model of propositional memory. An alternative framework for the flow of information into and between memory systems. Information flows into memory systems that operate in a serial, parallel, independent (SPI) manner (Schacter and Tulving, 1994). The flow is from a perceptual-representation system into semantic memory and then into episodic memory. Activated subsets of these systems interact with working memory (Baddeley, 2001).

ing rules. Do they encode, store, and retrieve information differently and so provide "outputs" different from those of the rest of the brain? Do their storage mechanisms express memory traces differently, with differing patterns of persistence or susceptibility to consolidation? Others are concerned that certain types of memory storage may start off in one way (e.g., declarative) but then become another (e.g., nondeclarative) through repetition in multiple contexts and/or the passage of time. That is, the ostensibly sharp boundaries of any memory taxonomy may neither be immutable nor adequately reflect dynamic changes in memory representation that occur during the course of learning. However, to be fair to the architects of declarative memory theory, these are in part issues for the future and precisely the sort of topics they have been attempting to address, notably in the many studies characterizing the nature of preserved learning in the presence of amnesia (Squire et al., 1993; Cavaco et al., 2004).

These computational- and algorithmic-level questions have to be addressed before we can proceed securely toward any mapping onto the neural substrate in which they are expressed—at the circuit, cellular, and even intracellular levels of analysis. As currently drawn, the taxonomy implies that types of learning and memory at the bottom of the hierarchy can be mapped onto specific brain areas, ranging from regions in the MTL to such structures as the striatum and cerebellum. Matters, however, are unlikely to be so simple. One controversial claim, made by Murray and Wise (2004), is that radically new concepts of the embryology and anatomical organization of major parts of the primate and rodent brain need to be taken on board by memory researchers, notably ideas most closely associated with those of Swanson (2000, 2004). One aspect of this is a shift away from thinking of brain functions as localized to discrete brain regions or to closely connected brain areas such as MTL, toward thinking in terms of "recur-

rent loops.” It is too early to assess this idea securely. However, one lesson of the last decade of functional imaging research in humans is that distributed cerebral networks for memory involving “top-down” interactions between the medial temporal and frontal lobes need to be considered and analyzed (Fletcher and Henson, 2001; Miyashita, 2004).

A last point about the taxonomy is the growing concern is that it does not readily capture the sense that the “seamless” control of behavior is almost certainly a matter of the coordinated regulation of numerous brain networks. When learning to drive a car for example, there is perceptual learning, motor control, knowledge of facts about road signs, and memory for previous similar traffic situations that one may have encountered. The taxonomy is suspiciously silent about how the outputs of the ostensibly independent forms of memory interact, compete, or are coordinated in the brain. Experimental work to date has been devoted largely to devising tasks that *dissociate* the psychological and anatomical components of memory processing rather than investigating how these entities compete or cooperate. As noted in Section 13.2, new developments in memory research are turning toward this more synthetic goal (Poldrack et al., 2001; White and McDonald, 2002). None of these comments and criticisms on their own definitively indicate that the standard memory taxonomy and its mapping onto brain areas is wrong, but they are grounds for caution.

### Inconsistencies Between the Animal Lesion Data and the Declarative Memory Theory

Several lines of inquiry have turned up data that appear inconsistent with the declarative memory theory or, at best, are handled awkwardly. Much of this is considered later in relation to other theories of hippocampal function, notably spatial, configural, and episodic theories. Studies of the neural basis of recognition memory in rats and of other forms representational memory in primates have been conducted as explicit tests of the declarative theory and so are considered here.

Hardly unique in science, there is conflict about the data. Like the proverbial housewives living in medieval tenements who always bickered at each other across the narrow alleyways (they were always arguing from different “premises”), there is a persisting conflict about the way studies of recognition memory in rats are perceived. Mumby summarized the situation fairly as one in which “most investigators are looking outside the hippocampus” (Mumby, 2001, p. 159) to explain the neurobiological basis of recognition memory. In contrast, Squire et al. (2004) continued to defend the view that damage to the hippocampus does impair recognition memory at long memory delays.

A range of techniques have been developed to study recognition memory in rodents that complement the DNMTS and VPC paradigms for monkeys. There are several DNMTS protocols in which rats are explicitly trained to learn a matching or nonmatching rule and selectively rewarded on correct choice trials. They include a Y maze nonmatching goal-boxes procedure (Aggleton, 1985; Aggleton et al., 1986), tasks in

which rats traverse runways to displace goal objects that are either familiar or unfamiliar (Rothblat and Hayes, 1987; Mumby et al., 1990; Kesner et al., 1993), and even procedures for rats using images on computer screens (Gaffan and Eacott, 1995). A continuous delayed nonmatching paradigm, teasingly called cDNM, uses a “go/no-go” digging response for the recognition of odors (Otto and Eichenbaum, 1992). Spontaneous novel object recognition (NOR), analogous to the VPC protocol for primates, is an increasingly popular paradigm for recognition memory first developed by Ennaceur and Delacour (1988). After prior habituation to the context of testing, the animal is confronted by two objects that it investigates and explores, though never formally rewarded for doing so. The objects are generally identical in a sample phase but differ in the memory test phase. Trial-unique goal boxes, objects, or smells are used for rodent DNMS, cDNM, and NOR, with the relative probability of the choice or the extent of spontaneous investigation of the novel cue serving as the index of memory of prior occurrence. One issue of concern has been that not all of the rodent studies have routinely varied the memory delay within the protocol as has been the custom in the primate work; this is important, as use of only short memory delays can yield inappropriate conclusions (Clark and Martin, 2005). There are also subtle but important differences of protocol across ostensibly similar paradigms. For example, some studies of NOR require all subjects to accumulate some minimum period of object exploration during each trial (e.g., 30 seconds), these trials of necessity then being of indeterminate duration; others have a set trial duration but then average the normalized exploration scores across subjects. Clark et al. (2000) presented data that favor the former approach, and they thereby set new standards for these types of experiment in rats (a move by the San Diego group into rodent work that may have been prompted by a certain frustration about the way so many rodent experiments were being conducted). Mumby (2001) provided a perceptive discussion of many other differences between these and the primate tasks discussed earlier.

Most of the data reported on rats indicates that restricted hippocampal dysfunction (lesions of various kinds, fornix section, intrahippocampal drug infusions) has minimal effect on these tasks (see Table 1 in Mumby, 2001). In contrast, perirhinal and postrhinal cortex lesions, including reversible inactivation using glutamatergic ligands and disruption of cholinergic neuromodulation, cause clear deficits (Bussey et al., 1999; Warburton et al., 2003; Winters et al., 2004; Winters and Bussey, 2005). There are exceptions to this pattern, but when taken as a whole it is inconsistent with the prediction from declarative memory theory that damage *anywhere* within this group of MTL structures, including the hippocampus, should cause a proportionate deficit in recognition memory. Starting with a study by Aggleton et al. (1986) using novel and familiar goal-boxes in a Y maze, a series of analytical studies led by Rawlins resolved why hippocampal dysfunction impaired nonspatial working memory in a radial maze but appeared to have no reliable effect on DNMTS (Rawlins et

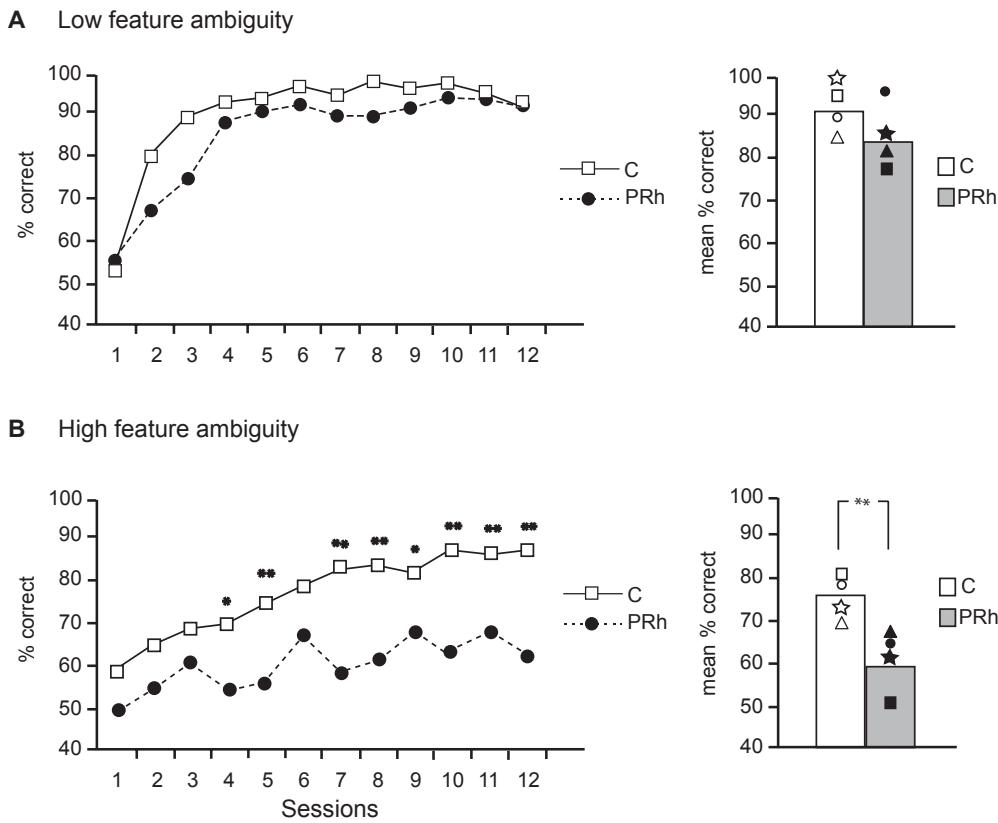

al., 1993; Steele and Rawlins, 1993; Cassaday and Rawlins, 1995, 1997). It turned out that the size of the goal box is critical, with small compact goal boxes being treated by rats as discrete “objects,” whereas larger boxes are treated as “spaces” and so engage spatial and relational encoding (see Sections 13.4 and 13.5). Hippocampal lesions only affect memory for large goal boxes. These findings have been complemented by concern that certain protocols for testing nonspatial recognition memory may have cryptic spatial or contextual components. For example, Nadel (1995) was the first to point out that the deficit in DNMTS at long memory delays in certain primate studies was confounded by the monkeys being, for practical reasons, removed from and then later returned to the WGTA testing apparatus at the longer but not the shorter delays. Control but not hippocampus-lesioned monkeys might then benefit from contextual cues aiding recall.

However, cryptic spatial processing is unlikely to be an issue for a different DNMTS protocol developed by Mumby et al. (1992a). They trained rats with memory delays varying from 4 to 600 seconds with the sample and choice components at opposite ends of a runway during a trial but scheduled equally often at both ends across trials. Subsequent to surgery, no impairment was seen in rats with aspiration lesions of the hippocampus, or of hippocampus and the amygdala, at any delay except the longest (10 minutes) at which the hippocampal lesion groups then performed more poorly than controls. Although sometimes cited as support for the idea that hippocampal lesions can affect recognition memory in rats, there is a caveat here also. Specifically, the within-subject comparisons showed that the control group got paradoxically *better* at the 10-minute delay rather than the lesion group getting worse. This improvement by controls was not seen in several later studies, and thus Mumby’s (2001) reasonable conclusion was that this single statistical difference was the exception to the rule that hippocampal lesions have minimal if any effect on rodent DNMTS. However, using a large test battery in the manner of Zola-Morgan and Squire (1985), Mumby et al. (1995) again found a small but significant hippocampal lesion deficit in DNMTS at the longest delay tested (120 seconds) relative to both no surgery and partial parietal cortex lesion control groups. Clark et al. (2001) later also secured a deficit in rats with excitotoxic hippocampal lesions at the longest delay tested (also 120 seconds). Thus, another equally reasonable way of summarizing the data is that when hippocampal lesion-associated deficits have been seen they have tended to be at long memory delays or with long list lengths (Mumby et al., 1992b; Steele and Rawlins, 1993; Mumby et al., 1995; Wiig and Bilkey, 1995; Clark et al., 2001). This would be consistent with the declarative memory theory were it not for the much greater sensitivity of these tasks to perirhinal lesions of comparable or even smaller size. Either the hippocampus is at the “apex” of declarative memory processing or it is not.

What might be the key difference between studies that find a deficit after hippocampal lesions (Clark et al., 2000; Broadbent et al., 2004) and those that do not (Ennaceur and

Aggleton, 1994; Winters et al., 2004; Forwood et al., 2005)? Lesion size or, more generally, the degree of hippocampal dysfunction is one possibility. For example, Ennaceur and Aggleton (1994) found no effect of fornix lesions on NOR at delays varying from 1 to 15 minutes but dropping to chance levels over 4 hours. Other studies using fornix lesions reported similar results, but it should be remembered that fornix lesions in monkeys have little impact on DNMTS and may leave many aspects of MTL function intact. Perirhinal lesions have consistently been observed to impair NOR (Bussey et al., 1999; Murray and Bussey, 1999). Consistent with these findings but drawing a very different conclusion, Clark et al. (2000) conducted a comprehensive study of NOR using groups of rats subjected to sham surgery, fornix lesioning, or radiofrequency and excitotoxic hippocampal lesioning. Importantly, they required the absolute accumulation of 30 seconds of total object exploration time by all subjects. Fornix-lesioned subjects did not show a deficit, consistent with earlier findings. However, rats with either type of hippocampal lesion showed impairments at a 1-hour memory delay. In a follow-up study by Broadbent et al. (2004), a deficit in NOR was observed as a function of hippocampal lesion size. Small lesions caused no impairment, whereas larger lesions did. Given the parallel, distributed nature of hippocampal processing (see Chapter 14), it is reasonable to suppose that many functions of the MTL that require hippocampal processing could continue relatively normally after partial lesions.

Finally, turning back to primates, Murray and Wise’s (2004) critique of the declarative memory theory offers several other examples of instances where the two sides in the debate draw different conclusions from a common set of data. One example has to do with whether the perirhinal cortex has only memory functions (Buffalo et al., 1998a; Teng et al., 2000) or also participates in aspects of perceptual processing. For example, Teng et al. (2000) reported that rapid learning of a discrimination between simple three-dimensional objects (e.g., a red versus a green peanut shell) is only slightly impaired by hippocampal lesions, notably over the first few trials of the day (which were described as more “declarative” in nature), whereas the much slower learning of two-dimensional pattern discrimination (e.g., N versus W) is unaffected by hippocampal lesions unless they extend to include damage to the tail of the caudate nucleus. In contrast, Bussey et al. (2002) reported that discrimination of compound visual stimuli with the ambiguity between the features maximized is strikingly impaired by perirhinal lesions, whereas the discrimination of those with minimal common features is unaffected. A follow-up study by Bussey et al. (2003) used morphed images to produce a single-pair discrimination task in which the two stimuli to be discriminated had either very high or very low feature ambiguity (Fig. 13–12). The results show a clear perirhinal deficit on the slowly learned, maximal feature ambiguity task. These findings are problematic for the declarative memory theory for two reasons. First, the theory asserts that the MTL receives

**Figure 13-12.** Perirhinal cortex and perception. Lesions of the perirhinal cortex, ostensibly part of a medial temporal lobe memory system, cause a deficit in the perceptual discrimination of stimuli with high-feature ambiguity (B) but not low-feature ambiguity (A). The symbols in the bar graphs on the right indicate scores of individual monkeys. (Source: After Bussey et al., 2003.)

perceptually processed visual inputs from the inferotemporal cortex and is not itself involved in making perceptual discriminations. Second, it asserts that rapidly learned visual discrimination tasks, other things being equal, are most likely to be learned in a declarative manner whereas slowly learned discriminations are acquired in a habit-like way, as in the Teng et al. (2000) study. Yet here it is the *slowly* learned discrimination that is most sensitive to lesions of the perirhinal cortex. Indeed, a body of data from rats, monkeys, and humans as well as relevant computational modeling support the notion that the perirhinal cortex has a role in object perception (Murray et al., 2005). Data from amnesic patients with restricted hippocampal damage or damage extending into neocortical structures of the MTL (identified radiographically) indicate that the discrimination of faces and scenes of ever greater similarity can pose a particular challenge for patients (Lee et al., 2005).

#### Certain Comparative Problems When Asserting that Declarative Memory Must Be Conscious

The insistence on MTL structures mediating memory that can be consciously declared is clearly problematic for a theory that seeks to encompass both humans and animals. In numerous

laboratory tasks, animals have been shown to remember things that people would describe as facts (e.g., that a certain food is safe to eat) and that they can remember events (e.g., that an initially novel object has been seen before). However, will we ever know whether an animal is conscious of its memories? Moreover, even if we did, how could an animal ever “consciously declare” that it knows or remembers something from the past? Does it have a sense of its own life in the way that humans do—of the state of mental awareness that Tulving (1983) called “autonoetic consciousness”? If the answers to these questions are negative, one is tempted to wonder whether a central feature of the theory lies more in the realm of metaphysics than in empirical science. In fact, a comprehensive theory of brain and mind should identify under what circumstances animals and humans are conscious, what they are conscious of, and perhaps why consciousness is advantageous for some but not other forms of memory (Zeman, 2002).

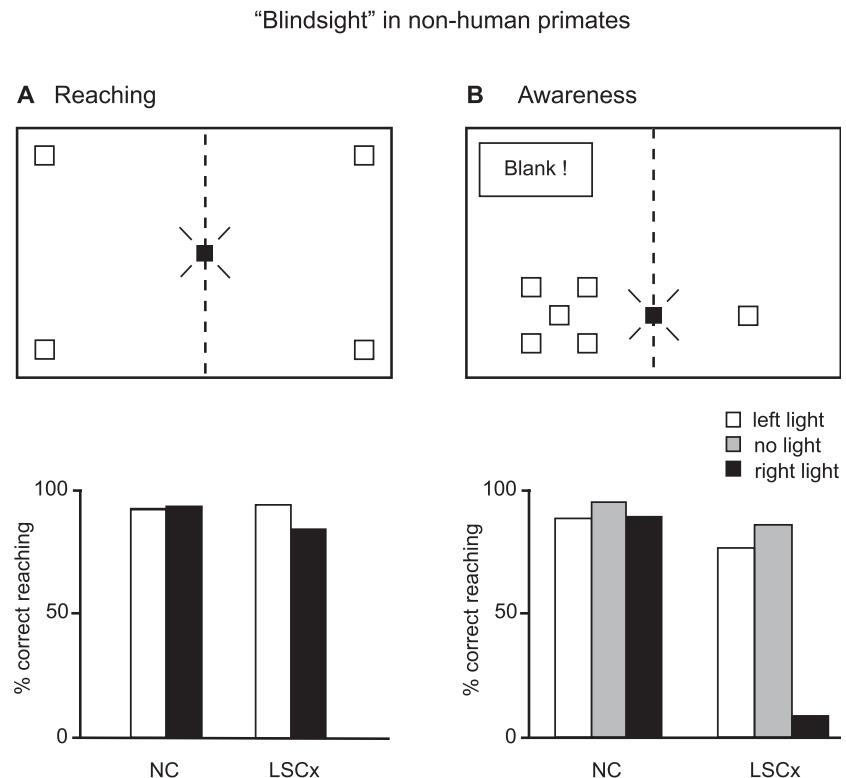

This issue is usually finessed in what was referred to earlier as the “folk psychology” approach to consciousness that the declarative memory theory has taken to date. Nonetheless, in the context of work on “blindsight,” animal experiments are making inroads into the issue of mental awareness. For example, Cowey and Stoerig (1995) devised an ingenious procedure

in which monkeys that had been trained to reach accurately toward one of several targets were also required to "report" whether they were visually aware of the targets. Monkeys were placed in front of a touch screen. Each trial began with them looking at a fixation point and ended with their reaching out to touch various images presented a little while later in the left or right visual field. Operated monkeys (with large unilateral striate cortex lesions) were observed to reach as accurately in their blind hemifield as normal monkeys (Fig. 13–13A). The "reporting" of awareness was achieved in a separate training condition in which the monkeys had to touch a specific area of the screen if a target failed to occur at a time when they might have expected to see one (the possibility of a target was indicated by an auditory cue). The lesioned monkeys *correctly* reported that they could not see a target when targets were deliberately not presented on selected trials to their intact hemifield, but the monkeys *incorrectly* reported not seeing targets that were actually presented to their blind hemifield (Fig. 13–13B). These "unseen" targets were the very ones to which, in the first training condition, the animals had reached accurately. To all intents and purposes, these monkeys lack "phenomenal" vision; that is, they lacked the ability to "comment on" seeing things to which they could reach accurately (Weiskrantz, 1997).

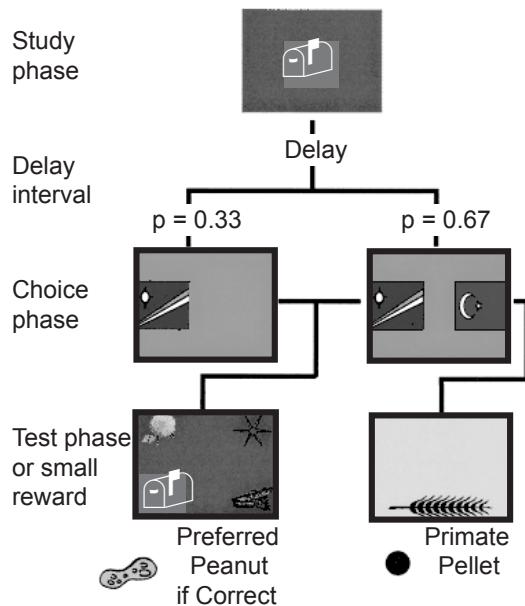

Analogous procedures might be developed for studies of memory in primates, the point being to devise a way of dissociating between the successful performance of a memory task and the quite separate display of awareness that one is (or is not) remembering. In an important step, Hampton (2001) exploited techniques developed in parallel for pigeons (Sole et

al., 2003) to examine whether rhesus monkeys know when they remember. Using computer-controlled techniques, each of two monkeys was briefly shown an image on a touchscreen (Fig. 13–14). The image then disappeared for a delay interval during which the animals may have sometimes remembered it and other times forgotten it. They were later tested for their memory of the image. What made this experiment different from conventional delayed match-to-sample testing was that the monkeys were allowed, for two-thirds of the trials, to choose between progressing to the memory test or declining to do it. Declining resulted in a guaranteed but less preferred reward than could be obtained by accepting to do the memory test and choosing correctly. For the remaining one-third of the trial sequences, the monkeys were not given a choice and were forced to take the memory test. The results showed that both monkeys performed more accurately on memory tests they had opted to take than on enforced tests. A control experiment included trial sequences that began without an image to remember during the delay interval; the monkeys routinely reacted to these sequences by declining to do the memory test when given the option to do so. Moreover, as the memory delay interval was extended (a procedure likely to promote forgetting), the monkeys showed a temporally graded reluctance to take the memory tests. Taken together, these results suggest that the monkeys' decision whether to take the memory test at the end of a trial sequence was likely to have been based on their own self-generated "awareness" of whether they could remember the image. This sort of procedure might be adapted to establish whether lesions of the hippocampal formation (or, better still, reversible inactivation) disrupt aware-

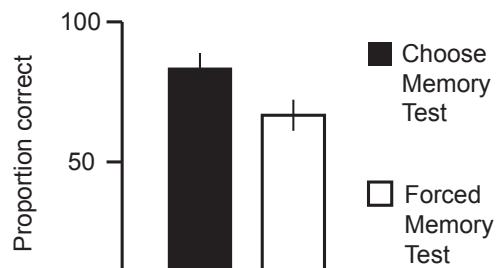

**Figure 13–13.** Blindsight in primates. Cowey and Stoerig's (1995) "commentary" procedure for studying visual awareness in primates. *A.* The animals watch the fixation spot (center) and then upon hearing a tone reach toward one of four peripherally located and briefly illuminated targets. Monkeys with striate cortex lesions can do this as well as control animals. *B.* The animals again watch the fixation spot and, upon hearing the auditory cue, reach for one of the five briefly illuminated lights on the left, the light on the right or, when no flash occurs, for the panel at the top left. Normal monkeys correctly identified all trial conditions. Monkeys with unilateral striate cortex lesions identified lights flashed in their good hemisphere but treated the right-hand illumination as if it had not occurred. Thus, monkeys display "blindsight" in being able to reach toward objects they "report" being unable to see. Can an analogous "reporting" procedure be developed in the domain of memory? (Source: Cowey and Stoerig, 1995).

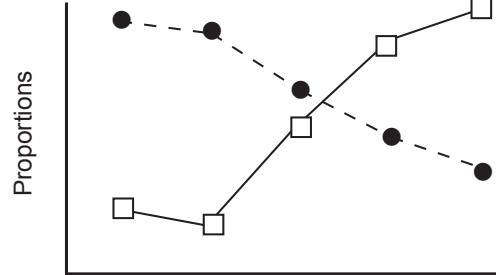

### A Metamemory - experimental design

### B Recognition Memory

C.

**Figure 13-14.** Metamemory. A. Monkeys were allowed, during two-thirds of the trials of a recognition test, to choose whether to take a memory test on the basis of their covert judgment of whether they could remember. B. Memory performance on trials when they chose to take the recognition test was significantly better than on the remaining one-third of trials for which they were forced to take the test. (Source: Cowey and Stoerig, 2001).

ness of memory to the same extent that they disrupt accurate performance. Might monkeys with hippocampal disruption show above-chance familiarity for a previously presented stimulus even though they “declare,” in the optional choice test, that they would prefer not to take the test? Might they know but not remember? A human imaging study of this issue (Kao et al., 2005) suggests that such a task, even if it could be developed for monkeys, would be likely to involve an interaction between the MTL, mediating successful memory, and the ventrolateral prefrontal lobe, mediating memory awareness.

#### Nondeclarative Memory: Are Spared Learning Abilities Nonpropositional or Learned Tasks That Can Be Performed Without Awareness?

A critical claim of the theory is the independence of declarative and nondeclarative memory. The two key differences claimed by Squire (1992) for these superordinate categories of memory relate to the “propositional” status of the information being processed and the necessity of “awareness” during the encoding and recall of such information.

The existence of spared learning in the presence of amnesia has been the subject of comment for about a century (Claparede, 1911; Weiskrantz, 1997). It is a particularly intriguing feature of the syndrome to discuss with students or present to a public audience. How can it be that H.M. could learn to draw in a mirror yet not remember doing so? How could he and other patients have this curious disconnection in

their conscious awareness of the past? Anecdotes about spared “unconscious” memory function abound. Each new generation of neuropsychologists add their own; an excellent example is an endearingly personal article entitled “Memories of H.M.” (Ogden and Corkin, 1991). Patient E.P.—one of the most profoundly amnesic patients to have been subject to detailed neuropsychological and neuroradiological examination in the San Diego neuropsychological studies—is another case in point.

During the first 2 or 3 years in which we visited his house, he was wary and slow to accept the idea that we wished to talk with him and administer tests. After some conversation, and with encouragement from his wife, E.P. would after a number of minutes seat himself at a table for testing. During the subsequent years, the same tester has visited his house more than 150 times. Now when she arrives he greets her in a friendly manner and moves readily and promptly to the table even when his wife is not present. Yet, his pattern of greeting and acceptance occurs without any recognition of who the tester is, and he will repeatedly deny that he has seen her before. (Stefanacci et al., 2000, p. 731.)

The declarative memory theory, perhaps more than any other theory of memory, has put forward this disconnection of consciousness as a centerpiece. It makes the distinctive claim that such “nondeclarative” learning is not merely spared, as others had claimed previously, but that such learn-

ing occurs in amnesics at a normal rate and in a manner indistinguishable from that of controls. To emphasize this key point, it is not only that amnesic patients *can* display classic conditioning, as Warrington and Weizkrantz (1968) were the first to describe, it is that they do so at a *normal* rate despite a lack of awareness of the fact of learning (Gabrieli et al., 1995). However, because certain ostensibly “nondeclarative” tasks may be subject to contamination of learning using a declarative strategy, findings from patients with mild amnesia who have residual declarative memory can be misleading. The importance of drawing firm theoretical conclusions only from those rare individuals with severe amnesia was a theme of an early critique of the declarative memory theory (Weiskrantz, 1997) and, in a paradoxical twist, one now taken up by Squire et al. (2004) in their careful comparisons of performance by people and animals with partial versus complete damage to the MTL (e.g., patient R.B. versus patient E.P.).

Nondeclarative learning does not, of course, usually take place outside of consciousness. Learning to ride a bicycle, for example, is a motor skill for which most of us are acutely conscious of what we are doing as we attempt to learn. The declarative memory theory makes the radical claim, however, that although aware of the act of learning this awareness does not play any *causal* role in the encoding or expression of learned motor acts. This is a rather interesting idea but one that is difficult to test rigorously. It cannot be tested by seeing what learning capacity remains while we are unconscious—not because we cannot then ride bicycles (though that too) but because the lack of “awareness” to which the theory makes reference is not a lack of consciousness as such but an absence of awareness *of* the information relevant for learning at the moment of motor recall.

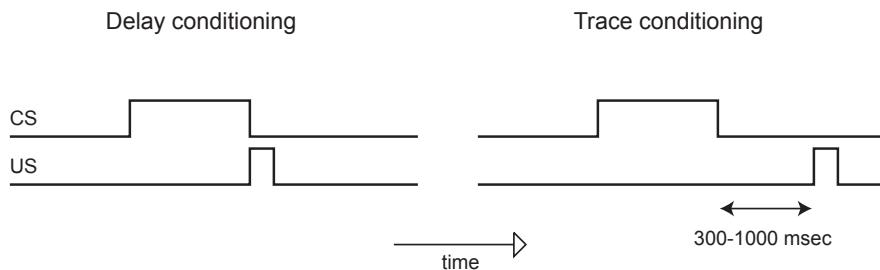

This absence of the *referent* of awareness is highly specific in the nondeclarative domain. For word-stem completion priming, for example, people are asked to think of a word—any word—that begins with the stem given as a cue. Subjects are aware they are being tested, aware that the test involves words, and attentive to the task in hand. Amnesic subjects, however, are unaware that the words they come up with are often words they were shown earlier. What they fail to “declare” is not the words themselves, but that they have the phenomenological attribute of being words they remember having seen earlier. This simultaneous sense of being tested in the present and bringing to mind events from the past is what is meant by “mental time travel” (Schacter and Tulving, 1994; Tulving and Markowitsch, 1998), and it is an attribute of mind that amnesics lack (Weiskrantz, 1997).

In a similar vein, studies of incidental learning suggest that unilateral MTL lesions can disrupt memory for information to which a person’s attention is not overtly directed until the point of recall. In a famous study, Smith and Milner (1981) gave subjects a series of small toys, one by one, asking them the likely price of the real thing (e.g., a car). Their attention at encoding was directed to the value of the toys. One by one, the toys were put down by the experimenter in various places on the table in front of the subjects, without the subject’s atten-

tion being drawn to the matter of location. Later, without prior warning, the experimenters asked subjects to recall where the objects had been placed. The subjects were never asked to pay attention to and, in that sense, be attentively aware of the location of the objects until the retention test. That normal subjects could do this task suggests that they may *automatically* encode attributes of a stimulus to which their attention is not directed despite paying attention to other attributes of the stimulus, such as its value. In contrast, people with large right MTL lesions were impaired. In this case, the experimental manipulation of “awareness” occurred at the point of encoding, but manifestations of this differential awareness only came to light at the point of recall. We return to the issue of differentiating “automatic” and “intentional” encoding in Sections 13.5 and 13.6.

This discussion leads us to suggest that the nondeclarative nature of nondeclarative memory may be less to do with whether the skill being performed can ever be “declared” than with whether subjects are consciously unaware of the prior occurrence of the stimulus at the time of recall. The importance of awareness rather than propositional status is particularly well revealed in studies of eyeblink conditioning, an advantageous paradigm for the present purposes as it can be studied in both humans and animals. In this form of conditioning, an initially neutral stimulus such as a tone is presented for a few hundred milliseconds before a puff of air to the eye. Through repeated pairings of these two stimuli, the subject develops a conditioned response (CR) to the tone (the conditioned stimulus, or CS). Eyeblink conditioning has been extensively studied in humans and animals and is known to obey the basic principles of classic (i.e., Pavlovian) conditioning (see Section 13.5). Learning depends on the contiguity and contingency between the CS and the puff of air (the unconditioned stimulus, or US). It is a form of conditioning for which the cerebellum was found to be essential (Clark et al., 1984). Following the observation that amnesics could acquire classic conditioning (Warrington and Weizkrantz, 1968) and that it occurs at a normal rate (Gabrieli et al., 1995), it had been widely assumed that this is not a form of learning in which the MTL is ever engaged. This turns out to be not quite right.

Two frequently studied forms of human eyeblink conditioning are named (somewhat inappropriately) the “delay” paradigm (in which, confusingly, the US follows the CS with no delay between the end of the CS and the onset of the US); the “trace” paradigm in which CS offset occurs 300 to 1000 ms prior to US onset (Fig. 13–15). As the CS and US are not contiguous in time, Pavlov suggested (and others since) that some “trace” of the CS must linger in memory if an association is to be formed with the US to allow effective conditioning (hence the name). Although no deficit is seen in amnesics using the delay paradigm, McGlinchey-Berroth et al. (1997) have shown that such patients have impaired trace eyeblink conditioning across a range of trace intervals. The contrast between these two protocols is instructive as what subjects learn to do in each case—to make automatic, appropriately timed CRs—can hardly be said to be nonpropositional in the former case but

**Figure 13-15.** Protocols for delay and trace conditioning. Time lines showing the onset and offset of the conditional stimulus (CS) and unconditional stimulus (US) in two distinct forms of classic conditioning. Appropriately timed CRs develop in both protocols, yet only one is thought to be hippocampus-dependent.

propositional in the latter. It is therefore an important test for the theory to identify what might be “declarative” about trace conditioning.

Clark and Squire (1998) used a differential trace conditioning paradigm in which the CS+ (a tone) was followed by the air-puff US, whereas a second stimulus, the CS- (a noise), was presented on its own. Sessions consisted of multiple presentations of each stimulus to human subjects, some of whom were subject to a delay paradigm and others to a trace paradigm. All were required to watch, attend to, and try to remember a silent movie (Charlie Chaplin’s “The Gold Rush”) while these CS and US events were happening, thereby commanding a great deal of their conscious awareness. At the end of the experiment, in addition to being quizzed about the movie, the subjects were asked a set of questions with true/false answers designed to explore their awareness of the stimulus contingencies. The key finding was that successful trace conditioning was correlated with levels of awareness of these contingencies. A subset of control subjects who showed good awareness of the CS predicting the US after the trace delay conditioned well. Other control subjects, and all amnesic subjects tested, were less aware or even unaware of the stimulus contingencies—they conditioned poorly. Awareness was unrelated to levels of conditioning in the delay paradigm, a result that is not universally obtained (e.g., Knuttilen et al., 2001). Furthermore, to explore whether the correlation between level of awareness and degree of trace conditioning was causal, Clark and Squire (1998) manipulated awareness directly. Manipulations that facilitated awareness facilitated eyeblink conditioning; manipulations that reduced it blocked conditioning. A subsequent critique (LaBar and Disterhof, 1998) queried Clark and Squire’s use of a differential conditioning protocol somewhat different from those used in many previous studies of human eyeblink conditioning; they also wondered whether a better “online” measure of awareness than a postexperimental questionnaire might be developed. Manns et al. (2000a) provided both in a study of normal subjects who showed a close predictive relation between developing awareness of the CS-US trace contingency and subsequent levels of conditioning. These investigators also showed that the critical feature of this awareness is the subject’s awareness of the CS-US contingency rather than their awareness of the likelihood of blinking. Thus, it appears that what is “declarative” about trace conditioning is an awareness of the fact that the tone predicts that an air-puff will come shortly—an awareness that can be expressed propositionally. This awareness may arise

through some interaction between hippocampus and neocortex during the course of conditioning and is somehow fostered by using the trace conditioning paradigm. By virtue of this, a suitably timed signal can be sent to the cerebellum where the eyeblink response component of the conditioning takes place. The eyeblink CR, a learned but automatic defensive response, can then be executed at the appropriate time.

To summarize, what is nondeclarative about nondeclarative learning may actually be the lack of awareness of what is being remembered at the point of recall, rather than any intrinsic inflexibility in what has been learned or a lack of propositional status of the content of learning.

#### Are Fact-Memory and Event-Memory Processed by a Common Brain System?

Superficially, amnesics present with a deficit restricted to episodic memory. They cannot remember events for any length of time, but their factual knowledge about the world and their knowledge of language are both intact. Semantic memory shows all the appearances of being preserved. The declarative memory theory holds that this dissociation is profoundly deceptive. It asserts that there is a “unitary” process underlying the formation of both event and fact memories. The reason amnesic patients display intact semantic memory is because so much of a person’s factual knowledge was acquired years earlier, extending from the years of childhood on through life. Consolidation of such memory traces would be long completed. Conversely, a patient’s failure of event memory often relates to relatively recent events such as a forgotten conversation of the day before.

Although most amnesic subjects have some residual episodic memory function, a few are claimed to have little or none. In Chapter 12, we noted the striking case of patient E.P., who has essentially no measurable recent episodic memory but who, becoming amnesic when adult, displays good factual knowledge of the world acquired earlier in life and remarkably good memory for spatial and other episodic-like information acquired during childhood. However, if this interpretation is correct, people who have sustained damage to the MTL at a much younger age should also show impaired semantic memory. Data concerning the effects of bilateral hippocampal pathology sustained early in life are relevant to this issue (Vargha-Khadem et al., 1997). Three young developmental amnesics who sustained brain injuries at birth, 4 years, and 9 years of age, respectively, were aged 14, 19, and 22 at the time

of first testing. The anoxic-ischemic episodes they had are likely to have affected the hippocampus preferentially. MRI measurements revealed hippocampal volumes ranging from 43% to 61% of normal. T2-weighted relaxometry measurements also revealed hippocampal abnormalities, but MR spectroscopy values were within the normal range. Additional MRI measurements in other brain areas suggested that bilateral hippocampal changes are not only the primary pathology but might be essentially the *only* pathology in all three cases (Mishkin et al., 1997).

The striking neuropsychological feature is that their amnesia is largely exclusive to episodic memory. They are temporally and spatially disoriented: forgetting the date and appointments, getting lost, mislaying their belongings. Despite severe problems of episodic memory, these children all attained levels of speech and language competence and of literacy and factual knowledge within the low average to average range. They all attended mainstream schools, and their acquisition of semantic information appears to be normal (or at least near-normal) as assessed by performance on the Wechsler Adult Intelligence Scale (WAIS) verbal intelligence tests. Their performance on a Basic Reading and Reading Comprehension subtest was normal in all three cases, as was their Spelling subtest (with the exception of one subject whose spelling is poor).

The pattern of memory preservation and memory loss shown by these children is in striking contrast to what would have been expected on the basis of the declarative memory theory. Vargha-Khadem and her colleagues argued that these three patients raise the possibility that the “basic sensory memory functions of the perirhinal and entorhinal cortices may be largely sufficient to support the formation of context-free semantic memories but not context-rich episodic memories, which must therefore require the additional processing provided by the hippocampal circuit” (Vargha-Khadem et al., 1997, p. 379). However, further research is required before such conclusions can be drawn with any certainty as later commentaries on these cases and parallel primate studies have recognized (Mishkin et al., 1998; Bachevalier and Vargha-Khadem, 2005). For one thing, the children appear to have *some* residual episodic memory, and this may have been sufficient for them to learn well in school, albeit more slowly than other children and perhaps only after frequent repetition. Moreover, although Vargha-Khadem and her colleagues interviewed the children’s parents, they did not report on any discussions with the childrens’ schoolteachers. It is difficult to believe that their teachers would have failed to notice their severe episodic memory difficulties and thus compensated for these problems with their teaching. The early damage to the brain may also have resulted in morphological reorganization of MTL structures in a way that does not occur when adults become amnesic. Certainly the MRI measurements do not all point to a completely destroyed hippocampus. Taken together, although fascinating cases, these concerns blunt the critical impact on declarative memory theory that they might otherwise have had.

Does it make sense to suppose that the memory of facts and events could depend on a single brain system? According to the theory, both types of information require the integrity of the hippocampal formation for their formation (encoding); and both result, after memory consolidation, in stable long-term traces in neocortex. Success in recalling either a fact or an event depends only on the “strength” of the traces established through consolidation. In contrast, Nadel and colleagues (Nadel and Moscovitch, 1997, 1998; Nadel et al., 2000) have argued that memory for an event requires access to a hippocampally based “contextual” trace (where the event happened) and a prefrontal “temporal” trace (when the event happened). Retrieval of event memory is a reconstruction based on both of these traces and other information about the event itself stored elsewhere in the neocortex. Retrieval of factual information, on the other hand, is not thought to require either a contextual or a temporal trace; it is context-independent.

In conclusion, we still do not understand the precise role of the hippocampus in episodic and semantic memory or, within the domain of episodic memory, in familiarity and recollection. The immediately preceding discussion, complementing Chapter 12, points to the need to develop new animal models of these forms of memory and of retrieval to help resolve the issues. We return to these important ideas in Section 13.6 after we have discussed the other major theories of the hippocampus: cognitive mapping and predictable ambiguity.

### 13.4 Hippocampus and Space: Cognitive Map Theory of Hippocampal Function

“Space,” wrote O’Keefe and Nadel (1978, p. 5), “plays a role in all our behavior. We live in it, move through it, explore it, defend it . . . yet we find it extraordinarily difficult to come to grips with space.” This strident rhetoric, together with discussion of the philosophical concept of space, introduced a book that outlined the then new “cognitive map” theory of hippocampal function. The theory has developed substantially over the past quarter century.

The primary stimulus for its development was the discovery of “place cells” in the hippocampus of freely moving rats (O’Keefe and Dostrovsky, 1971). These cells are neurons that, as discussed in Chapter 11, are characterized by patterns of firing that increase from a generally low level to higher rates as a freely moving animal moves through a particular region of space. As different place cells are responsive in different locations and are found throughout the septo-temporal axis of the hippocampus, it was natural to suppose that the collective firing of different place-cell ensembles in different environments might be the neural substrate of distinct “maps” of space. Observations on place cells were quickly followed by the discovery that lesions of a major fiber tract into the hippocampal formation, the fimbria/fornix, resulted in an apparently selective deficit of spatial, but not cue, learning by rats

in a circular maze task (O'Keefe et al., 1975). These two findings were the trigger for a comprehensive review of the literature and one that offered an imaginative reassessment of findings hitherto explained in other ways (O'Keefe and Nadel, 1978).

The cognitive map theory was the first of several spatial theories of hippocampal function. Its authors have since outlined modifications of the theory, beginning with Nadel's work on "context" (Nadel and Willner, 1980), through ideas about multiple memory traces stored in the hippocampus (Nadel and Moscovitch, 1997), and now incorporating neuroimaging findings from humans performing virtual navigation tasks (Burgess et al., 2002). O'Keefe has also explored the relevance of the theory to the neural basis of language, in particular spatial prepositions (O'Keefe, 1996). Other spatial memory theories include the "scene memory" hypothesis of Gaffan (1991), the "fragment assembly" hypothesis (Worden, 1992), and the closely related idea of the hippocampal formation being involved in "path integration" (McNaughton et al., 1996; Whishaw, 1998; Redish, 1999). There have also been ideas about the "metrics" in which spatial information is processed (Poucet, 1993) and a "dual," or "parallel-map," theory (Jacobs and Schenk, 2003). This latest development argues for a synergistic interaction of a directional "bearing map" and an allocentric "sketch map"—each mediated by distinct but overlapping subregions of the hippocampal formation. Like the ideas about path integration, it incorporates the discovery of another category of spatially tuned cells, the head-direction units (Taube and Schwartzkroin, 1987; Taube, 1998). These are cells, described in Chapter 11, that fire when a rat's head is facing a particular direction in a familiar environment irrespective of the animal's location. In parallel with this neurobiological theorizing, there has been continuing interest in the psychological literature concerning the concept of "cognitive mapping" (Gallistel, 1980) that dates back to Tolman's classic paper (Tolman, 1948). Although the term cognitive mapping was used in a slightly different sense by Gallistel, this renewal of interest has prompted debate that, in an unexpected turn, has cast doubt on the explanatory power of the concept (Bennett, 1996; Wang and Spelke, 2002). Mackintosh has also queried its adequacy as an account of how animals get from one place to another but expressed the view that the 1978 book "deserves its status as a modern classic" (Mackintosh, 2002, p. 181). Numerous reviews have been published (Poucet, 1993; Muller, 1996; Taube, 1999), as have two comprehensive books focusing on the neurobiology of spatial, context, and episodic memory (Redish, 1999; Jeffery, 2003).

### 13.4.1 Outline of the Theory

The five main suppositions of the original (1978) cognitive map theory relate to representation of the environment, navigation through it, the evolution of an ostensibly specialized spatial memory system, storage of spatial information, and the relevance of a specifically spatial system in animals to the mediation of episodic and semantic memory in humans.

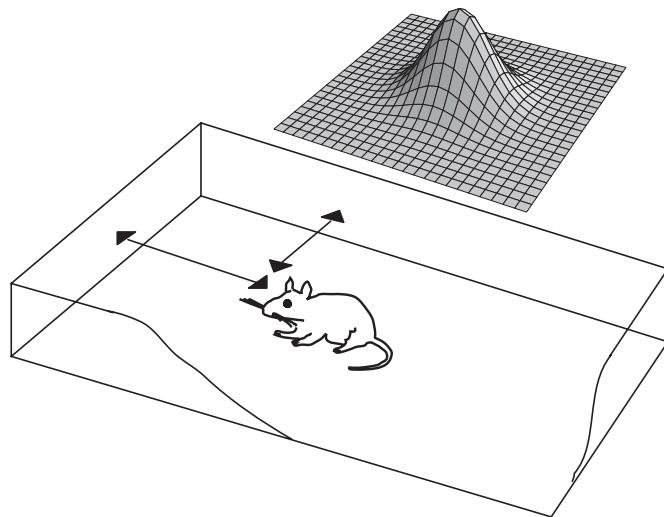

### Box 13-4 Cognitive Map Theory

1. *Representation:* The vertebrate brain has a neural system—the "locale" system—that organizes the encoding and representation of perceived stimuli with respect to an "allocentric" spatial framework, or "cognitive map." The spatial locations of landmarks are stored in this map during exploration. This locale system is in the hippocampus.
2. *Navigation:* The locale system is used for spatial navigation. The various anatomical components of the hippocampal formation are involved in mediating different aspects of spatial information processing, with distinct classes of neurons responsive to an animal's place, head-direction, view and its movement through space.
3. *Evolution and the laws of learning:* Spatial mapping evolved as one of the multiple memory systems of the vertebrate brain with its own distinctive learning rules. Other types of learning and memory include simpler associative mechanisms and certain geometrical tasks that can be acquired using "taxon" strategies. These other systems obey laws of learning that are different from those of the locale system.
4. *Sites of storage:* Spatial maps are stored in the hippocampus. They are not consolidated or stored elsewhere in the brain, although information stored in the hippocampus does interact with information stored elsewhere for the purpose of guiding navigational behavior. An intrahippocampal consolidation mechanism may nonetheless exist.
5. *Extension of the theory to humans:* Whereas the cognitive map is purely spatial in animals, it subserves the storage and recall of linguistic and episodic memories in humans. Lateralization enables the right hippocampus to maintain a primarily spatial function, whereas the left hippocampus incorporates a temporal sense and linguistic entities that together provide the basis for mediating episodic memory.

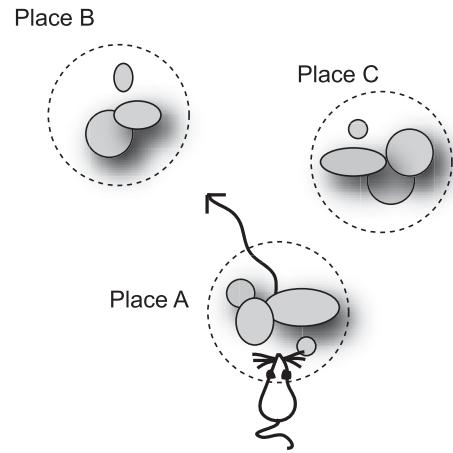

As already noted, numerous developments of the original theory have occurred since 1978, leading to slightly different ideas about spatial memory than those in the list in Box 13-4. In the discussion that follows, there are references to these developments, as appropriate. Although distinct, they are in the same genre as the original cognitive map theory.

The first of O'Keefe and Nadel's (1978) ideas—the concept of a "locale," or mapping system—implies that when forming memories of the world neural activity in the brain automatically encodes stimuli in a connected mental framework rather than as isolated stimulus traces or independent pairwise associations. This encoding happens, for example, as laboratory rats explore a novel environment (Fig. 13-16A). It occurs quickly, sometimes in one trial; and it relies on information from the place cells indicating the animal's location, particularly the distance from the boundaries of the test arena. Head-direction cells provide a representation of direction based on what are described as infinitely long vectors. This curiosity-driven exploration involves something more than perceptual learning about the identity of individual cues (objects, land-

**A Place cells are boundary vector representations of location**

**B The puzzle of navigation**

**Figure 13–16.** Place cells, boundary vectors, and the puzzle of place cell-guided navigation. *A*. As rats explore a simple environment in a test arena, they encode information about location, such as distance from the side walls, into a map-like internal representation. Place cells emerge as the interaction of two or more Gaussians (inset) whose centers are determined by the distance from prominent features such as walls. (*Source:* After O’Keefe and Burgess, 1996.) *B*. A

rat at place A wants to navigate to B but not to C. Place cells (gray circles and ellipses) have firing fields in these three areas. A subset of the cells with fields at place A fire with a certain probability with the animal there, but it is not clear how at place A the rat can activate the subset of place cells for place B but not those for place C to direct its choice behavior appropriately. Additional “goal cells” seem to be required to achieve navigation. (*Source:* After Morris, 1991.)

marks) or the development of familiarity that later enables recognition. The putative hippocampal mapping system also encodes where landmarks are located in relation to each other in some kind of geometrical framework.

The idea of an organized structure to memory is, of course, hardly unique to the cognitive map theory, as many other theories of human memory embody the same idea, including artificial intelligence-derived theories of semantic memory (Collins and Quillian, 1969) and connectionist theories of memory consolidation (McClelland et al., 1995; McClelland and Goddard, 1996; O’Reilly and Norman, 2002). Some form of memory organization would also be helpful for encoding one-time events in relation to static landmarks; and, partly for this reason, the hippocampus in humans could be helpful for encoding information into episodic memory. The recall of a specific event, such as what one did during a recent holiday, generally involves first remembering where one was before proceeding to remember with whom one spent the holiday or what unusual things happened. Gaffan (1991) was the first to make this point explicitly, later building it into a “scene-specific” theory of episodic memory (see Section 13.6).

The second supposition is that, once stored, *locale information can be used for spatial navigation*. Whereas the first proposition was that information is *stored* in a map-like framework, the second relates to how that information is *used*. How does an animal navigate using its “cognitive map”? This question prompted the supposition that the unusual anatomical circuitry of the allocortex (see Chapters 3, 4, and 8), so unlike the

canonical local circuits of neocortex (Douglas and Martin, 2004), could be precisely what is needed to perform the geometrical computations involved in finding the way around. This might include computations for encoding the distance and direction between landmarks, rotating the map for appropriate alignment with perceived cues, identifying the location and heading direction of the animal within it, and performing various other geometrical functions essential for effective allocentric navigation through space. In short: *Where am I? Where am I going? How do I get there?*

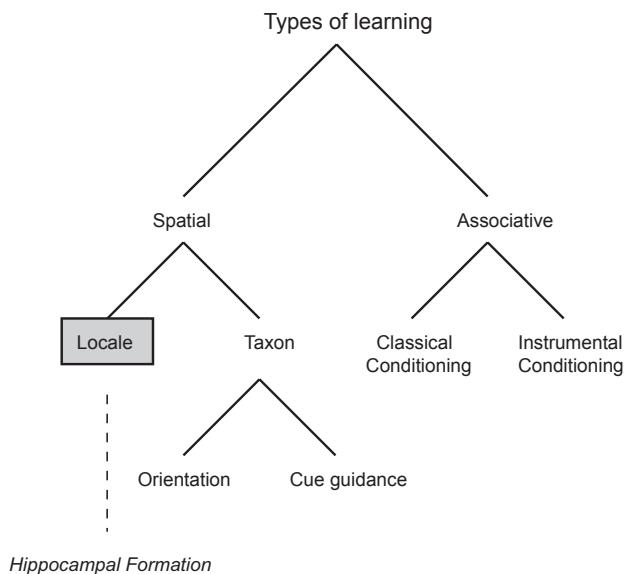

O’Keefe and Nadel (1978) offered several speculations about how such spatial operations could be implemented in the hippocampal formation. Considering the original ideas on representation and navigation together (Box 13–4, propositions 1 and 2), they supposed that sensory information entered the hippocampal formation via the entorhinal cortex, from which it projected into the dentate gyrus and then to succeeding stages of the trisynaptic circuit as it was then understood (but see the discussion of hippocampal connectivity in Chapter 3, Section 3.7). Different pyramidal cells were thought to be driven by different proportions of excitatory or inhibitory inputs. The group with mainly excitatory inputs (“place cells”) were defined as those that fired when an animal occupied a particular position in relation to a constellation of sensory cues (e.g., visual, auditory, olfactory). Because of the convergent nature of hippocampal circuitry, it was suggested that the probability (or rate) of place-cell firing should decline in a monotonic but nonlinear fashion as individual cues become obscured or are removed but be relatively insensitive

to the loss of any one cue. This prediction about place cells was upheld (O'Keefe and Conway, 1978). Other pyramidal cells ("misplace cells") were presumed to have, in addition, sensory-driven inputs relayed via feedforward inhibition such that they would *increase* their rate of firing when sensory cues were removed. This increased firing was held to be the neural event that triggered exploratory behavior, perhaps via the subiculum output through the fornix to the nucleus accumbens (see Chapter 3, Section 3.4.2). The original theory also stated that the firing of "theta cells" is coupled to the translational movement of the animal from one position in the map to another, an idea supported by studies in which the different frequencies of theta activity observed during jumping through space correlated directly with the distance moved rather than the force exerted (Morris, 1983). More recent neural modeling studies have modified these ideas substantially (see Chapter 14). The unfolding picture about the wide range of distinct inhibitory interneurons and their axonal connections (see Chapter 8) has also raised the specter of yet deeper subtlety at the level of local circuits.

Since 1978, there have been many technical and conceptual developments in hippocampal single-unit recording in freely moving rats. The development of multiple single-unit recording ("ensemble recording") with "stereotrodes" and "tetrodes" has shed fresh light on a range of theoretical issues: multiple place fields, local views, gating by the potential for movement, memory properties, multiple reference frames, pattern completion, and pattern separation (as discussed in Chapter 11). Numerous uncertainties have been clarified. It is now known, for example, that pyramidal cells acquire their place fields rapidly, fire in proportion to an animal's speed of motion, tend to be directionally sensitive only in directionally constrained environments (e.g., linear tracks), and show temporal precession in their phase relation to hippocampal theta as an animal moves through the cell's place field. Improved recording techniques have also established that single cells do not, in general, have place fields in different parts of a single environment, and that physically adjacent pyramidal cells may have place fields in quite different parts of the environment. A boundary vector model (BVC) has been developed (Hartley et al., 2000) according to which places can be modeled as the sum of two or more Gaussians, with the center of each Gaussian located by its distance from a specific environmental feature such as a wall (as in Fig. 13–16A). With this view, place fields represent probability distributions and do not specify precise locations. Certain theoretically unanticipated properties of CA1 place cells have also been discovered, such as their sensitivity to physical restraint, their apparent insensitivity to lesions of the dentate gyrus or CA3, and alterations in receptive field size and stability with aging (see Chapter 11). The discovery of head-direction cells in the presubiculum and thalamus (Taube et al., 1990a, b) and of "grid cells" in the dorsomedial entorhinal cortex (Fyhn et al., 2004; Hafting et al., 2005) are important additions to the idea that the hippocampal formation and interconnecting structures constitute, in animals, an essentially spatial system.

Notwithstanding these developments, we still do not fully understand how a map of space could be represented (Box 13–4, proposition 1) or used (Box 13–4, proposition 2) by means of hippocampal circuitry. The relation between location firing (in pyramidal cells of CA1 and CA3), head-directional firing (in the presubiculum and anterior thalamus), and movement firing (in the interneurons of the hippocampus and dentate gyrus) is also poorly understood. Those concerned with specific details might reasonably wonder, for example, whether the head-direction firing of presubiculum cells is a component of "locale" or "taxon" processing (or both). Various logical puzzles about the link between mapping and navigation have also been pointed out. For example, as place cells are defined as cells that fire only when an animal occupies a specific position in space, how can the mapping system access information pertaining to places other than the one presently occupied by the animal (Morris, 1991)? That is, if a rat is at place A and wants to navigate to place B but not to place C, how does it at place A access information relevant to going to B rather than going to C (Fig. 13–16B)? Place-cell firing on its own does not seem to help because the place cells corresponding to B and C cannot, *by definition*, fire until the animal gets to B or C, respectively. This kind of logical conundrum is clearly problematic for the theory, but it may not be fatal if goal cells can be identified. Perhaps these are in other brain areas (Hok et al., 2005). Other models of the neural implementation of goal representations are also being developed (Redish, 1999; Biegler, 2003). Several neural network and temporal difference learning models that grapple with these issues are outlined in Chapter 14.

The third feature of the theory is that *spatial mapping has evolved in response to specific environmental demands*, and that it *constitutes one of the multiple memory systems of the vertebrate brain* (Fig. 13–17). The emphasis on evolution, lacking prominence in the declarative memory theory, has been informed by studies of cache recovery in passerine birds, homing in pigeons, territory size and mating systems in small mammals, and other aspects of naturalistic spatial behavior (Sherry and Schacter, 1987b; Clayton and Krebs, 1995; Dyer, 1998; Healy, 1998; Shettleworth, 1998; Jacobs and Schenck, 2003). The "neuroethological" component of the thinking behind the cognitive map theory has been explicit from the outset (O'Keefe and Nadel, 1979; Nadel, 1991), fostering studies of sex and seasonal differences in spatial memory that might not have happened had all hippocampal research remained anchored solely in a paramedical context. Work in both vertebrate and invertebrate species has revealed both convergent and divergent evolution with respect to how to find food, water or sex—and then get safely back home. Studies of animal navigation have, however, revealed mechanisms that appear to have nothing to do with cognitive maps, such as ideothetic "path integration" by insects (Wehner et al., 1996) and rodents (Etienne and Jeffery, 2004) and the "snapshot" processing of landmarks by bees (Collett, 1992). The relevance of the neuroethological approach to hippocampal function and mechanisms has been the subject of cogent crit-

**Figure 13-17.** Multiple forms of memory in the cognitive map theory. Only the locale system, requiring cognitive mapping, is mediated by the hippocampus. The theory has less to say about other forms of learning and memory.

icism (Squire, 1993; Bolhuis and Macphail, 2001), but many see it as an important adjunct to the development of cognitive mapping theory.

However, the bulk of the work addressing the cognitive map theory has been conducted with the laboratory rat and, more recently, various laboratory strains of mice. A veritable “hippocampal industry” emerged, beginning with lesion/behavior studies and single-unit recording work on animals, that now finds modern expression in a variety of behavioral tasks used in conjunction with the full spectrum of contemporary neuroscience techniques. Particularly exciting are the technical innovations that complement classic lesion techniques, with the new tasks including ensemble single-unit recording from large numbers of hippocampal neurons (Wilson and McNaughton, 1993), monitoring the expression of immediate early genes (Guzowski et al., 1999; Vann et al., 2000), and reversible pharmacological interventions that are sufficiently sustained in time to investigate memory processes, such as systems-level consolidation (Riedel et al., 1999). Mice have nibbled their way onto the hippocampal stage with targeted gene deletions, hippocampus-specific deletions, and even inducible gene knockouts (Tonegawa et al., 1995; Mayford et al., 1996; Tsien et al., 1996; Abel and Lattal, 2001). The hippocampal research industry, which has seen the number of papers on rodent spatial representation and navigation rise from around 10 per year in 1980 to several hundred per year (Sutherland and Hamilton, 2004), owes a great debt to the cognitive map theory.

With respect to multiple memory systems, the scope of O’Keefe and Nadel’s (1978) original analysis was narrower than that encompassed in the declarative framework discussed earlier (Figure 13.4). Their book distinguishes only

between spatial memory and nonspatial associative learning (such as classical and instrumental conditioning). Whereas allocentric “locale” learning was held to be motivated only by curiosity and to be extremely fast, associative learning was thought to be motivated by rewards related to basic motivational needs (such as food for a hungry animal) and to be slower, cumulative, and governed by quite different learning rules. However, this spatial versus associative distinction has come under close scrutiny (just as it did in connection with recognition memory in the previous section of this chapter). Certain classic phenomena in the associative domain (such as “overshadowing” and “blocking,” to be explained later) have also been found to operate within the domain of spatial learning (Biegler and Morris, 1999; Chamizo, 2003) although subject to certain constraints associated with the perception and local processing of geometry (McGregor et al., 2004a). Associative learning can also be very fast, and in phenomena such as sensory preconditioning, is not obviously motivated by biological rewards. Although O’Keefe and Nadel’s original dichotomy now feels incomplete, understanding the boundaries between cognitive mapping and other forms of learning and memory is proving to be a fruitful area of research. Also of interest is how spatial and nonspatial systems compete or work synergistically to ensure the seamless control of behavior; and it remains a fundamental issue (White and McDonald, 2002).

The fourth proposition of the 1978 theory is that *allocentric spatial information is stored in the hippocampus*. Unlike the time-limited role for the hippocampus in the declarative memory theory, the original version of the cognitive map theory has both initial encoding and long-term storage in the one brain structure. Nadel and Moscovitch (1997) extended this idea in a “multiple-trace theory” of episodic memory in which memory retrieval episodes can initiate re-storage. The possibility of multiple traces—even for single episodes—leads to a different account of the temporal gradients of retrograde amnesia that are sometimes seen for information acquired prior to brain damage. The key difference from the account offered by the declarative memory theory lies in the impact of partial damage. Complete lesions at various time points after training should always result in temporally extensive, or “flat gradients,” of remote memory loss. In contrast, partial lesions might result in a reverse gradient if older information, recollected previously, had laid down additional traces in areas of the hippocampus spared by the lesion. The declarative memory theory makes no differential prediction as a function of lesion completeness.

Although the original cognitive map theory of hippocampal function was based largely on observations in rats, its extension and likely modification to account for primate and human hippocampal function was recognized at the outset. Proposition 5 in Box 13–4 recognizes that later chapters of O’Keefe and Nadel’s monograph addressed the relevance of their ideas to human semantic memory (e.g., Chapters 14 and 15) and, specifically, the way in which spatial relations are fundamental to certain linguistic prepositions that reflect

the knowledge of relations (e.g., “beside,” “near,” “above”). Although not originally influential in the human neuropsychology community, these ideas have nonetheless been extended to such domains as reasoning and abstract thought and are now an active area of research. For example, Gattis (2001) identified the sharp distinction between a “generalist” school of thought, in which space is merely a special case of “relational processing,” and a Kantian perspective, in which space (and time) are special. Nadel and Hardt (2004) strongly reasserted the latter position, whereas O’Keefe (2005) has continued his exploration of “vector grammar” and how it might explain the essentially various meanings of spatial propositions.

Cognitive science apart, one obstacle to pursuing these lines of thought has been in securing definitive evidence for causally linking hippocampal cell activity in humans to any such processes. Hippocampal damage in humans does not obviously disrupt a person’s ability to use spatial prepositions. Invasive single-unit recording in humans is rarely feasible, but some intriguing examples of “place cells” have been recorded from the human hippocampus with depth electrodes placed to monitor epileptic seizure activity (Fried et al., 1998; Ekstrom et al., 2003). Place cells have also been observed in the hippocampus of monkeys free to drive themselves around slowly in a motorized “cab” (Matsumura et al., 1999). Spatial correlates are therefore by no means unique to rodents, but securing single-unit evidence for vector grammar has not yet been achieved.

Functional brain imaging has also been used to study hemodynamic activation during human navigation. The problem here is that fMRI is a technique that does not obviously lend itself to the study of a mental process—navigation—that ostensibly requires subjects to be mobile. One solution is to use “virtual reality.” Whether virtual reality in subjects lying prone in a brain scanner really engages the same neural mechanisms as “true” navigation can be debated—place cells in rats being sensitive to whether animals are restrained or allowed to move (Foster et al., 1989)—but if one accepts that a virtual reality approach might be viable, modern computing software has certainly made it possible. Numerous studies have now examined whether the hippocampus and adjacent structures of humans are activated during apparent “navigation” through imaginary towns (Maguire et al., 1998), featureless arenas, and swimming pools (Thomas et al., 2001; Parslow et al., 2004) as well as other tasks that distinguish mapping from merely following a sequential route (Morris and Mayes, 2004). Burgess et al. (2002) made a strong case that virtual reality is informative and specifically discussed patterns of activation in relation to spatial frameworks, the dimensionality of space, and both orientation and self-motion. In contrast, a more cautious stance about the findings to have emerged from functional imaging of spatial navigation is presented in Chapter 12.

Finally, by way of introduction, is there anything special about space? Declarative memory theorists think not. In their view, a memory system exists in the MTL that processes all

forms of propositional knowledge, whether it comes to us via visual, tactile, olfactory, or other sensory modalities. Why, their concern continues, should space be any different? The “no different” perspective appears to look on memory processing of “space” as involving multimodal sensory information, with cues that may be familiar or unfamiliar and with the capacity to realize “declarations” of spatial knowledge such “A is near B.” Given this, why would encoding or storage be any different from that of other object-orientated information that is processed via the ventral stream of the perceptual processing pathways of the neocortex terminating in the inferotemporal, perirhinal, and parahippocampal cortices (Ungerleider and Mishkin, 1982)? Indeed, so absurd may it seem to think that space could be different, a major review of the functions of the MTL considered the adequacy of the spatial theory of hippocampal function in little more than a couple of paragraphs (Squire et al., 2004).

Not surprisingly, the opposing camp is resistant to being so subsumed. For those prepared to contemplate a neural system for cognitive mapping (including critics of O’Keefe and Nadel’s theory, such as the present author), thinking about space in this declarative way reflects a conceptual misunderstanding: Space is not a sensory modality. We do not have sensory organs for space or a cranial nerve devoted to it. Space is a construct of mental processing. Moreover, space has a structure that requires but is logically independent of the multimodal sensory information used to identify it. For example, many objects whose location we know are often hidden, whether it is acorns cached by a squirrel or food in a kitchen cupboard. It is precisely in this situation that spatial memory becomes so useful—the exact *opposite* of the situation that applies to normal recognition memory. Similarly, the appearance of a specific area of space can change across the seasons despite its containing inanimate or sessile living things that do not ordinarily move around. What does not change when a cupboard door is closed, a tree loses its leaves, or a rock becomes covered in snow is the location of the remembered item. There is, in short, a geometric “stability” about remembered space that is independent of the appearance of the stationary objects and landmarks that, paradoxically, define that stability (Biegler and Morris, 1993). This paradox is at the heart of why pattern separation and pattern completion are network operations at the heart of hippocampal processing (see Chapter 14). The closely related concept of “context” is also not necessarily something that is “out there” waiting for a sensory/perceptual system to process it; it is a neural construct (Jeffery, 2003). These and other features of “space” could have been major driving forces in the evolution of the distinctive cognitive systems that mediate it.

This completes the initial overview of the five key features of the cognitive map theory. A selective presentation of relevant data follows, in four successive sections, followed by a concluding critique. The relevance of the theory to humans is not considered further, and the reader referred to the very different perspective offered in Chapter 12.

### 13.4.2 Representing Spatial Information, Locale Processing, and the Hippocampal Formation

A key concept with respect to the representation and storage of spatial information is the distinction between egocentric and allocentric space. Egocentric space refers to the locations of objects relative to the viewer—to the left or the right—directions that necessarily alter as the viewer moves around. Representing this kind of space is not thought to require a cognitive mapping system. Allocentric space, on the other hand, is a representation of spatial relations within some kind of absolute framework. For a freely moving subject, an allocentric representation is required to identify whether an object or landmark has actually moved in relation to others. In contrast, objects are constantly “moving” in egocentric representations. The distinction between egocentric and allocentric space has not always been appreciated by critics of the cognitive map theory, with some incorrectly assuming that the theory predicts that lesions of the hippocampal formation must impair any and all spatial learning tasks (e.g., Nadel and Hardt, 2004). Many spatial tasks given to animals, such as the simple T maze task described in Section 13.2 and certain touchscreen tasks, are ambiguous because they can be solved using either an allocentric or an egocentric strategy. The study of exploratory behavior has provided a key test of this feature of the cognitive map theory together with studies examining how animals localize objects in space. Lesion studies and observations of immediate early gene activation have contributed to a detailed examination of this issue.

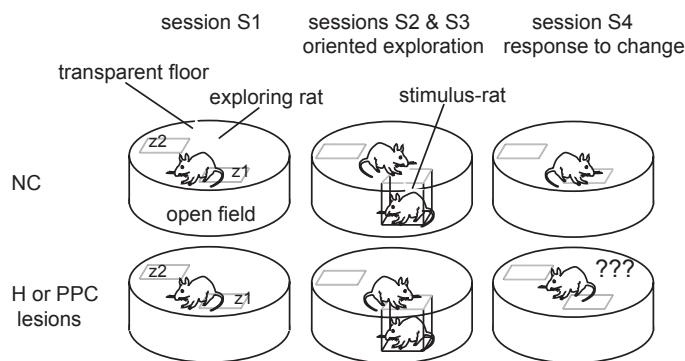

#### Lesion Studies of Exploratory Behavior Reveal the Importance of Allocentric Spatial Representation

It has long been known that rats explore spontaneously, and the phenomenon has been systematically in the laboratory for years (Berlyne, 1950, 1966; Halliday, 1968; Archer and Birke, 1983; Renner, 1990). Placed in a novel test arena, the rats remain motionless for a period of time and then start to move around, first at the periphery and then throughout the available space, where they explore objects and landmarks one by one, often returning to an object just investigated until they finally come to rest in one corner. This is not mere movement; it is exploration to gain information. For example, renewed exploration can be triggered easily after habituation by introducing a novel object into the arena, a phenomenon exploited in the visual-paired comparison task (see Section 13.3). Hippocampal lesions impair certain aspects of exploration. They tend to make animals hyperactive yet also disinclined to visit all regions of a space systematically and less likely to display habituation of activity over time (O’Keefe and Nadel, 1978; Whishaw et al., 1983). O’Keefe and Nadel (1978), Morris (1983), and Renner (1990) have repeatedly made the point that the hippocampus-dependent information-gathering function of exploratory behavior should be clearly distinguished from any motor functions to which the hippocampus

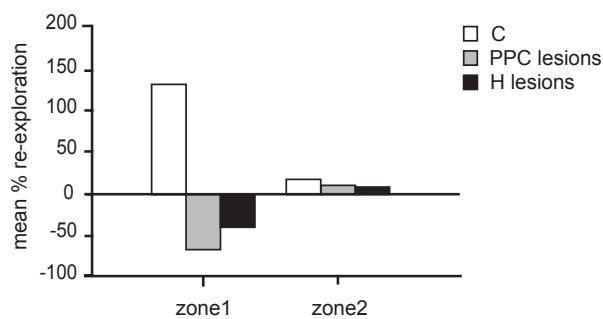

contributes (Vanderwolf and Cain, 1994). There remains, however, the question of what information is gathered.

As the cognitive map theory asserts that this curiosity-driven exploration is the basis for encoding a “map,” a critical experimental prediction is that renewed exploration would be triggered by alterations in the spatial arrangement of familiar objects. Critically, hippocampus-lesioned subjects should display selective failure of renewed exploration to object displacement but not to object novelty. Using a paradigm developed by Thinus-Blanc et al. (1987), Save et al. (1992a) compared the impact of small dorsal hippocampal lesions, anterior and posterior parietal lesions, and sham lesions on exploration in a circular arena containing five objects. In a systematic series of short exploration sessions, the animals became familiar with the initial set of objects and their spatial locations, after which the critical manipulations of spatial dislocation and object novelty were introduced. The results showed renewed exploration by controls and anterior parietal cortex-lesioned animals in response to spatial dislocation; there was no detectable reaction by hippocampus- or posterior parietal-lesioned subjects. In contrast, renewed exploration was shown by all groups in response to object novelty. However, the effect was not large. In an ingenious follow-up of this dissociation, Save et al. (1992b) examined exploration at a particular point in space that was triggered by the *absence* of an expected object (Fig. 13–18). Rats that had been subject to preexperimental surgery first explored an open circular arena that was slightly unusual in that it had a transparent floor. Another rat, in a small box, was sometimes placed underneath this floor in full view of the exploring animal. In a sequential four-phase experiment, the experimental rats first explored the open but empty arena. They were then given two successive opportunities to explore the arena again with the “stimulus rat” visible at one “zone” of space, and the study ended with the final phase that, like the first, had no stimulus rat available under the floor. A neat feature of this design is that the overt visual appearance of the arena was identical in sessions 1 and 4. As expected, introduction of the stimulus rat in session 2 triggered extensive investigation centered on the zone above the stimulus rat’s location, and this habituated between sessions 2 and 3. The key test was session 4 with the stimulus rat now removed. In control rats with sham lesions, exploration was focused at the zone, but this did not occur in animals with dorsal hippocampal or posterior parietal lesions. The use of a recall paradigm may have made the magnitude of the effect much larger. Taken together, these findings imply three things: (1) exploration can be triggered in normal rats by object novelty, spatial novelty, and the absence of an expected object; (2) damage to hippocampus and posterior parietal cortex selectively impairs exploration triggered by spatial novelty, including the absence of an expected object; (3) when it occurs, this exploration is not merely activated but spatially directed in an appropriate way. Such findings are consistent with the construction of a “map” of space in the manner predicted by the cognitive map theory.

### A Response to spatial change in rats with HPC and parietal cortical (PPC) lesions

### B Response to remembered places by C, HPC and PPC lesioned rats

An outstanding puzzle is why similar disruption of exploration induced by spatial novelty was seen in the posterior parietal cortex-lesioned group, a finding not predicted by the theory if map storage is in the hippocampus. The absence of direct anatomical connections between this structure and the hippocampus led Parron and Save (2004) to wonder whether there may be some larger neuronal network involving the interconnected regions of the retrosplenial and entorhinal cortices. In a follow-up study using the same behavioral procedures, they observed that lesions of these cortical structures also caused disruption of renewed exploration in response to spatial novelty. This finding adds to a growing body of evidence from exploration and navigation tasks that the processing of spatial information extends beyond the hippocampus (Poucet and Benhamou, 1997; Kesner, 2000; Whishaw, 2004a; Hafting et al., 2005).

For example, although some studies have suggested that neurons in the entorhinal cortex are only weakly modulated by the position of the animal (Quirk et al., 1992; Frank et al., 2000), the dorsomedial region of the entorhinal cortex has “grid cells” whose firing shows multipeak fields that are small, stable, and directionally insensitive (Fyhn et al., 2004; Hafting et al., 2005). These firing fields are unaffected by hippocampal lesions, implying that their existence is not secondary to “upstream” hippocampal processing that might be projected back to the entorhinal cortex. Instead, they suggest that at the border between the entorhinal and postrhinal cortex (a region almost certainly lesioned in the Parron and Save, 2004, study of exploration) there is an allocentric, view-independent

**Figure 13–18.** Exploration guided by the absence of an expected stimulus. *A*. In a multiple phase study, rats explored an arena with a transparent floor that sometimes revealed the presence of another rat under one zone (z1). Normal and both hippocampus- and posterior parietal cortex-lesioned rats explored differently when this second rat was removed: only control animals spent more time in z1 than z2, reflecting their recall of the now absent “cue” animal underneath. *B*. Data showing greater exploration of the area where the now absent animal had been located. See text for more details. (Source: After Save et al., 1992b.)

representation of space. This implies that steps in the computation of allocentric space can occur upstream of the hippocampus, although the multipeaked properties of entorhinal “grid” cells indicates that an individual entorhinal cortex cell provides a metric rather than a specific indication of location. Perhaps ensembles of entorhinal cells are able to “disambiguate” on their own, or they may provide a Fourier-like input to the dentate gyrus and hippocampus, where single-peaked cells are primarily observed. The discovery of the entorhinal grid cells will have a big impact on the cognitive map theory, but the full implications remain to be worked out.

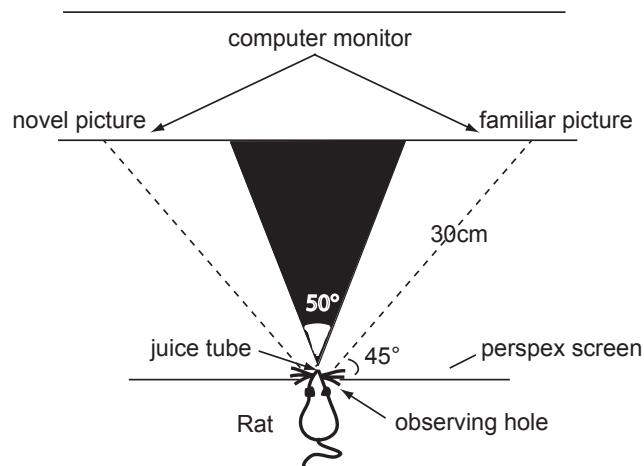

### Immediate Early Gene Studies Reveal Anatomical Dissociations with Respect to Environmental Representations

Instead of using lesions, visualizing the expression of immediate early genes (IEGs), such as *c-fos*, *Arc*, and *zif-268* (Morgan et al., 1987; Link et al., 1995; Lyford et al., 1995; Tischmeyer and Grimm, 1999), has been used to examine the patterns of activation in multiple brain areas during both spatial and nonspatial tasks. Some of these studies have focused on the representation of the environment, others on spatial navigation, and yet others on memory consolidation (Dragunow, 1996; Guzowski, 2002). Different IEGs are used in different studies. The choice can take advantage of the fact that some IEGs are regulatory transcription factors that influence the activity of other “downstream” genes (e.g., *c-fos*), whereas

other IEGs are effector genes that directly affect cellular physiology (e.g., *Arc*).

There are several features of the IEG approach that are noteworthy. First, from a low level of basal expression in animals, experience-dependent activation of IEGs is correlated with increases in neuronal activity (Herrera and Robertson, 1996). There is, for example, a broadly similar activation profile for *c-fos*, *zif-268*, and *Arc* in association with spatial learning, with some indication of differential sensitivity to manipulation of task demands (Guzowski et al., 2001). Second, the imaging observations made after sacrifice are from animals whose brains are normal at the time of testing; thus, IEG mapping links behavior to physiology in a manner that complements the single-unit recording studies of Chapter 11. This does not preclude combining the lesion and IEG approaches, and studies using such a combined approach have revealed alterations in activity in areas remote from the site of the lesion (Aggleton and Pearce, 2001). Third, although the analytical focus of a given study may be on activation of a specific brain structure, the approach does not require a “prospective choice,” as quantitative measures may be taken of a large number of brain structures. The drawback of the IEG approach is that, unlike single-unit recording for which the measured output is a signal that is well understood in information-processing terms, the “meaning” of an IEG signal is unclear. There has been substantial discussion about the possible functions of IEGs, ranging from metabolic replenishment to regulation of synaptic plasticity, memory consolidation, and even memory retrieval (Guzowski, 2002).

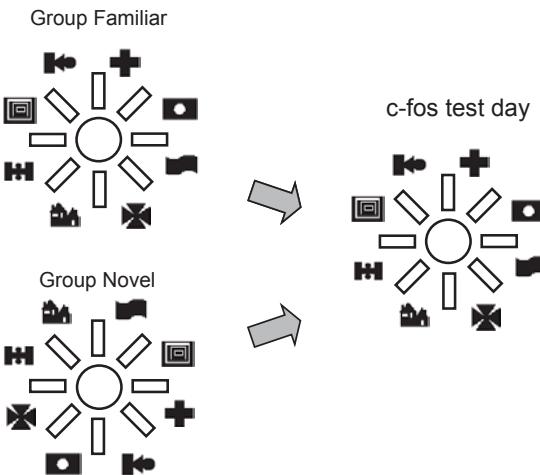

The technique was first used in relation to behavioral studies of exploration by Hess et al. (1995), who observed widespread hippocampal IEG activation in various subfields. This was a valuable first step, but it did not speak to whether the hippocampus encodes information allocentrically. IEG activation may merely occur in the hippocampus in response to novelty, stress, or the motor activity that accompanies exploration. An important step forward was made in a study using *c-fos* by Wan et al. (1999) who presented rats with computer-displayed images in which novelty was introduced as either new stimuli or novel spatial arrangements of hitherto familiar stimuli, a comparison analogous to the original lesion studies just discussed (Save et al., 1992a,b). A within-subjects protocol was used in which the images were presented bilaterally such that familiar stimuli were presented to one eye and novel stimuli (or novel rearrangements of familiar stimuli) to the other eye (Fig. 13–19). As the projections of the rat visual system are largely crossed, it was possible to compare normalized patterns of activation in the two hemispheres within individual animals. Any nonspecific *c-fos* activation associated with novelty, stress, or motor activity was effectively and elegantly “subtracted” out. The key finding was that novel rearrangements of familiar stimuli to one eye differentially activated the CA1 region of the hippocampus. Novel stimuli activated the perirhinal cortex, as previously shown by Zhu et al. (1995). Brown and Aggleton (2001) summarized a body of work using this approach.

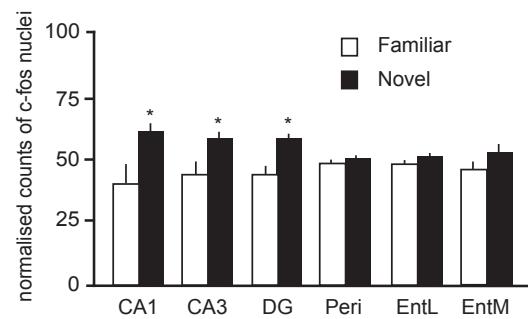

**Figure 13–19.** Bilateral viewing technique to image immediate early genes such as *c-fos*. Novel and familiar visual patterns are presented simultaneously to each eye. The largely crossed visual system of the rat enables the various *c-fos* patterns to be compared within individual animals and then averaged. (Source: Courtesy of M. Brown and J. Aggleton.)

A limitation of the bilateral viewing technique is that there is no behavioral output of the simultaneous processing of novel and familiar stimulus combinations in the two hemispheres—indeed, no way of establishing whether the animals even attend to the cues. Jenkins et al. (2004) therefore followed up the Wan et al. (1999) study by a systematic analysis of normalized *c-fos* patterns in animals running through and making choices in a radial maze task (see below for a description of this classic navigation task). Following a procedure first developed by Suzuki et al. (1980), they first trained rats with eight distinctive cue cards placed between the arms of the maze. Then, on the final day of training, the cue cards were left in their standard arrangement for half the animals (Group Familiar) or shifted to a novel spatial arrangement for the others (Group Novel) (Fig. 13–20). Spatial novelty caused *c-fos* activation in CA1, CA3, and the dentate gyrus, whereas no changes were observed in the surrounding cortical regions such as the perirhinal and parahippocampal cortex. This was not due to differential sensitivity of the imaging method between hippocampus and cortex because successful *c-fos* activation following spatial novelty was seen in the posterior parietal cortex. In addition, animals in a companion study were shown to be using the cue cards in their representation of the maze, as indexed by behavioral sensitivity to cue rotation. These findings nicely complement the lesion observations of Save et al. (1992a,b). That the hippocampal formation can detect alterations in the spatial arrangement of cues and respond by differential activation of an IEG strongly suggests that the information encoded about the familiar stimuli presented earlier must have included some representation of their spatial layout in the image or in the room. They support the notion that the hippocampus is both necessary for and involved in the representation of space. However, they also point to unexpected involvement of the posterior parietal cortex as well.

**A Spatial arrangement of cues during training (left) and c-fos measurement period (right)**

**Figure 13-20.** Immediate early gene activation reveals regional patterns of sensitivity to spatial novelty. *A*, The spatial arrangement of the cues placed between the ends of the arms of the maze was retained between training and the *c-fos* test session for Group Familiar but was changed for Group Novel. *B*, The normalized

*c-fos* patterns show the differential sensitivity of structures in the hippocampus (CA1, CA3, DG) versus neocortical regions such as perirhinal and entorhinal cortex (medial and lateral). (Source: After Jenkins et al., 2004.)

Guzowski et al. (1999) introduced a highly illuminating new technique in which it is possible to identify time-locked expression of IEGs using fluorescent *in situ* hybridization (called catFISH after the cellular compartment in which time of expression is observed). It was first applied to the imaging of *Arc* on its own and later extended to enable simultaneous imaging of *Arc* and *Homer*. The catFISH technique enables a within-subject comparison of a different kind in which the population of neurons activated by one experience (e.g., exploring a box) can be distinguished from a second population activated by a later experience (e.g., exploring a different box). *Arc* RNA first appears as discrete small intranuclear signals within 2 to 15 minutes of the cells being activated (e.g., the activation of a place cell as an animal occupies its place field). After 20 to 45 minutes the nuclear signal disappears, and a cytoplasmic mRNA signal develops that is translocated to dendrites. As the time course of the nuclear signal is distinct from the cytoplasmic signal, the activity history of individual neurons at two time points can be inferred (see this chapter, figures in color centerpiece). Two predictions of the cognitive mapping theory were then tested. First, it was established that a common population of place cells was activated when the animals explored the same box (A) on two successive occasions, with the same population of cells expressing *Arc* mRNA in dendrites (signaling the first visit to the box) and in the soma (more recent visit). Second, they observed *Arc* RNA expression in two distinct but overlapping populations of cells on sequential visits to two different boxes (A then B). In boxes approximately 70 cm in diameter (about the same as those used in many studies of place cell firing fields), they found that approximately 38% of the CA1 pyramidal cells showed both the dendritic and the somatic IEG signals, whereas others displayed only one of the two signals. The standard *c-fos*

technique would not have revealed that the activation response of the different environments was specific, whereas *Arc* catFISH provides novel information about the information content of neuronal activation.

In an extension of this work, Vazdarjanova and Guzowski (2004) have compared the sequential IEG activation patterns in CA3 and CA1 in an exploration task very like that used by the Marseille group: a box containing objects that can be moved about. Exploiting a further technical innovation, confocal images of *Homer* reflected neuronal activity that had occurred approximately 30 minutes before sacrifice, whereas nuclear images of *Arc* reflected more immediate neuronal activation. The study revealed that when confronted by two object arrangements successively (A then B), cells in area CA3 showed discontinuous activation patterns that were highly suggestive of “pattern separation.” However, when confronted with either identical or very similar boxes (A then A or A’), the patterns overlapped very well, suggestive of “pattern completion.” The patterns in CA1 were more continuous across these environmental manipulations. Integration of distinct CA3 and CA1 ensemble representations may provide a refined representation of spatial context reflecting intrahippocampal processing of information projected from the entorhinal cortex. The observations of Leutgeb et al. (2004) on the firing properties of CA3 and CA1 cells in various boxes and contexts are consistent with this conclusion.

#### Distributed Representations, Pattern Separation, and Pattern Completion

The lesion and IEG studies of exploratory behavior and reactions to novelty clearly point to a role for the hippocampus in representing spatial information, but on their own they say lit-

tle about *how* spatial information is represented. Single-cell and ensemble recording is the way forward to understand and quantify the representational structure of information (see Chapter 11) guided by neural network models of how the system might work (see Chapter 14). There is also a role for behavioral studies in identifying neural network processes such as pattern separation and pattern completion that act on such representations (Rolls and Treves, 1998).

With one approach to “pattern separation,” Gilbert et al. (1998) trained hungry rats to forage for food on a “cheeseboard” apparatus with a series of food wells arranged in a row such that the separation between the wells varied from 15 to 105 cm. Training took the form of pairs of trials, a sample trial followed by a choice, with as many as 16 trial-pairs per day. During each sample trial, the rats ran from a start box at the periphery of the cheeseboard to displace a single object over one of the wells to secure food. During the choice trial that followed a few seconds later, two identical copies of this same object were placed to cover two wells, with one object covering the same baited well, the other an empty one farther down the row (i.e., delayed matching to place). This task provided a way to measure how easily the rats could discriminate spatial locations in memory as a function of their distance apart. Prior to being lesioned, choice performance was very good, as high as 80% on even the smallest distance and rising to 90% at the largest separation. Large electrolytic lesions of the hippocampus caused performance at the smallest separation (15 cm) to fall to chance, but there was a graded recovery, as this distance increased reaching nearly 90% at the largest distance (105 cm). Performance was also unaffected by changing the start location by 180° between sample and choice trials. This pattern of performance indicates that one function of the hippocampus may be to “separate” patterns of spatial information, this being possible without the hippocampus for widely separated cues but not for cues close together. Findings consistent with this interpretation using a radial maze task had also been reported by McDonald and White (1995). In a follow-up study using the cheeseboard, Gilbert et al. (2001) showed that discrete neurotoxic lesions of the dentate gyrus (DG) caused a comparable pattern of impairment, whereas CA1 lesions had no effect. This dissociation is intriguing, but it raises the puzzle of how spatial information, orthogonalized at the level of the granule cells in the DG, is able to influence target structures of the hippocampus in animals that have been subjected to CA1 lesioning. The usual “output” for information, however effectively it is processed in DG, would no longer be available. An output route via the ventral hippocampus is one possibility as the CA1 lesions were restricted to the dorsal hippocampus. There may also be the possibility of output directly from the CA3 to the lateral septal nucleus, but the route to the neocortex is then indirect. It would be interesting to explore this route, as the finding hints at a radical new conception of information flow within the hippocampal formation.

Another innovative approach to pattern completion has involved molecular-genetic techniques to address what is, in effect, a systems-level issue. Nakazawa et al. (2002) engineered a mutant mouse in which the NR1 subunit of the *N*-methyl-

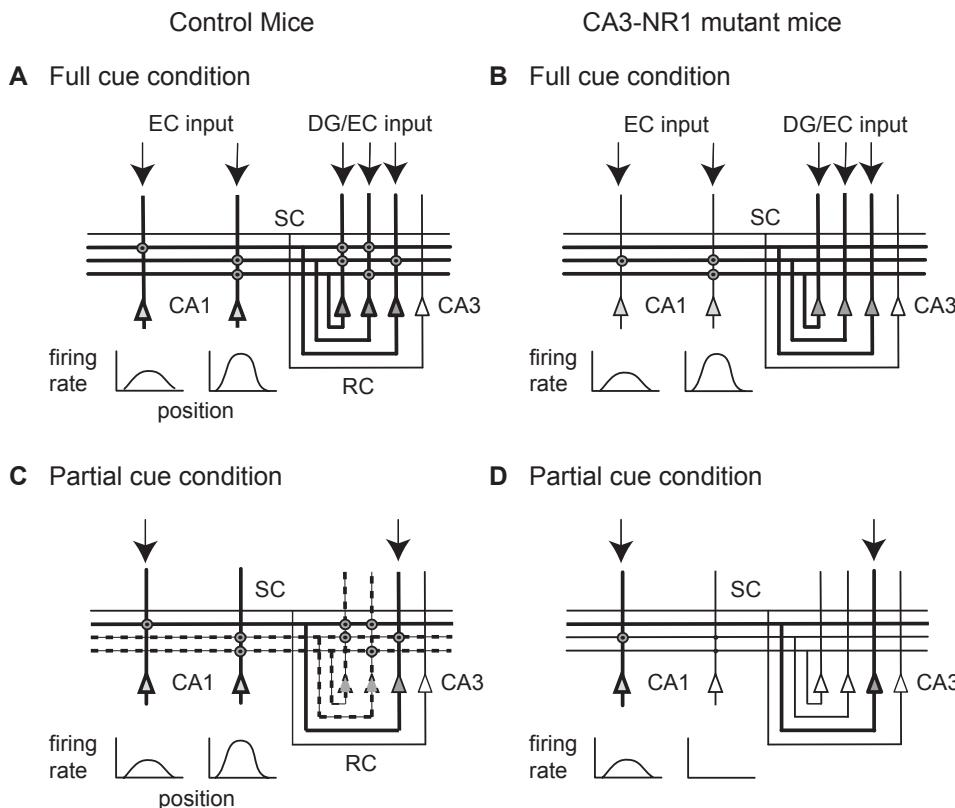

D-aspartate (NMDA) receptor (see Chapters 6, 7, and 10) was excised selectively in the CA3 region of the hippocampus. Using the Cre-Lox technique to realize this selective ablation, the resulting progeny (CA3-NR1 knockout mice) were shown to have normal physiology and behavior on a range of tests but certain highly specific impairments. For example, whereas LTP was normal in the mossy fiber input to CA3 and in the CA3 output to CA1, it was absent in the longitudinal association pathway of CA3. This pathway is likely to be important for building associative spatial relations between cues in an environment (McNaughton and Morris, 1987; Treves and Rolls, 1994). When trained in a watermaze (see Fig. 13–23, below, for a description of this task), the mice learned normally with all cues present but showed selective deficit in recall when tested with a subset of the training cues. Interestingly, place-specific firing of CA1 complex-spike cells was also “fuzzier” in the mutants when recording sessions took place using partial cues. Nakazawa et al. (2002) interpreted this observation as implying a role for NMDA receptors in area CA3 of the hippocampus in pattern completion, and they outlined a model of the way areas CA3 and CA1 may interact during the storage of information (Fig. 13–21). This study also nicely illustrated the power of adult-onset, cell type-restricted genetic manipulations in the integrative study of the molecular, cellular, and neuronal circuitry mechanisms underlying spatial cognition, a considerable advance on first-generation transgenic techniques (Nakazawa et al., 2004).

### 13.4.3 Using Spatial Information: Spatial Navigation and the Hippocampal Formation

The second key idea in cognitive map theory is that neural activity in the hippocampal formation occurs during and is required for spatial navigation. Allocentric navigation utilizes the information stored as a “map” during earlier locale processing, and reading information out of maps requires hippocampal place cells to fire. Other cognitive processes related to navigation involving the hippocampus include the ability to mentally rotate a stored representation to align it with a current view, to discover and use shortcuts, and so on. A key prediction is that the integrity of the hippocampal formation is absolutely required for locale-based navigation. This prediction led to the development of a number of novel navigational tasks for rats, the first of which was the radial maze.

#### Radial Maze

The radial maze is an apparatus in which rats (or mice) are given the opportunity to collect food hidden at the end of arms of the maze that radiate out from a central choice area (Olton and Samuelson, 1976). In its simplest version, a hungry rat is placed on the maze and allowed to run around until it has collected all the food. Once the food at the end of one maze arm has been eaten, it makes sense to avoid that arm, which normal rats gradually learn to do. Once mastered, the rats run to each arm without revisiting arms a second time (Fig. 13–22A). They have, in effect, solved a special case of the

**Figure 13-21.** Pattern completion in the storage and retrieval of spatial memory using areas CA3 and CA1. Note the interconnecting circuitry of CA3 and CA1, emphasizing pathways that form NR-dependent modifiable synapses in CA3. *A, B.* Basic wiring of CA3 and CA1 illustrates a possible encoding mechanism for pattern completion. In normal and CA3-NR1 knockout (KO) mice (left and right columns, respectively), a full cue input (top row) is provided to CA3 from the dentate gyrus (DG) or the entorhinal cortex (EC) and to CA1 from the EC (downward-facing arrows). During learning,

the normal mice make associative changes in synaptic efficacy in the commissural-association pathway (small circles representing potentiated synapses), whereas CA3-NR1 KO mice do not. *C, D.* In later testing under partial cues (bottom row), a fraction of the original input is provided (fewer downward arrows) to activate any memory traces formed during training. Only control mice are able to benefit from the associative plasticity in CA3 that “completes” the pattern and so provides an output to CA1 that can then be used for spatial recognition and navigation. (Source: After Nakazawa et al., 2002.)

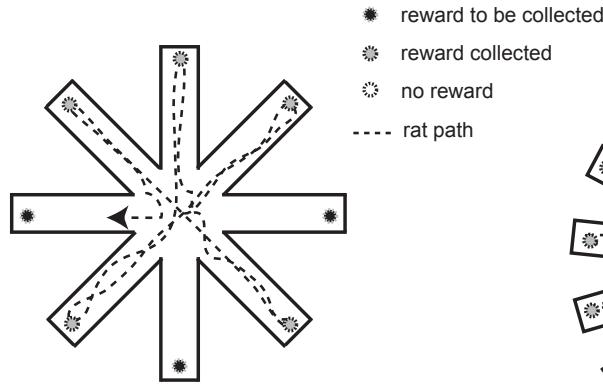

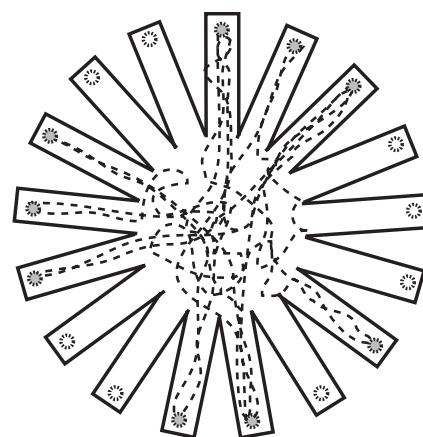

“traveling-salesman’s problem” of getting everywhere with the least effort. Olton (1977) reported that rats with various lesions that deafferented or defferented the hippocampus (e.g., fornix or entorhinal cortex lesions) were severely impaired in their initial learning. Whereas normal animals collected all available food from the ends of the maze arms with little or no retracing, those with lesions moved around the maze haphazardly, making numerous repeat entries into arms from which they had already obtained food. The initial interpretation of these data was that these surgical disconnections of the hippocampus disrupted spatial navigation and so supported the cognitive map theory.

However, Olton began to doubt his interpretation following a study suggesting that the deficit was really in trial-specific “working memory.” This term was introduced into the animal literature by Honig (1978) to refer to the memory of information useful for only a single trial in a behavioral task.\*

Olton and Papas, 1979) adopted a modification of the task, originally suggested by Jarrard (1978), in which both sham-operated and fornix-lesioned rats were tested in a 17-arm radial maze in which a fixed set of arms were baited before each trial and others were never baited (Fig. 13-22B). Following pretraining as normal animals, these investigators found that fornix-lesioned rats were impaired in remembering to avoid repeat entries into arms from which they had collected the available food but were as successful as the sham-lesioned animals in avoiding the arms that were never baited. Essentially the same results were obtained whether the baited arms were arranged adjacent to each other or were mixed haphazardly with the never-baited arms. This finding conflicts with the cognitive map theory, as neither a disturbance of spatial representation nor of navigation can explain the dissociation between failure to avoid repeat entries into the initially baited arms and successful avoidance of the never-baited arms.

Olton et al. (1979) therefore argued for a distinction between the anatomical mediation of “working memory” (i.e.,

\*Working memory” has a different meaning in human memory research, where it refers to a limited capacity consisting of several subsystems such as a phonological store and visuospatial sketch pad (Baddeley, 2001).

**A** The 8 arm radial-maze**B** A 17 arm radial-maze with some maze-arms baited and others unbaited.

**Figure 13–22.** Radial maze. A. The eight-arm radial maze is a task in which rats run from a central region to collect food reward from the ends of the maze arms. The path shown is of a rat that has successfully made five choices without retracing its path and has three arms remaining where food is available (notional path data). B. A 17-arm radial maze with baited and unbaited arms. The path shown

memory required for only one trial) and “reference memory” (i.e., memory used for a series of trials). They proposed that in radial maze tasks in which some arms are baited and some unbaited, the animal uses working memory to keep track of which arms it had entered as the trial proceeds and reference memory to avoid entries down arms that never contained food. Olton’s insistence on thinking about reference and working memory as independent rather than interacting memory systems carries with it the implication that the animal is reading out from two memory systems simultaneously as it works its way from choice point to choice point—a prescient idea, as many behavioral tasks are likely to involve multiple memory systems. In any event, if the hippocampus is involved exclusively in working memory, not only could this account for the data it also implies that there may be a subset of allocentric spatial tasks for which the integrity of the hippocampal formation is not required—spatial reference memory tasks.

The results of the Olton et al. (1979) study were, on the face of it, damaging to the cognitive map theory; but several problems soon became apparent. First, Olton examined a variety of lesions but, strangely, never looked at discrete hippocampal lesions. Second, there is nothing to stop rats choosing adjacent arms in the standard radial maze, thereby performing perfectly without having to remember anything about the spatial layout of the maze. The path shown in Figure 13–22A indicates that our notional rat did not do this, but many radial maze studies ran into this problem. It was solved by placing doors between the central area and the maze arms that prevented successive left or right turns by allowing the experimenter to control the timing of the animals’ choices. However,

might be that of a fornix-lesioned rat, initially trained preoperatively, that is selectively visiting the maze arms that are always baited, making occasional repeat errors at these arms but successfully avoiding the maze arms that are never baited. (Source: After Olton and Papas, 1979.)

even with doors, it is unclear whether a spatial map is guiding successive choices in this task (Brown, 1992; Brown et al., 1993). Third, in the Olton et al. (1979) study, the animals were initially trained as normal animals and were lesioned only after asymptotic performance had been reached. This training arrangement leaves open the possibility that the integrity of the hippocampal formation is required for the initial learning of which arms to avoid but perhaps not required for retention. Using animals that had undergone surgery prior to training, a series of studies by Jarrard (1978, 1986) established that the initial learning of place reference-memory in an eight-arm radial maze task in which four arms were never baited is consistently impaired by both complete hippocampal aspiration lesions and by more selective ibotenic acid lesions of the hippocampus and dentate gyrus. These studies were important for introducing the most selective type of hippocampal lesion that has yet been developed. In the process, the cognitive map theory was partially salvaged as the integrity of the hippocampus is required for initial learning. However, the long-term storage of information about which arms are baited or unbaited may be outside the hippocampal formation (Barnes, 1988). The theme that the hippocampal formation may be required for the initial learning of a spatial task with eventual storage in the cortex is one that recurs in many tasks, including the next one we consider.

### Watermaze

Further evidence that the integrity of the hippocampal formation is essential for allocentric spatial reference memory came with the introduction of the watermaze (Morris, 1981).

**Box 13–5**  
**Watermaze**

The watermaze has become one of the most widely used tasks in behavioral neuroscience. It was developed to study spatial learning and memory but is now often used as a general assay of cognitive function for testing new drugs or other treatments of the nervous system.

The basic task is simple. Animals, usually rats and mice, are required to escape from water onto a hidden platform whose location can normally be identified only using spatial memory. There are no local cues indicating where the platform is located. Conceptually, the task derives from “place cells,” as these cells also identify points in space that cannot be defined in relation to local cues. This simple water escape task is then embedded into a variety of sometimes quite complicated training and testing protocols to investigate specific theoretical issues.

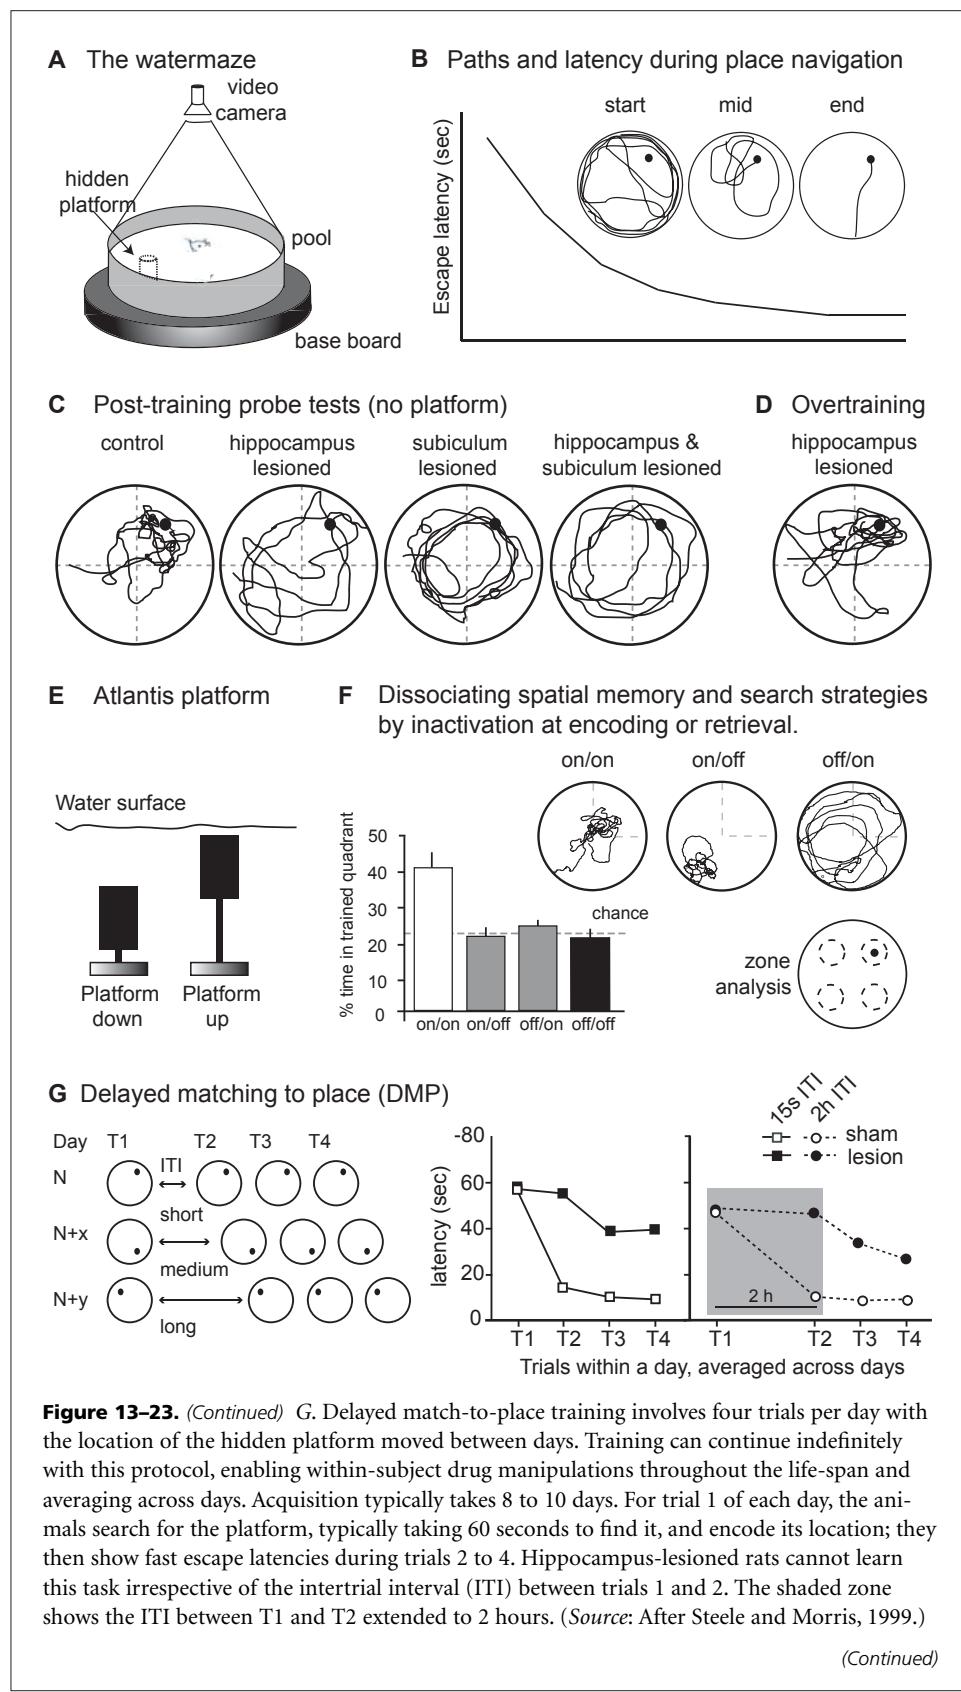

**APPARATUS**

The apparatus consists of a large circular pool, generally 1.5 to 2.0 m in diameter, containing water at around 25°C made opaque by adding milk or other substance (e.g., latex) that helps hide the submerged platform. The water in the pool is filled and drained daily via an automated filling and draining system. The choice of water temperature, around 13°C below body temperature, is sufficiently stressful to motivate the animals to escape but insufficiently stressful to inhibit learning. There is a stress reaction (corticosterone release) on day 1 of training, but this habituates over days. If the pool temperature drops to 19°C, performance improves, but when it drops to 12°C, it gets worse, reflecting the inverse U-shaped function relating stress to cognitive function. The pool is located in a laboratory room with distinctive two- and three-dimensional distal cues that aid orientation or surrounded with hanging curtains that occlude these room cues. Cues may then be hung inside the curtains so they can be rotated relative to the room when this degree of experimental control is required. A video camera is placed above the center of the pool to capture images of the swimming animal and is connected to a video or DVD recorder and an online computer system running specialized tracking software. The top surface of the hidden platform, usually about 10 to 15 cm in diameter and thus between 1/50th and 1/100th of the surface area of the pool, is 1.5 cm below the water surface (Fig. 13–23A).

**PROTOCOLS**

“Reference memory” protocols have been widely used in which the platform is in a fixed location relative to the room cues across trials and days. The animals are placed in the water at and facing the side walls of the pool at different start positions across trials, and they quickly learn to swim to the correct location with decreasing escape latencies and more direct swim paths (Fig. 13–23B). The tracking system measures the gradually declining escape latency across trials and parameters such as path length, swim speed, directionality in relation to platform location, and so on. Observation of the animals reveals that, having climbed onto the escape platform, they often rear up and look around, as if trying to identify their location in space. Rearing habituates over trials but then dishabituates if the hidden platform is moved to a new location.

**Figure 13–23.** Watermaze. A. Axonometric drawing of a typical watermaze setup with overhead video-camera and rat swimming to find the hidden platform. B. Representative escape latency graph and swim paths across various stages of training: initial swimming at the side walls, then circuitous paths across the area of the pool, and finally directed path navigation. C. The hidden platform is removed for posttraining probe tests. Whereas normal or sham-lesioned controls swim to the target quadrant (NE, within dotted gray lines), rats with hippocampus, subiculum, or combined lesions do not. (Source: After Morris et al., 1990.) D. Overtraining of hippocampus-lesioned rats can result in quite focused search patterns during a probe test. (Source: After Morris et al., 1990.) E. Atlantis platform. The hidden platform is at the bottom of the pool where the swimming rat cannot bump into it by chance. Online automated data capture of swim paths is used to determine whether the rat swims within a virtual zone around the platform’s location, raising the platform to within 1.5 cm of the water surface when a criterion is reached. This protocol trains highly focused search patterns. (Source: After Spooner et al., 1994.) F. Reversible hippocampal inactivation with a glutamate antagonist during training (encoding) or at retention (retrieval) results in poor probe test performance compared to the controls, which have the hippocampus working continuously. Analysis of the search patterns show that rats trained with the hippocampus “on” during encoding, but “off” at retrieval display searching at the wrong location in the pool, as quantified using zone analysis. (Source: After Riedel et al., 1999.)

**Box 13–5**  
**Watermaze** (*Continued*)

During or after training is complete, the experimenter conducts a probe trial in which the escape platform is removed from the pool, and the animal is allowed to swim for 60 seconds. Typically, a well trained rat swims to the target quadrant of the pool and repeatedly across the former location of the platform until it starts to search elsewhere (Fig. 13–23C). This spatial bias, measured in various ways, constitutes evidence for spatial memory. Rats with lesions of the hippocampus and dentate gyrus, subiculum, or combined lesions, do poorly in posttraining probe tests.

However, if rats with hippocampal lesions are given “overtraining” (typically consisting of a large number of trials over many days), performance can improve in probe tests. Even rats with hippocampal lesions can show quite localized searching (Fig. 13–23D).

Numerous other protocols have been developed to test specific hypotheses. Many involve cryptically moving the hidden platform. This might be a “reversal” procedure in which, after one location has been thoroughly trained the platform is moved to a different quadrant of the pool. Because it is hidden, it is not apparent that anything has changed until the animal fails to find the platform in its usual place. The focus is on how the animal reacts to this change and how quickly it learns the new location. The relearning that occurs with the reversal protocol has been used in a major “factor analysis” of the determinants of watermaze behavior across strains of mice.

As the animals sometimes “bump” into the submerged platform by chance, one useful innovation is an “on-demand” or “Atlantis” platform that is initially at the bottom of the pool and becomes available only when the animal swims in its vicinity for some predetermined time. An automatic release system allows the platform to rise gently to near the surface of the water (it remains hidden). This procedure results in acquisition of a highly focused searching strategy that focused on the target location during training. Reversible inactivation of the hippocampus with a drug that blocks excitatory neurotransmission after the training is completed results in animals displaying localized searching at inappropriate places in the pool. Pharmacological inactivation during training results in failure to develop this search strategy because the animals cannot learn the place at which to execute the strategy in the pool (Fig. 13–23E). The accuracy of the searching can also be measured using a zone analysis that measures time spent in a virtual zone around the place where the platform is located.

With other protocols, the platform can be moved to a new location each day, creating what is called the “delayed matching to place” (DMP) procedure (Fig. 13–23F). The animal cannot know, with this procedure, where the platform is hidden on trial 1 of each day; it can only search for it. However, if it can encode this new location in one trial, the animal finds the platform much faster during trial 2 and subsequent trials of that day. The memory delay interval between trials 1 and 2 (ITI) can then be systematically varied to explore how well one-trial spatial memory is remembered, a procedure with some similarities to delayed matching and non-matching tasks used to examine recognition memory. Rats with complete hippocampal lesions cannot show the rapid, one-trial learning required for the DMP task and are just as poor at a short ITI between trials 1 and 2 as a long one (Fig. 13–23G). Treatment with an NMDA antagonist such as D-AP5 results in a selective deficit in memory at a long ITI, but the animals can learn with short memory intervals between trials (see Chapter 10, Section 10.9).

Other variants include alterations to the apparatus, such as constraining the path of the swimming animal to minimize navigational demands (e.g., an annular watermaze), decreasing the number of available extramaze cues between training and testing to look at pattern completion, the use of floating platforms, and yet other manipulations. A radial watermaze has also been introduced, combining the virtues of the radial maze with the ease of training to escape from water. This has proved invaluable for testing transgenic mice expressing familial Alzheimer mutations.

**TREATMENTS AND CONTROLS**

A wide variety of treatments have been explored including lesions, drugs, and molecular-genetic alterations. They alter watermaze “performancez” in various ways, but experimenters must be cautious, as such alterations need not be specific deficits (or improvements) in spatial learning or memory processes per se. Lesions or drugs may have a direct effect on learning mechanisms, and many seem to do so, but they may also affect an animal’s ability to see the extramaze cues or their motivation to escape from the water rather than learning per se. Factor analytical studies reveal that many molecular-genetic alterations influence the probability of mice to stay at the side walls (thigmotaxis) instead of swimming into the center of the pool and that this effect is statistically independent of spatial memory.

Accordingly, treatments must be accompanied by relevant control conditions. A common protocol is to include trials in which the escape platform is made visible, the idea being that treatments that merely affect motivation to escape should impair performance in this task as well as the basic task. It is unclear how sensitive this assay is, but it does provide a first pass at detecting gross sensorimotor abnormalities. As blind rats have been claimed to do surprisingly well in the watermaze (except in probe trials), other psychophysical techniques have been introduced offering precise control of the spatial frequency of cues that are more sensitive to subtle visual deficits. The use of sham-lesioned animals, vehicle-infusion conditions, “floxed” mice, and other pertinent manipulations has also become widespread to ensure that any alterations in spatial learning in the experimental group are not an unintended by-product of achieving the treatment.

#### **WATERMAZE AS AN ASSAY**

As our understanding of the impact of various treatments has developed, the watermaze has gradually been subsumed into test batteries and assays for investigating aspects of brain function other than just hippocampal function. This is a strength of the assay but also an analytical weakness. The task is so sensitive to manipulations of normal brain function in many brain areas, not just the hippocampus, that it can be used almost like a “litmus test” of the “normality” of brain function. This is valuable, as it brings behavioral observations of function into fields of neuroscience that have historically relied exclusively on stress (corticosterone release), neuropathology (stroke research), biochemical analyses (Alzheimer’s disease), or electrophysiology (development of cognitive enhancing drugs). The analytical weakness is that a task affected by such a wide variety of treatments is gradually being revealed as having less “specificity” than was once believed.

Innovation in the development of new training protocols is enabling the simplicity and speed of learning to escape from water to be retained in the arsenal of behavioral tools at the disposal of neuroscientists. Arguably, the watermaze illustrates both themes of this book: (1) a tool to study hippocampal function and (2) an illustration of how studies of hippocampal function have had a wide impact on neuroscience in general.

#### **SELECTED REFERENCES**

Morris, 1981, 1984; Sutherland and Dyck, 1984; Brandeis et al., 1989; Good and Morris, 1994; Nunn et al., 1994; Whishaw and Jarrard, 1996; Gallagher and Rapp, 1997; Lindner et al., 1997; Sandi et al., 1997; Lipp and Wolfer, 1998; Morgan et al., 2000; Prusky et al., 2000a; D’Hooge and De Deyn, 2001.

Morris et al. (1982) trained rats to find a hidden escape platform in a circular pool of opaque water. Some had been subjected to “hippocampal” aspiration lesioning (damaging the hippocampus, dentate gyrus, and subiculum), others cortical control lesioning (damaging the same small amount of cortical tissue in the region of the parietal cortex as was necessarily damaged when making the hippocampal lesion), or no surgery (unoperated control). The cortical “control” lesion was included in this and many other early rat studies (in contrast to the monkey work discussed in Section 13.3). In the watermaze, both the normal *and* the cortical tissue-lesioned groups quickly learned to swim toward the hidden platform from any starting location; only the hippocampus-lesioned group was impaired in executing directed swim-paths. Performance during a posttraining probe test showed that both control groups swam persistently across the exact spot where the platform had been located during training, a pattern of behavior that could not occur during training and was arguably reminiscent of “free recall.” In contrast, the hippocampus-lesioned group swam all over the pool. The

deficit in escape latency disappeared when the platform was made visible, indicating that the impaired place navigation was unlikely to be secondary to any change in motivation to escape from the water and reappeared when it was subsequently hidden again. Similar results were obtained in the first study to use neurotoxic lesions in the watermaze by Sutherland et al. (1983), investigators who were primarily responsible for popularizing the task (Box 13–5).<sup>†</sup>

Over the years since the watermaze was developed, there have been numerous replications of the deficit in place-navigation learning caused by hippocampal lesions. Other pertinent findings concern the impact of lesions to structures afferent or efferent to the hippocampus and of fiber pathways interconnecting these structures, as comprehensively reviewed

<sup>†</sup>There have been differences in opinion about the name “watermaze” for an apparatus that is not obviously a maze. Some describe it as a “water task,” others as a “milk bath,” and many use an acronym “MWM.” The use of the term “maze” is appropriate, as it is an apparatus in which the animal has to find its way around—and that is what one does in a maze. By analogy, golfers play on a “golf course” not “golf fields.”

by D'Hooge and De Deyn (2001). For example, deficits in place navigation have been reported after selective lesions of the entorhinal cortex (Schenk and Morris, 1985), perforant path (Skelton and McNamara, 1992), dentate gyrus (Sutherland et al., 1983), area CA1 (Nunn et al., 1994), medial septum (Hagan et al., 1988; Kelsey and Landry, 1988), fornix (Morris, 1983), and subiculum (Taube et al., 1992). Deficits are generally seen only after bilateral lesions. The overwhelming consensus is that the integrity of the hippocampal formation and its afferent and efferent connections is essential for the acquisition and/or consolidation of normal, appropriately directed spatial navigation.

However, as with the radial maze, further study has revealed lesion dissociations that are not predicted by the cognitive map theory and point to a functional heterogeneity that underlies normal performance. Dysfunction in a variety of structures has an impact on performance, notably damage to neocortical structures such as the retrosplenial and parietal cortices, frontal cortex, basal forebrain, striatum, and cerebellum—an issue addressed in the critique below. A problem with the watermaze is that its procedural simplicity belies an underlying complexity with respect to the numerous sensorimotor and cognitive processes that, in practice, it engages. That it has been classified as a “spatial memory task” should not lull users into believing that other sensorimotor and cognitive processes are not involved. It would be tidy if the impact of lesions or other dysfunctions of distinct brain areas or neurotransmitter systems is isomorphic to the spatial mapping or navigation processes identified within the theory, but the data point to a more complex picture in which the hippocampus engages with other brain structures to mediate effective performance.

Before considering navigation in the watermaze in detail, it should be noted that many dry-land place-finding tasks have also been developed, including the earlier Barnes arena task first developed in the context of studies linking hippocampal LTP to spatial learning (Barnes, 1979), a place preference task in which rats are systematically rewarded by intracranial brain stimulation for visiting a particular location (Fukuda et al., 1992), similar appetitive place preference tasks (Rossier et al., 2000), and a place avoidance task. These tasks are conceptually similar but, being on dry land, the animal can stop moving and is also more likely to use olfactory and somatosensory (vibrissa) cues. This is likely to make them less dependent on visual cues than the watermaze. With place avoidance, the mirror image of place navigation, animals are trained stay away from a location to avoid the punishment of mild foot-shock (Bures et al., 1998). Place avoidance has been used extensively to examine the differential role of allocentric versus ideothetic cues in location learning by allowing the circular arena to rotate slowly in relation to extramaze cues. Rats can be successfully trained to avoid a sector defined in relation to room cues or in relation to its location on the rotating arena. An interesting commercial twist on place navigation and place avoidance is incorporated into modern robot vacuum cleaners, a good example of a biologically inspired artifi-

cial navigation system (Trullier et al., 1997). These machines clean the floor as they work their way around a living space and typically incorporate two key features of spatial memory. They “remember” where in the room to go to get their battery recharged and to avoid recleaning places that they have already moved across.

### **Varied Training Protocols Reveal the Importance of the Dorsal Hippocampus for Spatial Navigation**

A key distinction regarding the watermaze is between thinking of it as an *apparatus* and as a *task*. Sometimes described as the latter, it is really an apparatus in which a wide variety of training protocols can be carried out to address specific issues. Some modifications have come into widespread use, others not. One was a modification of the original spatial reference memory protocol (Morris et al., 1986a) that for various reasons was not taken up by other laboratories. It involves training rats to choose between two visible platforms, one of which is rigid and offers escape from the water, the other floating and so offers insufficient buoyancy for escape. Local-cue and spatial versions of this task were compared. Hippocampal lesions impair the spatial task but have no effect on the procedurally similar cue task. In many respects this is a more rigorous test of the dissociation between locale and taxon strategies proposed in the cognitive map theory than the comparison between the hidden and visible platforms of the “standard” watermaze task because it compares two tasks of comparable difficulty. It also removes the “recall” element of the standard procedure because the navigational demands are minimized and the animal need only approach either platform and then use spatial recognition to decide whether it or the other platform is associated with escape. Interestingly, the hippocampus-lesioned group displayed first-choice performance that, starting at 50%, gradually rose above chance. The effect was not large, but it was both detectable and statistically significant—a first suggestion that allocentric place navigation is possible after hippocampal dysfunction. One possibility is that it is easier in this task to bridge temporally discontiguous gaps in the processing of relevant sensory information (Rawlins, 1985).

Although a consensus emerged that the standard hidden platform reference memory version of watermaze spatial navigation is a “hippocampal task”—being easy to train and producing reliable, replicable results in different laboratories—the impact of such lesions is more variable than many may appreciate. First, the sensitivity of the “cue task” (which is unimpaired by hippocampal lesions) has been called into question following the observation that rats with experimentally reduced visual acuity display impaired place navigation but are unimpaired in the cue task (Prusky et al., 2000b). This dissociation falsely masquerades as a deficit in place learning. Although a nice “proof-of-principle,” it is unlikely that hippocampal lesions cause any change in visual acuity. However, regionally nonselective transgenic manipulations and many

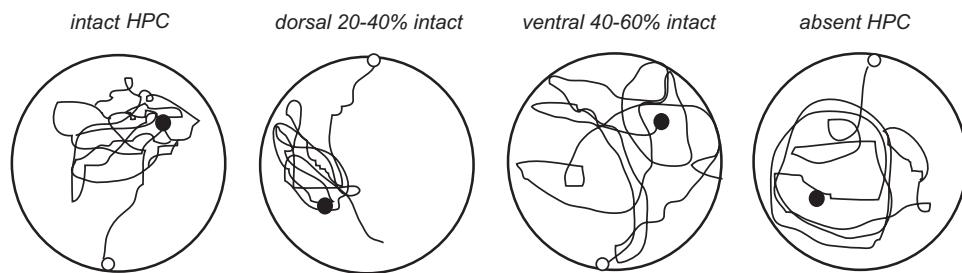

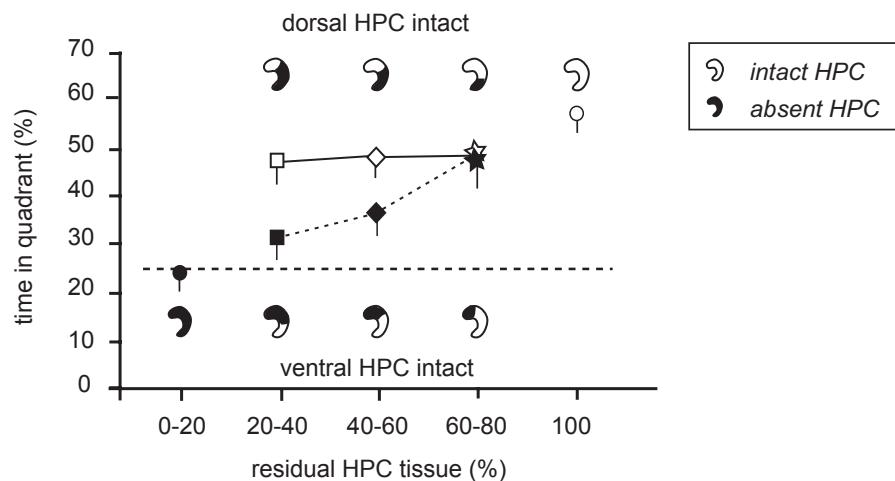

peripherally administered drugs may affect visual acuity. Psychophysical procedures have therefore been introduced to provide a more rigorous test of sensory acuity than the cue task (Prusky et al., 2000a; Robinson et al., 2001), and it would be valuable to see these used with selected transgenic lines. Those with cell- and region-specific mutations are also unlikely to be impaired, but the important lesson that needs to be taken on board from these sensory studies is that caution must be exercised about treating the watermaze as an ostensibly selective assay of memory function. Interestingly, the cue task is impaired by dorsal striatum lesions (McDonald and White, 1994), a sensitivity that is more likely due to the role of this structure in habit learning than any sensory impairment.

Second, as in the two-platform task, some place navigation does take place in rats with hippocampal dysfunction. Using overtraining in the standard, reference-memory single platform procedure, Morris et al. (1990) found that rats with lesions in the hippocampal formation could learn to escape to the platform with short escape latencies after about 80 trials of training. Overtraining never obviated slightly elevated escape latencies relative to those of the controls; but after a mixed series of hidden and visible platform trials, probe test performance was spatially focused in the correct training quadrant and quantitatively indistinguishable from that of the controls (Fig. 13–23D). This slow, incremental spatial learning was apparent in animals with hippocampal or subiculum lesions, whereas those with combined hippocampus and subiculum lesions failed to learn despite extensive overtraining. Eichenbaum et al. (1990) also showed incremental learning in rats given fornix lesions when the animals were consistently trained from a single location. Probe test performance was, however, sensitive to the use of novel starting locations around the pool. Animals subjected to retrohippocampal lesioning that encompassed the region of the entorhinal cortex containing the entorhinal grid cells also showed gradually improving probe test performance, but analysis of the paths taken revealed accuracy in swimming across the correct platform location but little indication of “recognizing” that this was the correct place to stop and search (Schenk and Morris, 1985). However, not all studies have observed effects of entorhinal lesions on spatial reference memory in the watermaze (Bannerman et al., 2001), raising the possibility of functional heterogeneity across the medial, intermediate, and lateral regions of the entorhinal cortex. A key issue may be whether such lesions encroach on the dorsal region containing the grid cells (Hafting et al., 2005).

A third important issue, first raised by Andersen in relation to the “lamella theory” of hippocampal information processing (Andersen et al., 1971, 2000), is how much hippocampal tissue is actually required for learning or retention. This was a fresh way of looking at the impact of lesions on function—focusing less on whether a lesion causes a *deficit* than if normal performance is still possible with a partial lesion of a specific size. Moser et al. (1993) discovered that aspiration lesions of the ventral hippocampus that leave only small “min-

islabs” of dorsal hippocampus intact allow normal learning. In contrast, lesions of the dorsal hippocampus that left the ventral hippocampus apparently intact did not. They suggested that a relatively small number of lamellae in the dorsal hippocampus, if adequately connected to entorhinal cortex, the septum, and other brain regions, were sufficient for learning. A follow-up study using ibotenic acid lesions confirmed these findings (Moser et al., 1995). The second study was conducted because the aspiration lesions of the original study may have inadvertently left the ventral hippocampus deafferented, and thus the apparent dissociation between dorsal and ventral hippocampus could have been an artifact. In fact, similar results were obtained with as little as 27% of dorsal hippocampus being required for normal spatial learning that was indistinguishable from that shown by sham-lesioned controls (Fig. 13–24). In parallel, Jung et al. (1994) observed that the firing fields of place cells were less spatially selective in the ventral hippocampus. Taken together, these observations fit well with anatomical studies of the connectivity between the entorhinal cortex and hippocampus, with particular zones of the dorso-medial entorhinal cortex preferentially projecting to the dorsal (septal) hippocampus of the rat. Detailed anatomical analyses have suggested the concept of “parallel closed loops” as the substrate for both reverberation and the processing of functionally distinct sets of cortical information (Amaral and Witter, 1989; Witter et al., 2000) and of “functional differentiation” along the long axis of the hippocampus (Moser and Moser, 1998b). (For further discussion, see Chapter 3.)

Other studies using the watermaze, T maze alternation, and contextual fear conditioning are consistent with this dorsal-ventral (i.e., septo-temporal) gradation of function (Bannerman et al., 1999; Richmond et al., 1999). The search for a specific function for the ventral hippocampus has included a return to J.A. Gray’s ideas about a possible role in fear and anxiety (Bannerman et al., 2004). For example, Kjelstrup et al. (2002) found that rats with selective lesions located in the ventral pole of the hippocampus were less fearful on an elevated cross maze and showed decreased neuroendocrine stress responses. These animals did, however, display normal contextual fear conditioning. Bannerman et al. (2002) have also implicated the ventral hippocampus in anxiety as ventrally lesioned animals freeze less to unsignaled foot-shock in a test chamber. They also show less neophobia (the fear of novel foods). However, the notion that the ventral hippocampus is not involved in spatial learning at all can be overstated. De Hoz et al. (2003) observed that changing the reference memory training protocol to one involving fewer trials but over a larger number of days enabled rats with large dorsal hippocampus lesions (i.e., only ventral tissue intact) to learn just as effectively as rats with only spared dorsal tissue, as measured by posttraining probe tests. Similarly, Broadbent et al. (2004) found that ventral hippocampal lesions encompassing approximately 50% of total hippocampal volume can impair spatial memory in a watermaze reference memory task. Thus, the dorsal/ventral distinction is not clear-cut.

**A** Search patterns during probe tests of representative animals with partial or complete lesions**B** Relation between size of residual tissue and performance during the probe test

**Figure 13-24.** Partial lesions reveal a dissociation of function along the longitudinal axis of the hippocampus. *A*. After training by animals with spared tissue volumes of different sizes that began at different ends of the longitudinal axis of the hippocampus, posttraining probe tests (hidden platform absent) revealed a graded change in animals in which only ventrally located tissue was intact but good

performance in animals with dorsal tissue. *B*. Quantitative assessment of the probe tests show near-normal performance of rats with as little as 20% to 40% of the dorsal hippocampus intact. *Inset*. Parasagittal diagrams of the hippocampus show the locations of intact (white) and lesioned (black) tissue along the longitudinal axis. (Source: After Moser et al., 1995.)

A fourth important issue is asymmetry in the impact of lesion size on initial acquisition versus retention. Retention is more sensitive. If normal rats are trained in the watermaze and then given small lesions of the mid- or ventral hippocampus immediately after training, memory retention is impaired. However, such lesions have no effect on learning or later retention when given before training (Moser and Moser, 1998a). This dissociation is paradoxical from the perspective of thinking about the hippocampus as a distributed associative memory system (Rolls and Treves, 1998) because such systems are generally robust in the face of partial damage. However, the finding is not necessarily incompatible with such a perspective if encoding and trace storage takes place across an extended region of the longitudinal axis in normal rats. Animals given lesions before training would use the remaining tissue, and normal learning should occur provided there was enough of it. Small lesions created after training may indeed damage only a small proportion of the synaptic storage sites but may nonetheless interrupt inputs to and outputs from such sites, even when neurotoxic lesions are used.

To test this idea more rigorously, Steffenach et al. (2002) investigated whether the integrity of the longitudinal-association pathway of CA3 pyramidal cells is critical for integrating such distributed information. In animals previously trained as normal rats in the standard reference memory task, a single transversely oriented cut of no more than 3% of the hippocampal volume was made bilaterally through the dorsal CA3 region (the lesion shown in Figure 13-1, panel 5B). Memory retention was impaired. These knife cuts inevitably damage cells as well and possibly some Schaffer collaterals coursing to CA1, but no impairment was observed in controls deliberately given small, equivalent-sized neurotoxic lesions of CA3 cells but leaving the longitudinal fibers intact. This study is unusual amongst behavioral studies in using FluoroJade tract-tracing to observe degenerating fibres on either side of the cut.

Taken together, these studies led by the Trondheim group have definitively established that the efficient acquisition and retention of spatial memory requires only a small “minislab” of hippocampal tissue, preferentially although not exclusively in the dorsal hippocampus. The integrity of longitudinally

oriented, translamellar connections of CA3 pyramidal cells in this minislab is essential for normal functioning. It is not yet known if this is a deficit in memory retrieval or consolidation, but varying the interval after initial training before the longitudinal cut is made would be one way of investigating this question (see discussion of memory consolidation below).

### Spatial Recognition Does Not Require CA3 Cells

If cognitive mapping involves both spatial representation and navigation, the question arises of whether different parts of the hippocampal formation are involved in recognizing a place versus navigating to it. Using a modification of the watermaze that involved changing it to no more than a circular swimming track, Brun et al. (2002) have shown that CA3 lesions can leave CA1 place cell firing fields and spatial recognition intact. Rats were intensively trained to swim in an annular watermaze for a hidden platform that could rise from the bottom of the pool at a specific location once the animals had completed two or three laps of the pool. They displayed “knowledge” of this potentially safe place in the pool by hesitating or by swimming more slowly there during the successive laps. Complete CA3 lesions leave this “spatial recognition” intact, while complete lesions of the hippocampus impair this ability (just as they impair navigation in the open pool). This finding complements the further finding that CA1 place cells can be normal in rats with CA3 lesions, which points to the importance of the direct pathway from layer III of the entorhinal cortex into CA1 (Brun et al., 2002). Taken together with the study of Steffenach et al. (2002), there is therefore a double dissociation, reflecting the importance of the longitudinal connections in CA3 for navigation and the direct perforant path input to CA1 for spatial recognition. It would, nonetheless, also be valuable to damage the cells of origin of the layer III input to investigate the impact on CA1 place cell firing and, if the lesion could made be large enough while remaining selective (a tall order), on behavior as well.

### Place Cells, Head-direction Cells, and Navigation

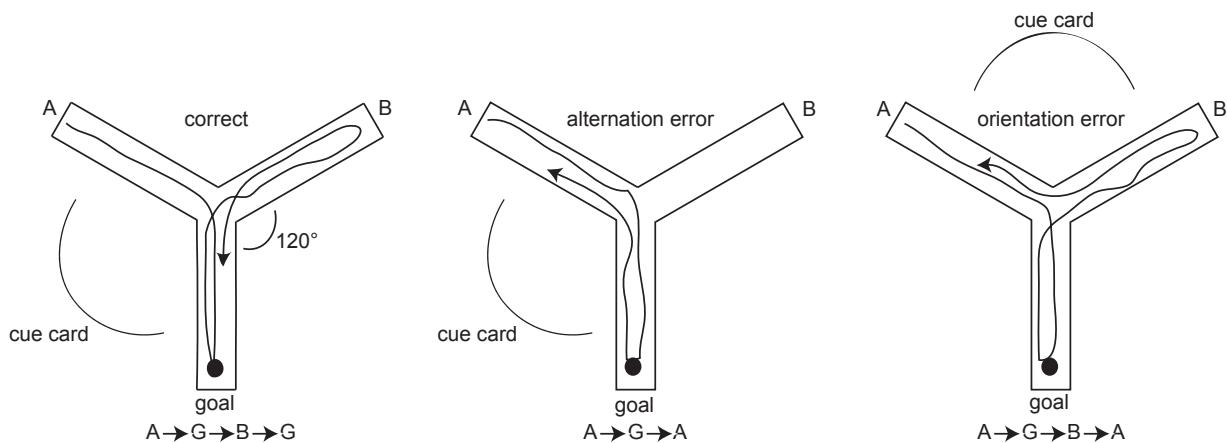

Although these lesion studies indicate that the integrity of at least part of the hippocampus is necessary for spatial navigation, it does not require that place and head-direction units are the critical neural mediators of navigation. Indirect evidence that these cells are important has come from a number of studies in which pharmacological or genetic manipulations cause alterations in both place cell firing and spatial learning (Mizumori et al., 1994; Wilson and Tonegawa, 1997; Kentros et al., 1998; Rotenberg et al., 2000; Cooper and Mizumori, 2001). However, an alternative possibility is that these cells only provide information about current location and direction, and other still unidentified cells mediate the representation of goals and carry out the information processing responsible for navigational choices—the problem identified in Figure 13–16B. Such cells may or may not be located in the hippocampal formation.

Prompted by tantalizing observations on the relation between place cells and navigation by O’Keefe and Speakman (1987) and their dependence on the spatial reference frames used by the animals for specific tasks (Gothard et al., 1996; Zinyuk et al., 2000), Poucet and colleagues embarked on a systematic research program to identify whether the firing of place cells is critical for navigational decisions and goal identification (Lenck-Santini et al., 2001, 2002). As behavioral and cell firing had to be obtained simultaneously, they began by returning to the use of traditional mazes. The principle guiding this work was that altering place cell firing fields by rotating or otherwise changing environmental cues should also be associated with systematic changes in navigational behavior if place cell firing and navigation are causally related.

Lenck-Santini et al. (2001) trained rats in a continuous spatial alternation task on a Y maze. One arm of the maze (G) served as the goal where food could be obtained. The animal had to alternate its visits to the other arms (A, B) to secure food in G. Thus, the correct sequence would be A → G\* → B → G\* → A → G\* → B and so on that secured reward (\*) upon every visit to G, whereas an incorrect sequence might be A → G\* → A → G, which did not (Fig. 13–25). This incorrect sequence was classified as an “alternation error” because the animal returned to A when it should have gone to B. A different, and initially much rarer, sequence might be A → G\* → B → A in which, having correctly alternated between A and B after a visit to the goal, the animal then returned to A instead of going back to the goal. This was called an “orientation error.” A prominent cue card was located on one side of the maze. Once all the animals were trained and performing well (around 80% correct choices), a total of 47 single units were recorded while the animals continued to run on the maze. Various manipulations of the cue card (rotation, removal) were systematically made to observe the impact on both place cell firing and behavior. As expected, the probability of correct alternation sequences declined during these manipulations; but more importantly, they did so in a systematic way. Pairs of recording/behavior sessions were compared. The second session of each pair was categorized as a “consistent” session when the location of a place field on the Y maze relative to the goal arm was the same as during the first session; it was categorized as “inconsistent” when the cue manipulation between the pairs of sessions caused some shift in the relative location of the place field to the goal. Behavioral choice performance was significantly poorer on inconsistent sessions. Moreover, an analysis of the kinds of errors made by the animals indicated that alternation errors occurred occasionally on consistent sessions, whereas inconsistent sessions were characterized by a striking increase in orientation errors. These findings indicate that the locations of place fields in a learned spatial navigation task are relevant to performance. Inconsistent place fields were statistically associated with disorganized spatial behavior. Similar observations were also made by Dudchenko and Taube (1997) with respect to head-direction cells.

In a follow-up study, Lenck-Santini et al. (2002) attempted to compare the value of correct place cell firing in a “locale”

## The relationship between the spatial firing of CA1 cells and spatial navigation

**Figure 13-25.** Relation between place cell firing and spatial navigation. Rats from whom CA1 cell recordings were made simultaneously were trained to alternate on a Y maze such that the correct order of arms would be A to Goal, then B, then back to Goal, and so on (A → G → B → G, and so on) (left panel). With the cue card in its training position, errors occurred rarely but when they did occur

tended to be alternation errors (middle panel). However, when the cue card was rotated (as shown) or removed or the goal location was rotated, orientation errors increased in frequency. They occurred when the cells were induced to display place fields that became out of register to their standard positions. (Source: After Lenck-Santini et al., 2001.)

task that required spatial memory with that in a “taxon” task that did not. They reasoned, in keeping with the cognitive map theory, that inappropriate place fields induced by cue manipulations should have a greater effect on behavior in the locale task. They used a place preference task, one of the appetitive analogues of the watermaze (Rossier et al., 2000), in which rats search around a large circular arena for food they receive if they enter a virtual circular zone located at one particular position in the arena (the food drops into the zone from a hidden feeder above—a scientific version of “manna from heaven”). In animals from which place cell recordings were being taken simultaneously, this task was conducted in one of three ways: with the virtual zone defined as at a distance from a cue card at the periphery of the arena, with it placed adjacent to the cue card, and with the zone defined by a local cue explicitly outlining its area. The key finding was that certain manipulations, such as visibly rotating the cue card while the animal was in the apparatus, created shifts between the expected location of the virtual zone as defined by the animal’s place fields and by the now rotated cue card. In brief situations of ambiguity (a few minutes), most rats searched in a region defined by the various place fields that were being recorded rather than as determined by the now rotated cue card. This did not occur in the taxon task when the zone was adjacent to the cue card or visibly identifiable by local cues. Poucet et al. (2003) argued that spatial searching behavior correlates well with place firing fields only when the rat is likely to be using a place navigation strategy. Data showing a correlation between the ability of an animal to find a goal on a linear track and the alignment of place fields with salient room cues is consistent with Poucet’s interpretation (Rosenzweig et al., 2003). Place firing fields, however, may be maintained in a taxon task when ani-

mals alternate between locale and taxon tasks (Trullier et al., 1999).

However, as noted by Jeffery (2003), the findings of these studies are only correlational. Experiments in which neural representations of location (e.g., place fields) are manipulated directly, rather than indirectly via environmental manipulations, are required to provide a yet more rigorous test of the role of place cells in mediating behavior. It is not obvious, however, how this might be done. Dudchenko (2003) took the same view with respect to head-direction cells and suggested that selective disconnection lesions might be a way of teasing apart cause and effect.

#### Knowing Where, Getting There, and the Puzzle of Hippocampal Involvement in Path Integration

The term “spatial navigation” has been unpacked in various ways. The original theory made only a binary distinction between locale and taxon processing during navigation, as if there are only two ways to get from A to B. However, evolution has discovered numerous other ways to navigate, ranging from “path integration” to “local views” (Benhamou, 1997; Biegler, 2000; Rodrigo, 2002). Inspired in part by ideas relating the hippocampal theta rhythm to aspects of movement monitoring and control (Vanderwolf et al., 1973), a series of studies by Whishaw explored the possibility of functional dissociation in navigation between “getting there” and “knowing where” (Whishaw et al., 1995). They recognized that spatial learning in the watermaze involves both learning the layout of distal cues and the development of navigational strategies to use this learned information. Following the several observations that hippocampus-lesioned rats may be able to acquire spatial information slowly, Whishaw et al (1995)

wondered if fimbria-fornix lesions might disrupt only the “getting there” component and not the “knowing where.” This line of reasoning was to lead to unraveling the different senses of “getting there.”

Although rats with fimbria-fornix lesions normally have a profound deficit in watermaze place navigation when trained to a hidden platform from several starting points, they display several indications of having learned the platform location when trained using a careful shaping procedure. They learn to head in the correct direction, slow their speed of swimming when approaching the vicinity of the platform, and search in the correct quadrant when the platform is removed. Although not as effective as control animals on all measures, there is clear evidence that fimbria/fornix-lesioned animals can learn something about location. However, a substantial deficit reappears when the animals are switched to the delayed matching-to-place (DMP) protocol in which the hidden platform is moved from one location to another between days. Whishaw et al. (1995) suggested that this profile is consistent with disruption of a process associated with getting to a hidden platform, not one of learning its location. This interpretation was backed up by a later study that, following visible platform training from three starting locations around the pool, included probe tests from a novel start location. Once again, fimbria/fornix-lesioned rats swam in the correct direction toward the now hidden platform, implying some knowledge of where it was located. Neither they nor the control rats could do this if vision was temporarily occluded (Whishaw, 1998). In both studies, section of the fimbria-fornix was complete, and the findings were in no way due to partial damage. Whishaw (1998) also drew attention to similar data demonstrating some indication of effective place navigation after prior visible cue training in the studies of Morris et al. (1982). Morris et al. (1990), in contrast, had argued that acquiring a spatial representation that encoded a single escape location might occur slowly in rats with hippocampal lesions, with the “map” stored in the neocortex, provided interference could be minimized. Visible platform training may help in this respect, particularly if many trials are undertaken. Both the “getting there” and the “slow learning” ideas can account for the failure of rapid learning in the DMP protocol in both Whishaw’s and Morris’s studies. Moreover, the data concerning a novel start location are ambiguous because the experimenter cannot constrain the animals’ swimming patterns in the open pool during earlier training. The view from the ostensibly novel start location is likely to be familiar.

The focus by Whishaw (1998) on the “getting there” component of spatial navigation is important. One the many ways of getting from A to B is “path integration” (often called dead-reckoning), a process that has been extensively studied in a variety of animal species (Mittelstaedt and Mittelstaedt, 1982; Wehner et al., 1996; Etienne et al., 1998). Path integration was identified as the evolutionary building block of the “fragments” within the fragment-fitting extension of the cognitive mapping theory in which small parts of space (the fragments) are assembled by an annealing process into a larger map of an

entire area (Worden, 1992). Path integration operates using ideothetic cues (i.e., cues generated during the course of movement) that may be vestibular, kinesthetic, or visual flow in origin. McNaughton et al. (1991) and Bures et al. (1998) have joined Whishaw in emphasizing the importance of path integration to hippocampal function. Redish (1999) shares this view of its importance but places the path integrator outside the hippocampus.

A special case of path integration, referred to as “homing,” has been extensively studied in hamsters (Etienne and Jeffery, 2004). It occurs when an animal, having left its nest site to forage for food, somehow keeps a continuous record of the distance and direction it has moved and uses this information to take a relatively direct path back to the nest. This is not a matter of retracing its steps as the paths out may be circuitous, whereas those back are direct. Field studies with desert ants have also revealed the accuracy of this form of home-base navigation and imply that it is an evolutionarily old form of navigation. It solves the problem of getting food and then getting home again without recourse to any “map.” Laboratory studies of mammals using rotating arenas, movable nest boxes, and foraging trips in the dark have established that homing can function in total darkness, that it accumulates errors over both time and the circuitous movements of the animal, and that it typically returns the animal to a point near but just short of the home-base by a vector likely to intersect the initial part of the outward path. The animal can then switch to searching using local cues (e.g., olfaction) to find the exact spot of a nest or burrow entrance. As path integration accumulates errors over time, it is not surprising that the vector processor can be “reset” by visual or olfactory cues, such as familiar landmarks or territory-defining odors. In addition, as many rodents are nocturnal and live in burrow systems, a self-motion monitoring system of this kind is likely to be helpful in many situations. Etienne’s view is that the neural algorithms used to yield directional and positional information in rodents remain elusive. Path integration capacity develops postnatally, presumably as specific local circuits that process the relevant sensory information become functional, and it is first observed as young pups abandon their sole use of olfactory cues to find the dam in the nest box in favor of forays in the world beyond. Right from the start, the very rapid and very direct return paths they display appear to be guided by path integration.

The idea that the hippocampal formation might be involved in path navigation has been offered by a number of investigators (Wiener, 1993; McNaughton et al., 1996; Bures et al., 1998; Whishaw, 1998). Whishaw and colleagues (Whishaw and Tomie, 1997; Whishaw et al., 2001) trained rats on an arena similar to that used by Etienne in which they spontaneously carried large food pellets back to their next box that was either visible or hidden at the edge of the arena. Search paths from the home-base were circuitous and marked by several pauses as the rats tried to find the cryptic food pellet, but the return path was much more direct. In normal animals, the return paths continued to be direct in the dark, suggesting

guidance by a homing vector. However, return paths were clearly disrupted in fimbria/fornix-lesioned animals, which often took circuitous routes around the circumference of the arena and quantitative changes with respect to both direction and velocity. However, data from Alyan and McNaughton (1999) have cast doubt on this finding because rats with hippocampal lesions seem to be able to home accurately in the dark, a finding that led Redish to place the path integration machinery outside the hippocampal formation (Redish, 1999). The precise role of the hippocampus in path integration remains unclear, but the topic has been of considerable interest for neural network modeling (see Chapter 14).

#### **13.4.4 Comparative Studies of Spatial Memory and the Distinction Between Spatial and Associative Learning**

The third key feature to highlight about the cognitive map theory is the dual claim (1) that allocentric spatial mapping evolved as a distinct, independent memory system of the vertebrate brain mediated by a specific brain area and (2) that spatial learning is qualitatively distinct from associative learning in that it is rapid, flexible, and uniquely encodes information into map-like representations. These two strands of an “adaptive specialization” hypothesis of hippocampal function (Sherry and Schacter, 1987; Papini, 2002) have been investigated in two contrasting research constituencies: by students of comparative cognition (who are broadly sympathetic) and by general process learning theorists investigating possible differences between spatial and associative learning (who are not).

#### **Comparative Studies Using Avian Species and in Naturalistic Situations**

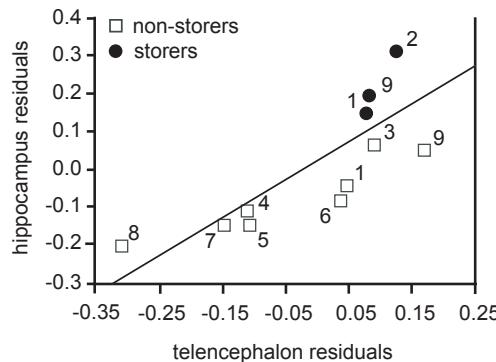

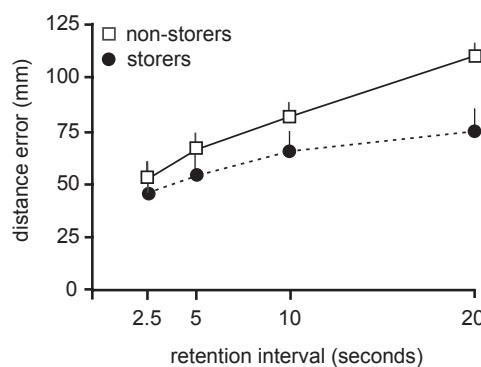

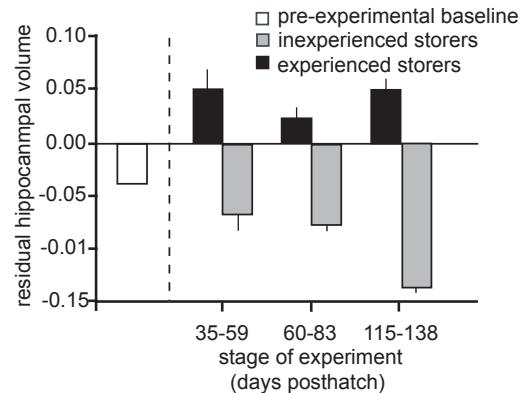

The original cognitive map theory put value on adopting a “neuroethological” as well as a neuropsychological approach to structure/function relations, an aspect reaffirmed by (Nadel, 1991, p. 224). “It is important,” he wrote, “to adopt a perspective on brain and behavioral organisation that takes into account ecological, evolutionary and ethological aspects of the animal under study.” The argument is that if space is important because “we live in it, move through it, explore it, defend it,” there will have been selection pressures of various kinds favoring the evolution of effective cognitive mechanisms for representing and navigating through space. Since 1978, study of the hippocampus in relation to “naturalistic” spatial behavior, in both field settings and the laboratory, has thrown up some striking brain/behavior correlations in several avian and mammalian species.

One finding is that the relative volume of the hippocampus in certain species of passerine birds (e.g., tit species in Britain, chickadees in North America) is larger in the subspecies that store seeds than in those that do not (Krebs et al., 1989; Sherry et al., 1989) (Fig. 13–26A). For example, the hippocampal formation of the food-storing marsh tit is 31% larger than the

non-food-storing great tit, even though the animal and the rest of its forebrain are much smaller. The importance of this correlation between the relative size of the hippocampus and cache recovery derives from the argument of Andersson and Krebs (1978) that food-storing is an evolutionarily stable strategy provided the animal that stores seeds utilizes the privacy of memory to relocate seed caches. Not surprisingly, the alternative strategy of tagging sites with some visible marker to avoid having to use memory is vulnerable to intruders, which then steal the caches. Ingenious field studies of tits in a wood near Oxford using radiolabeled seeds to enable the relocation of nonrecovered caches provided evidence that some kind of location memory is involved (Shettleworth and Krebs, 1982; Shettleworth, 1998). Similar observations were made in corvids that cache in the autumn but do not retrieve until the winter or early spring (Balda and Kamil, 1989). Effective food caching by scatter hoarders therefore relies on memory. A nice feature of this fieldwork is the implied reminder that memory can be allied to “privacy.” Like us, there are things animals do and remember and keep to themselves.

Food caching is not an isolated case. Sherry et al. (1992) pointed out that artificial selection among pigeon breeds appears to have had an effect on hippocampal volume similar to that of natural selection among passerine birds—the hippocampus of homing pigeons being larger than that of nonhoming domestic breeds. Studies of brood parasitism are also interesting: Female cowbirds that lay their eggs in the nests of other unsuspecting birds have a larger hippocampus than male cowbirds (Lee et al., 1998). Cowbirds doing this have to seek out and remember the locations of possible nests and then time their egg laying to coincide with that of the host bird. The occurrence of a common neuroanatomical feature in unrelated species ostensibly exposed to similar selection pressures raises the possibility that convergent evolution is responsible—the development of an adaptive specialization.

A potential problem with naturalistic studies is that they can be overly suggestive. As Shettleworth somewhat guardedly put it, “animals show many behaviors for which explanations in terms of human-like understanding readily come to mind: the animal has a cognitive map, a concept, a theory of mind . . . a leap of imagination may be necessary to grasp that behaviors so readily explicable by such intuitively appealing mechanisms are accomplished in completely different ways” (Shettleworth, 2001, p. 279). She and Krebs were among the first to appreciate that field studies had to be followed up, where possible, by rigorous laboratory analogues. They went on to create an avian laboratory setting in which food storing and retrieval could indeed be studied under controlled conditions, confirming the observations of the role of spatial memory in cache recovery first discovered in the wild. A typical avian food-caching laboratory is an indoor room with “trees” where seeds can be hidden (Fig. 13–26B). Such rooms are often described as “large,” but they are of course much smaller than the areas over which the birds normally forage in their natural habitat, an issue always to be borne in mind when a

(Source: After Krebs et al (1989). B. Laboratory aviary used to study storing, window-shopping (see text), and other food-caching protocols in birds. (Source: Courtesy of Nicola Clayton.) C. Spatial memory is

laboratory study yields a null result. Researchers using this kind of facility were faced with the challenge of how to compare cache memory by a species that *does* store seeds with the spatial memory displayed by a species that *does not*. Shettleworth and Krebs did this by creating a paradigm called “window shopping” in which seeds that could be retrieved later were placed “on display” behind Perspex screens in holes drilled into the trees. Thus, during the initial sampling trials, the birds were allowed to fly into the aviary without storing or retrieving—merely to see what was on offer and where. Later, the Perspex screens were removed, and the birds (presumably armed with their credit cards) could fly back and collect what they had seen earlier. In this and other one-trial associative paradigms (Clayton and Krebs, 1995), the act of caching was finessed while still allowing comparisons of spatial memory between storers and nonstorers. Other approaches include operant paradigms with “peck screens” (an avian touch-screen) to cast light on what qualitative aspects of memory might be better with a large hippocampus. In this way, Biegler et al. (2001) found that coal tits (a food-storing species) per-

more persistent over time in coal tits (a storing species) than great tits (a nonstoring species). (Source: After Biegler et al., 2001). D. Relative hippocampal volume at different stages of development. The structure becomes larger if the young marsh tits are allowed to store sunflower seeds (black bars), but it regresses and shows more apoptotic cells if the birds are given powdered seeds that cannot be cached. (Source: After Clayton and Krebs, 1995.)

form better than great tits (a nonstoring species) on a task assessing the persistence of memory over time (from 2.5 to 25 seconds) but not on tasks that assess the fine-grained resolution or, somewhat surprisingly, the capacity of memory (Fig. 13–26C). This is an important reminder that not all parameters of spatial memory are better in storers than nonstorers.

Another question that seminaturalistic studies have made possible concerns the ontogenetic development of the caching-associated difference in hippocampal size. How does experience interact with any genetic predisposition? In a classic study, Clayton (1995) reared juvenile marsh tits (a food-storing species) under conditions in which they were either allowed to store seeds or prevented from doing so (by giving them only powdered food). Tits allowed to store had the usual large hippocampal volume (Fig. 13–26D). However, birds that were prevented from storing showed a gradual decline in hippocampal size and the highest proportion of apoptotic neurons. These findings suggest that hippocampal volume, and perhaps neurogenesis also (Patel et al., 1997), may be partially regulated by activity-dependent factors such as the behavior

of the animal, a concept captured by the slogan “use it or lose it.” If so, it might be expected that relative volume in a species might also be seasonal. Specifically, the onset of hoarding behavior might be the trigger for an increase in volume, with regression later. This has been confirmed in black-capped chickadees (Smulders et al., 1995) and appears to be due to a net increase in cell number (Smulders et al., 2000). The possibility that it is merely due to a general seasonal mechanism operating on both food-storing and nonstoring species is less likely given that seasonal changes in volume have been shown *not* to occur in at least one nonstoring species (Lee et al., 2001). Males of this same species do, however, show changes in the size of song-related nuclei, such as the higher vocal center (HVC) and archistriatum (RA) across the seasons that correlated with song stereotypy. It therefore seems reasonable to infer that changes in the relative volume of the hippocampus of food-storing avian species results from a species-specific and regionally specific form of structural plasticity that occurs in response to seasonal pressures to engage in food-caching and later retrieval. One slightly puzzling finding is that the seasonal variation in size is, in black-capped chickadees, associated with the time of year when caching occurs, but hippocampal volume regresses in the winter—the very time when caches are recovered. Why retrieval places less of a demand on the need for a large hippocampal volume than memory encoding is unclear.

Allometric brain/behavior relations in the avian brain are intriguing, but they are a “chicken and egg” problem! What causes what? Lesion studies were a first step in investigating causal relations, it being essential to check that lesions of the avian hippocampus impaired location memory, just as such lesions do in mammals. These studies confirmed this prediction (Sherry and Vaccarino, 1989). Hampton and Shettleworth (1996) went on to show specificity to location rather than color memory after hippocampal lesions, and work using reversible inactivation in chickadees has both borne out this claim and established that it operates at the time of memory encoding (Shiflett et al., 2003). These and other studies (Columbo et al., 1997) have established that the functional integrity of the avian hippocampus is required for spatial memory (Macphail, 2002), but they do not really nail down whether the variation in the size of the hippocampus is causally related to the very changes in behavior with which they are correlated. Nor is it clear to what aspect of spatial or other information processing the avian hippocampus contributes. Work on homing pigeons has shed light on the second of these issues.

### **Homing Pigeons Reveal Hippocampus-dependent and Hippocampus-independent Components of Navigation**

Homing pigeons have a remarkable ability to fly back to their lofts over long distances from both familiar and unfamiliar release sites. The possible contribution of the hippocampus to homing behavior has been the subject of a comprehensive

series of visual-sighting and radio-tracking experiments by a group based in Pisa in Italy over the past two decades. Early studies suggested that the integrity of the hippocampal formation was critical for aspects of the navigation required, particularly near the home loft, but more recent work has pointed to a more complex picture.

Pigeon homing seems to be guided by a multiplicity of strategies and mechanisms, in part because of their need to cope with differing environments and potential variation in weather conditions. When released from an unfamiliar location, experienced homing pigeons fly off with a “vanishing bearing” in the correct direction of home (this being the compass bearing that the bird takes measured from the release site to last sighting after release). To do this, it was suggested by Kramer (cited in Rodrigo, 2002) that they use a “long-range navigational map” that may, at least in Italy, be partly reliant on odors (Papi, 1990). A problem with this concept is that it is far from clear how the pigeons learn such a map. In any event, they also keep flying in the correct direction and have long been thought to have some kind of a “compass” to do it (Schmidt-Koenig, 1961, cited in Gagliardo et al., 1999). Once they approach the vicinity of the loft, they recognize the landmarks and the layout of the area they are used to flying around at home and so find their way back to their perch in the loft. It is not just the loft area that may be spatially familiar; the birds can also learn about the landmarks at familiar release sites and even the roads over which they may fly. Indeed, Italian pigeons stylishly display a classic superiority in matters navigational by following old Roman roads such as the SS Aurelia (Lipp et al., 2004).

The early lesion studies established that pigeons with telencephalic lesions, including the hippocampal formation, have vanishing bearings from an unfamiliar release site that are as accurate as controls (Bingman et al., 1984). Their long-range navigational map is therefore intact. They also reach the vicinity of the loft but sometimes have difficulty finding it—unless they have been given sufficient postoperative experience of the loft vicinity (Bingman et al., 1987). This implies that the “sun compass” can work as well, this having been learned through sightings of the sun at different times of day when outdoors at the loft site. More recent studies have confirmed that the hippocampus plays only a small role in the navigational map. Acquisition and retention is independent of the hippocampus if the birds acquire their navigational map during free flights (Ioale et al., 2000). However, young birds can also learn the navigational map when held in an outdoor aviary. Under these conditions, learning seems to be hippocampus-dependent; but perhaps surprisingly, its retention is not (Gagliardo et al., 2004). The reason for this difference is that hippocampal lesions disrupt the process by which sun compass information is used *only* in the context of new learning (Bingman and Jones, 1994). Use of this compass requires that the animals keep track of time and orient in an appropriate direction to the angle of the sun given the time of day. When “clock-shifted” by being kept on artificial light-dark schedules, the orientational bearing is shifted from the correct homeward

direction. Experienced pigeons later subjected to hippocampal lesioning show the usual clock-shift effects, indicating their successful use of the sun compass. However, the hippocampus is necessary for learning to use this sun-compass information.

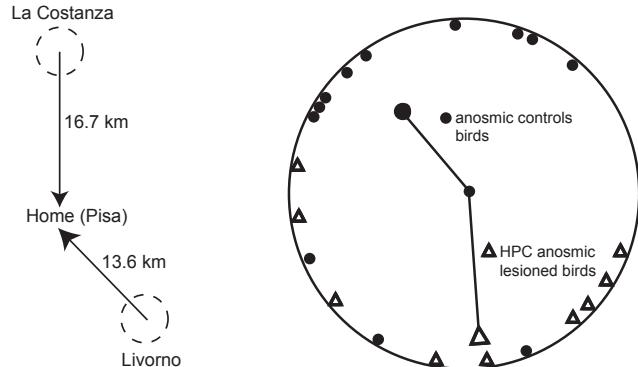

Landmarks they have learned about at a familiar release site can be used for homing in two distinct ways: "pilotage" in which they use the perceived layout of the landmarks to head toward the loft or "site-specific compass orientation" in which they use the landmarks to recall the sun compass direction in which to fly. Whereas pilotage requires quite a sophisticated spatial representation, site-specific compass orientation does not. Although pigeons with lesions of the hippocampal formation can learn to use familiar landmarks to navigate, it is possible that they do it in only one of these two ways. Gagliardo et al. (1999) studied experienced pigeons rendered anosmic by means of nasal zinc sulfate (a procedure that prevented the use of their navigational map) to compare the manner in which control and lesioned birds used familiar landmarks. As shown in Figure 13–27A, the birds were released on a number of occasions from La Costanza, north of Pisa, and from Livorno, situated southeast of Pisa. Prior to the critical test days, the birds were clock-shifted in their lofts by 6 hours. This should have no effect on the vanishing bearings taken from a release site if the birds use a representation of the spatial layout of the landmarks to find their way home. However, if they use site of the landmarks around each now familiar release site to work out a site-specific compass orientation, a 6-hour clock shift should result in an approximately  $120^\circ$  error in the initial flight direction. The results of test releases from both sites indicated a striking difference between the controls and the birds with hippocampal lesions (Fig. 13–27B). The controls headed in the correct direction, with only a small deviation of  $34^\circ$  in the direction expected given the clock shift; the lesioned birds showed a mean bearing error of  $154^\circ$  in the counterclockwise direction. Thus, the controls were using pilotage, whereas the lesioned birds were not. There is no conflict here with the earlier findings demonstrating that learning to use the sun compass requires the hippocampus because these were experienced homing pigeons that had

learned about the sun compass long before attaining hippocampal lesions. Given the multiplicity of ways that pigeons can navigate, these data represent an unambiguous demonstration of the critical role of the hippocampal formation in landmark learning in a naturalistic setting.

Although ostensibly supporting a close link between spatial memory and hippocampal function, one must recognize that the cytoarchitectonic appearance and intrinsic circuitry of the avian hippocampus is very different from that of the typical mammalian hippocampus described in Chapter 3. There are both similarities and differences between the avian and mammalian brain (Jarvis et al., 2005), but both Lee et al. (1998) and Macphail (2002) make the case—largely on embryological grounds—for the avian hippocampal formation being considered homologous to the hippocampus and dentate gyrus of mammals. Certain arguments seem unconvincing or circumstantial, such as the presence of synaptic plasticity (this also occurs outside the hippocampus) and the claimed similarity in neurotransmitters used (but similar neurotransmitters are used all over the brain in numerous orders of animals). Electrophysiological studies are also equivocal. For example, Bingman et al. (2003) reported some evidence of "space-specific" firing of hippocampal cells in homing pigeons trained in a small plus maze, but the correlate was transitory and less clearly tied to space than in recordings from rats. The possibility remains that greater spatial specificity would be observed in a task in which the pigeons were allowed to engage in homing, but this is not yet technically feasible. One prominent avian behavioral biologist, writing about the pigeon brain, noted that: "the pigeon and rat hippocampal formation reside in different forebrain environments characterized by a *wulst* and neocortex, respectively. Differences in the forebrain organization of pigeons and rats, and of birds and mammals in general, must be considered in making sense of the possible species differences in how the hippocampal formation participates in the representation of space" (Bingman et al., 2003, p. 117). Clearly, there are differences of opinion on the similarity of the avian and mammalian brain, and it is tempting to wonder if some of those who work on birds are making a virtue of necessity in sup-

**Figure 13–27.** Avian hippocampus and landmark learning. A. The home loft of the pigeons was near Pisa. The animals were extensively trained to fly home (to Pisa) from either of two release sites, La Costanza and Livorno. B. When rendered anosmic and clock-shifted by 6 hours, the controls headed in the correct direction whereas the hippocampus-lesioned birds showed greater variability around a mean, reflecting the expected shift of  $120^\circ$ . The reason a clock shift of 6 hours is expected to produce a deviation of  $120^\circ$  rather than  $90^\circ$  is because at around midday in summer the azimuth of the sun moves about  $20^\circ$  per hour. (Source: After Gagliardo et al., 1999.)

**A Home and two release sites**    **B Vanishing bearings of anosmic birds released from Livorno**

porting a claim for homology, aware of wider interest in the brains of mammals. Although understandable, the issue has to be resolved on the basis of all the evidence.

### Comparative Studies of Spatial Memory in Rodents

Hippocampal-oriented neuroethology studies have been conducted in mammals as well, but the research is less well developed. One idea about mammalian hippocampal evolution is that sexual selection may have led to a relative increase in hippocampal volume of certain polygynous male rodents, an important case because sex differences evolve slowly and thus any correlated differences in cognitive function and neuroanatomy are especially strong evidence of an adaptive modification of the brain. In support of this idea, Jacobs et al. (1990) found that polygynous male meadow voles, which have an area over which they range about five times larger than that of females, show a corresponding sex difference in hippocampal volume (Fig. 13–28). In contrast, in monogamous prairie and pine voles, male and female hippocampal size is equivalent. Earlier laboratory studies revealed that males of the polygynous meadow vole are superior to females in place learning in Tolman's sunburst and other mazes (Gaulin and Fitzgerald, 1989; Gaulin et al., 1990). The interaction between natural and sexual selection has also been revealed in studies of subspecies of kangaroo rats, some of which store food and some of which do not, some polygynous and some monogamous. In comparisons across species, hippocampal size was found to be largest in males and scatter hoarding in polygynous Merriam's kangaroo rats (Sherry et al., 1992; Jacobs and Spencer, 1994).

One proposed modification of the cognitive map theory, inspired by the allometric studies, pigeon homing work and by the discovery of head-direction cells, is the parallel-map theory of Jacobs and Schenk (2003). This explicitly identifies a "bearing map" (in which olfactory gradients or distal cues

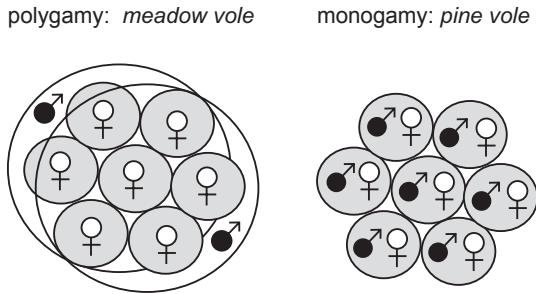

are used to establish a sense of direction) and a "sketch map" (which is an allocentric representation of local landmarks). The two mapping systems are held to be mediated by and to interact at different subregions of the hippocampal formation; the primary evidence for this is the consistent patterns of distinctive search strategies seen in spatial tasks after selective lesions or other pharmacological forms of intervention. It is too early to assess the status of this proposed modification of the original cognitive map theory, but Jacobs (2003) made the case that it is pertinent to issues of evolution and ontogeny across a range of species, including other vertebrates. Jacobs and Schenk also used it to offer novel explanations of certain hitherto puzzling lesion and pharmacologically induced dissociations in task performance by laboratory rats.

The relative volume of a brain area is a limited measure. It is important to know whether this reflects variation in cell number (and, if so, of what cell type), cell proliferation or cell death, dendritic arborization, synapse number or density, or other neuronal processes. Finer grain neuroanatomical or biochemical measures could offer insights into precisely what covaries with the type of information stored—capacity or temporal persistence. Given that neurogenesis may be under hormonal control (Galea and McEwen, 1999), there has been considerable interest in the possibility that seasonal changes in hippocampal volume reflect neurogenesis (Barnea and Nottebohm, 1994). Neurogenesis is influenced by environmental enrichment in some strains of mice (Kempermann et al., 1998) and by voluntary activity in running wheels (van Praag et al., 1999). There is evidence for seasonal changes in spatial learning ability and fine-grained aspects of hippocampal anatomy (Jacobs, 1995). However, Jacobs' own studies of possible seasonal variation in wild caught squirrels revealed no difference in cell proliferation or total neuron number in the hippocampus that co-varied with seasonal variation in demands on spatial memory (Lavenex et al., 2000). Chapter 9 discusses neurogenesis in the dentate gyrus in more detail.

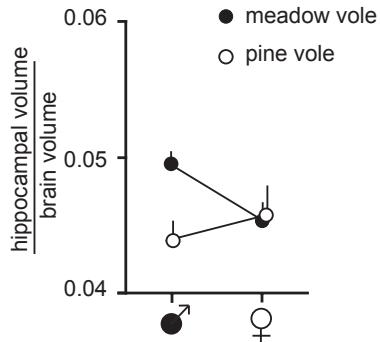

**Figure 13–28.** Sexual selection influences hippocampal size. A. Space use by mammalian species with different mating systems. Under polygamy, male home ranges encompass several smaller female ranges; under monogamy, males and females share a joint home territory. (Source: After Jacobs, 1995.) B. Relative hippocam-

pal volume in polygamous meadow voles and monogamous pine voles. The argument is that the hippocampus needs to be larger in a male meadow vole, which has to patrol a much larger territory. (Source: After Jacobs et al., 1990.)

#### A Male and female range size

#### B Relative hippocampal volume

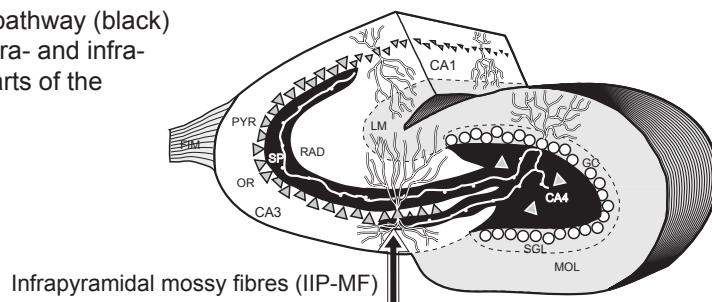

Neuroanatomical studies have nonetheless revealed consistent genetically stable variations in the intrinsic circuitry of the hippocampal formation across strains of mice (Lipp et al., 1999). Schwegler and Lipp (1981) discovered that the length of the infrapyramidal mossy fibers (IIP-MFs) is negatively correlated with two-way avoidance learning (a task impaired by hippocampal lesions) (Fig. 13–29A,B), a finding that holds across a number of mouse (and rat) strains (Schwegler and Lipp, 1983). Later work showed that it is positively correlated with performance in spatial tasks, including the radial maze and reversal learning in the water-maze (Crusio et al., 1987; Bernasconi-Guastalla et al., 1994). Mouse strains, such as C57/BL6, known to be good at spatial learning have an extensive infrapyramidal mossy fiber system. Other strains, such as DBAs and BALB/C, have a limited infrapyramidal mossy fiber system. However, such correlations, although striking, should be treated cautiously not least because there may be other covariates. For example, BALB/C mice have retinal problems and limited vision; and DBA mice are reported to have deficiencies in protein kinase C (PKC), an enzyme implicated in synaptic plasticity.

To try to unravel the reported correlations and take a step toward causation, postnatal injections of thyroxine (Fig. 13–29C) have been successfully used to induce variations in infrapyramidal mossy fibers within a single strain and corresponding variations in the learning rate (Lipp et al., 1988; Schwegler et al., 1991). Still, the anatomical disquiet remains: These injections may be having other unmeasured effects. Some measure of behavioral specificity has been realized by the finding that the correlations with infrapyramidal mossy fiber length holds for spatial working memory on a radial maze but not cue working memory (Crusio et al., 1987; Schwegler et al., 1990). However, later studies revealed strain-specific covariations between the extent of the infrapyramidal mossy fiber distribution and both intermale aggression (Guillot et al., 1994) and paw preference (Lipp et al., 1996), which are clearly unrelated to spatial learning and memory; and there is a report of failure to observe the correlation with radial maze performance (Roulet and Lassalle, 1992).

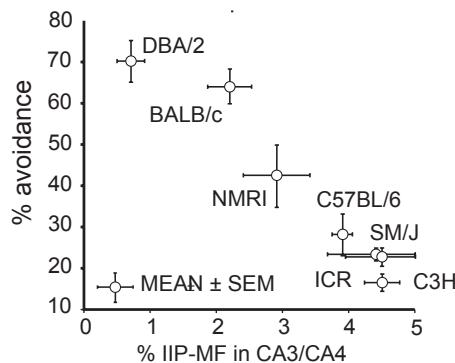

Lipp et al. (1999) recognized that these “noncognitive” findings may not fit well with some prevailing theories of hippocampal function but are relevant to a “multifunctional” view in which the dorsal hippocampus mediates spatial

**Figure 13–29.** Avoidance learning and infrapyramidal mossy fibers. A. Relative location of the supra- and infrapyramidal mossy fibers (IIP-MF) projecting from the dentate gyrus (DG) to area CA3. memory functions whereas the more ventral region is more relevant to emotional and aggressive behavior. They also suggested, partly on the basis of studies of the survival of various mouse strains through successive harsh winters at a Russian field station that “behavioral reactivity” rather than spatial memory may be the parameter of greatest adaptive significance in relation to the infrapyramidal mossy fibers.

To conclude this subsection, allometric brain/behavior correlations in birds and mammals have revealed several findings consistent with spatial interpretation of hippocampal function, but they have not definitively established that it is only spatial, rather than other kinds of memory, with which changes in hippocampal volume or structure are correlated. More analytical studies are required to unravel precisely what features of memory correlate with changes in hippocampal volume or circuitry. Identifying evolutionary adaptations, attributing them definitively to particular selective pressures, and then relating them to specific mosaic variations in brain size or circuitry is a slow, painstaking task (Lipp et al., 1999). The criticism has been made that studies of evolutionary function not only do not, but *cannot*, provide information about neurobiological mechanisms (Bolhuis and Macphail, 2001; Macphail and Bolhuis, 2001). However, even if this logical point were to be accepted, the implications are hotly debated (Hampton et al., 2002). Shettleworth (2003) offered a thoughtful defense of studies of the “neuroecology” of learning. She highlighted, by way of example, striking data from two populations of chickadees by Pravosudov and Clayton (2002). Instead of comparing different strains or species, they tested the “adaptive specialization” hypothesis in a single species, black-capped chickadees. One population was living in Alaska, where winters are fierce, and the other in Colorado. The different latitudes at which these distinct populations of a common species live might have resulted in a quantitative difference in the degree of selection pressure. Birds were caught in the autumn, around the time that seasonal volume changes should be maximal, and brought to a laboratory in California. Once there, the Alaska population was observed to be better at food storing and retrieval than the Colorado birds, better on spatial but not color memory (an allometric correlation analogous to earlier lesion data (Hampton and Shettleworth, 1996), and had relatively larger hippocampal volumes. It is not unreasonable to conclude that “mosaic” evolution of brain structure driven by natural selection on particular behavioral capacities (Barton and Harvey, 2000) will continue to contribute to understanding qualitative and quantitative differences in the hippocampus within and across species.

### **Maps, Spatial Representations, and Geometry: Is Spatial Learning Qualitatively Different from Associative Learning?**

The other strand of the adaptive specialization idea is the issue of whether hippocampus-dependent spatial learning is *qualitatively* distinct from associative learning. The cognitive map theory asserts that spatial learning is different from “taxon”

learning in being rapid, flexible, and uniquely encoding information into maps. As noted above, the animal learning constituency is suspicious of this idea.

The claim that spatial learning is qualitatively different would be stronger if the psychological properties of either type of learning could be shown to be specific to that type of learning. A particular sticking point has been whether certain phenomena known to occur in classical conditioning, such as “blocking” and “overshadowing,” do or do not occur in the spatial domain. Blocking refers to the ability of one stimulus to block learning about another, and overshadowing is a differential sharing of associative strength when two stimuli are conditioned together. Modern animal learning theories, discussed in more detail in Section 13.5, rely on “error-correcting” learning rules in which changes in the associative strength of a stimulus occur only when the expected outcome of that stimulus differs from the actual outcome. Although such rules enable learning to be rapid and flexible, stimuli compete with each other for associative strength rather than become linked together in anything like a “map.” The conditioning phenomenon that most directly established the idea of error-correcting learning and captured everyone’s attention when it was first discovered is blocking (Kamin, 1968). A stimulus, call it A, is arranged to predict reinforcement ( $R^*$ ). After several pairings of A and  $R^*$  have occurred and the associative strength of A has reached an asymptotic value, a second stimulus is added (B). Stimulus B now also predicts  $R^*$ ; and one might expect, given the contiguous pairing of B and  $R^*$ , that this association would be readily learned also. Often, however, little appears to be encoded about the relation between B and  $R^*$ . The prior learning of the  $A \rightarrow R^*$  association is said to block learning about B. An important control is one in which stimuli A and B are introduced together for the first time in the second phase of a blocking experiment and arranged to predict  $R^*$ . Under these conditions, both the  $A \rightarrow R^*$  and the  $B \rightarrow R^*$  associations are learned (although overshadowing sometimes occurs and is determined by such factors as stimulus salience or proximity). Many other control procedures have been conducted among a vast array of experiments investigating blocking and the processes responsible for it (Mackintosh, 1983).

One reason hippocampus-dependent learning might be thought to be qualitatively different from conventional associative conditioning is because hippocampal lesions do not reliably affect blocking. An early conditioning study indicated that there may be an effect of partial hippocampal lesions on blocking (Ross et al., 1984), but at later more definitive experiments indicated that blocking can occur normally in animals with complete hippocampal lesions (Garrud et al., 1984; Holland and Fox, 2003). Of greater concern for the cognitive map theory is whether blocking occurs between locale and taxon learning or even within the spatial domain. A comprehensive program of work led by Chamizo has shown that blocking can occur in the radial maze between intra- and extramaze cues (Chamizo et al., 1985) and entirely within the spatial domain in the watermaze (Rodrigo et al., 1997). In the

later experiment, analogous to the studies using classical conditioning, the pool is surrounded by heavy black curtains and two-dimensional cues hung at specific locations within it (A, B, C, and so on). This spatial array of cues can then be rotated collectively from trial to trial; in this way, the experimenter can be confident that a rat's directed navigation in the pool is determined by this array rather than by other, experimenter-uncontrolled cues. In addition, although swimming is permitted at certain phases of the experiments (to enable learning and later testing of what has been learned), the animals can be either allowed to swim or placed on the platform during the critical blocking phase when another cue (X) is added. Blocking occurs normally. Chamizo (2003) summarized a wide range of such experiments and concluded that there is as yet no basis to suppose that spatial learning differs from conventional conditioning with respect to the use of an error-correcting learning rule. Mackintosh (2002) recognized certain tensions in the associative account between the occurrence of blocking, as required by animal learning theory, and other evidence that rats often learn about the locations of all available landmarks in simple exploratory tasks, as we saw in the work of Save et al. (1992a,b) earlier. However, he shared Chamizo's skepticism and asserted that "the behavioral evidence does not seem to have supported O'Keefe and Nadel's original hypothesis that true spatial learning or locale learning is quite distinct from associative learning" (Mackintosh, 2002, p. 165).

There remain some difficulties in accepting these conclusions without qualification. First, no lesion studies of blocking in the spatial domain have been conducted, and we must take on trust that the spatial memory seen in these studies is hippocampus-dependent. This seems likely, but we have already noted instances in which multitrial spatial reference memory tasks in the watermaze can be learned by rats with hippocampal lesions. The definitive hippocampus-dependent task in the watermaze is now recognized as being the DMP paradigm, and one-trial blocking experiments have not been conducted. Second, placement on the hidden platform may be insufficient for much learning with the kind of hanging cues used in Chamizo's laboratory. This is because two-dimensional cues at the periphery are known to be much less effective than three-dimensional cues, the animals cannot explore them proximally (e.g., using vibrissa movements), and the constellation of cues in the "blocking" phase of training (A, B, X) may be sufficiently similar to those in the earlier training phase (A,B) that the animals do not notice the difference. The outcome is then apparent rather than true blocking. Although various controls argue against this, the data measures reported are sometimes the proportion or ranking of animals showing an effect rather than absolute tracking data (such as time spent in a quadrant or zone).

Partly for these reasons, Biegler and Morris (1999) developed a food reward task in a large arena in which to explore blocking under conditions in which (1) the local cues were three-dimensional objects that could be explored by the animals in a multisensory manner, and (2) there was explicit

directional polarization provided by a specific arrangement of distal extramaze curtains. The task involved learning the location of food in relation to two identical landmarks, with a third and later fourth cue added to disambiguate two possible places where food might be found. The paths taken by the animals were tracked automatically. Blocking was again seen in the spatial domain, and this occurred despite the animals noticing and exploring the added landmark during the blocking phase (as shown by the tracking data) but then choosing not to learn about its association with reward. The use of an "instrumental" rather than a classic conditioning paradigm introduced complications, as the conditions across groups could not be exactly matched on the first trial of the blocking phase, though Biegler and Morris (1999) argued that this did not invalidate their conclusion. Unpublished lesion studies were also conducted, but performance was too poor in animals given lesions before training for any useful information to be obtained about the role of the hippocampus in blocking using this paradigm.

One point noted by Biegler and Morris (1999) concerns a potentially interesting difference between blocking in the spatial and conditional domains. With conventional conditioning, the relations learned, such as  $A \rightarrow R^*$ , are conditional ('if-then') associations (and not necessarily temporal although often described as such). Relations must be more than that in spatial learning because the Landmark  $\rightarrow R^*$  association must provide some information about the distance and direction from a landmark (L) that food is to be found. Under circumstances in which a memory representation must be formed of the *nature of the relation* between two cues, blocking may obey different rules. For example, when the relation between two spatially dispersed landmarks L1 and L2 and food has been learned, the addition of a third landmark, L3, may not always result in blocking simply because the location of  $R^*$  is already predicted. The relative spatial location of the new cue L3 to the old cues L1 and L2 may be critical to its incorporation into an associative or "map-like" representation. Blocking may be more or less likely as a function of whether the vector (argument and direction) from L3  $\rightarrow R^*$  is similar to or different from the vectors from L1 and L2 to  $R^*$ . The conclusion of Chamizo (2002, 2003) that spatial information interacts during learning in apparently the same way as it does during conventional conditioning is probably secure, but there are issues to do with vectors and geometry that deserve further investigation.

Swimming against the tide of this developing experimental skepticism in the animal learning constituency, Cheng and Gallistel have gone farther than O'Keefe and Nadel (1978) in suggesting that the brain possesses a "geometric module" for space that operates according to distinctive learning rules (Gallistel, 1980; Cheng, 1986; Margules and Gallistel, 1988). This followed observations of the behavior of rats searching for food hidden at one corner of a rectangular enclosure. Despite the presence of disambiguating cues located at the four corners (visual or olfactory), the rats ignored them and searched systematically at *both* the correct corner and

the diagonally opposite corner. These two corners are geometrically equivalent in a symmetrical rectangle. These findings seemed to imply that rats were more sensitive to environmental shape than to local features, such as the distinctive cues—hence the proposal of a geometric module. Observations and models of place cells—specifically their determination by boundary vectors—are consistent with both this and O’Keefe’s preferred local feature view (O’Keefe and Burgess, 1996; Hartley et al., 2000; Lever et al., 2002).

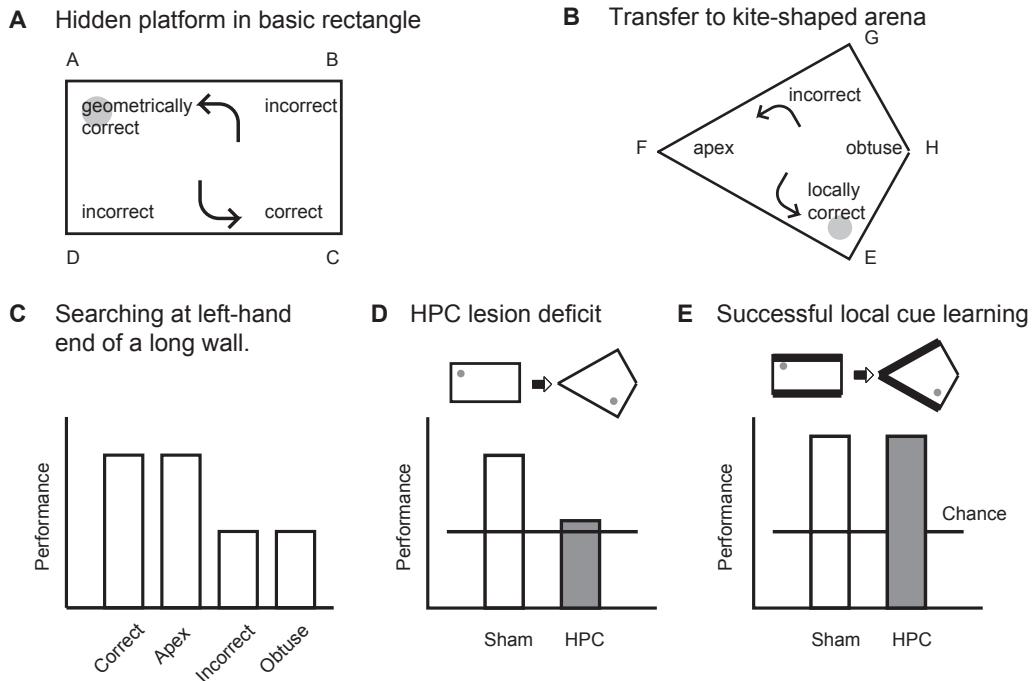

In an ingenious test of the geometric module idea, Pearce et al. (2004) wondered if the symmetrical search patterns seen in a rectangular array reflected the operation of a specialized geometric module or something simpler. The animal learning constituency enjoys wielding Occam’s razor, and this issue represented another opportunity. Might the rats have instead learned only the “rule” of searching at a corner defined by one long wall on the right and one short wall on the left? To test this, they first trained rats to search for a hidden escape platform in a rectangular watermaze and observed, in a conventional probe test with the platform absent, focused searching at both the “correct” corner and the geometrically equivalent corner (Fig. 13–30A). This result is identical to that found by Cheng and Gallistel in the food-rewarded task. The animals were then transferred to training in a kite-shaped maze (Fig.

13–30B). Training continued to the one corner with a long wall on the right and short wall on the left. In posttraining probe tests, preferential searching was now observed at the correct location but also at the apex of the maze (Fig. 13–30C). This finding makes no sense if the animals are using a geometric module representing the shape of the kite but is readily explicable if the animals have learned to search preferentially at the left-hand end of *any* long wall. Interestingly, rats with hippocampal lesions were poorer at learning to search at the correct corner unless prominent disambiguating local cues were added to walls on either side of the apex during training (Fig. 13–30D,E). Once these local cues were added, the training corner and the apex were easily distinguished visually and hippocampus-lesioned animals then learned as well as sham-lesioned controls. The implication of this ingenious study is that there need be no recourse to an abstract geometric module to learn these kinds of tasks and no need to suppose that the hippocampus mediates such a module. The data are, however, consistent with the boundary vector model of place cells in which their location is fixed by intersecting vectors from local cues.

Yet more abstract geometry is implied by the observation that rats trained to forage for food in the center of a square arena can transfer to searching at the “geometric” centre of rectangular and triangular arenas (Tommasi and Thinus-

**Figure 13–30.** Geometry and the shape of spatial learning to come. A. Rats trained to find an escape platform in one corner of a rectangular watermaze also search in the geometrically equivalent corner. B. The rats were then transferred to swimming in a “kite-shaped” arena, with the platform again located at the corner with a long wall on the left and a short wall on the right. C. During posttraining probe tests, the rats now searched at the correct location and at the apex. D. Hippocampus-lesioned rats (gray shading) are poorer than

sham-lesioned controls when learning to search correctly in the kite maze. E. When disambiguating local cues were added to the long walls of the rectangle and on either side of the apex, hippocampus-lesioned animals could learn as rapidly as controls. The bar graph data have been simplified to the long walls of the rectangle and either side aid the description of this study. (Source: After Pearce et al., 2004.)

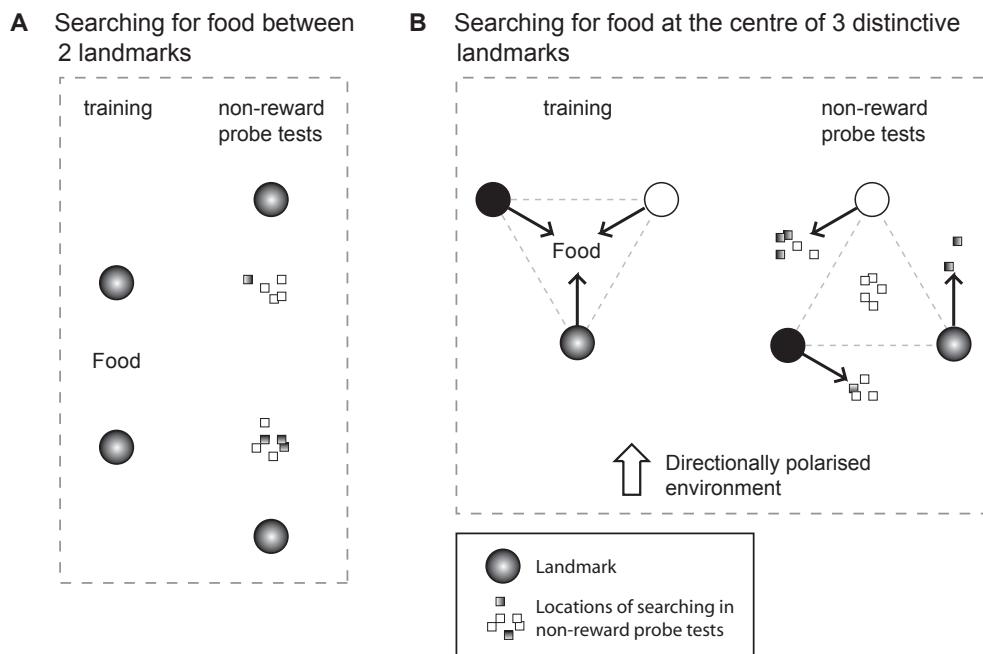

Blanc, 2004). This result is not, however, always observed. One classic series experiments contrasted a map-like representation of space to one based on vectors (Collett et al., 1986). Vectors encode distance and direction. In a directionally polarized environment, a vector representation would be one in which object A may be represented as a vector with a specific “argument” (i.e., length) and “angle” from landmark P. Many objects (A, B, C, and so on) both visible and hidden, may be represented in such a way, but it does not require there to be any “map” of space. Specifically, there may be no encoding of the relative locations of A, B, and C to each other. To test this idea, gerbils were trained to find sunflower seeds at particular distances and directions from landmarks in a room that provided cues enabling directional polarization but not localization. The landmarks were then manipulated in various ways. In one manipulation, animals were first trained to find food hidden halfway between two identical landmarks. The two landmarks were then moved farther apart. If the animals had learned to find reward at some abstract “centre” of the array, they would be expected to search preferentially at a common point, now a bit farther from each of the landmarks. Instead, searching occurred at two distinct locations, each at the appropriate distance from each landmark along the line between them (Fig. 13–31A). In a yet more striking example of vector-based representation, the gerbils were trained to find sunflower seeds at the center of a triangular array of three distinctive landmarks (Fig. 13–31B). The landmark array was then rotated by 60° such that the vectors representing reward location from each landmark were now *outside* the array

rather than inside. Astonishingly, a significant proportion of the search visits during a posttraining probe test with the rotated array were *outside* the landmark array. This striking pattern is not to be expected had the animals learned a “map” of space with food at the center of the landmark array. It is consistent with the encoding of three independent vectors specifying the distance and direction of food from each of the three landmarks. During training, these vectors meet at the single, central point; after rotation they do not. Collett et al. (1986) did not go on to conduct lesion studies, so we do not know the impact of the hippocampal dysfunction. However, in a conceptually similar lesion study using the watermaze, Pearce et al. (1998) found that hippocampus-lesioned rats could be trained to locate a hidden platform at a specific distance and direction from a visible landmark that moved places within the pool between days. It seems that the hippocampus is not required to encode vectors across multiple trials but may be necessary to assemble multiple vectors into a map-like representation.

With respect to multiple types of memory, there are good grounds to believe that there has been selection pressure to develop map-like spatial representation and navigation systems in vertebrates. However, the studies comparing spatial learning with conventional associative conditioning have revealed fewer differences than might have been expected on the basis of the original cognitive map theory. The possibility that spatial information is fundamentally associative, in contrast to the position adopted within cognitive mapping theory, has to be considered. Section 13.5 takes up this

**Figure 13–31.** Maps or vectors? A. Gerbils were trained to find food halfway between two landmarks (large circles). When the landmarks were moved farther apart in a posttraining probe test, the animals searched at two distinct locations (small squares denote time spent searching). B. Gerbils were trained to find food in the

center of an array of three distinctive landmarks in an environment in which directionally polarization is determined by other distal cues. When the landmark array was rotated by 60° in a probe test, a substantial proportion of the searching was now outside the arena. (Source: After Collett et al., 1986.)

issue further; but before turning to that, we discuss the issue of where allocentric spatial information is stored in the brain.

### 13.4.5 Storage and Consolidation of Spatial Memory

A fourth major proposition of cognitive map theory is that the memory traces required for allocentric representations through a familiar place are stored in the hippocampal formation itself. This storage is held to be distributed, possibly along both the longitudinal and transverse axes of at least the dorsal hippocampus for even a single memory, such that damage to the structure should cause a loss of both processing capacity (encoding, retrieval, and navigation) and storage sites (local alterations in synaptic weights). Hippocampal damage should therefore cause a “flat” gradient of retrograde amnesia for spatial information, as first shown by Bolhuis et al. (1994). In contrast to the retrieval of factual information by humans or contextual fear by rats, where gradients are observed (see Section 13.3), the integrity of structures in the hippocampal formation is also claimed to be essential for successful recall of episodic memory in humans (Viskontas et al., 2000; Cipolotti et al., 2001; Maguire, 2001). Moreover, very remote episodic memories may still elicit neural activation of the hippocampus long after they were first acquired (Nadel et al., 2000), although the use of “reminders” prior to brain scanning has raised a query about the true age of ostensibly old memories in imaging work. Given the very different perspective on these matters in declarative memory theory, it is no surprise that memory consolidation has become one of the battlefields of contemporary cognitive neuroscience.

We have seen that the “standard model” of memory persistence (see Section 13.3) is that some systems-level process of hippocampus-dependent memory consolidation takes place after learning that, by enabling an interaction of hippocampal and neocortical ensembles, secures the stabilization of memory traces outside the hippocampus (Squire and Alvarez, 1995a; Kapur and Brooks, 1999; Manns et al., 2003). The neurological function of such systems-level consolidation presumably has nothing to do with the protection of memory against brain damage. Exploiting the unfortunate occurrence of relevant brain damage in humans, or its experimental creation in animals, is just a technique for revealing this neurological process. Rather, consolidation is thought to have two functions. First, it engages mechanisms that “gate” whether memory traces are to be retained. Second, once consolidation is complete, a lasting neocortical memory site exists that would enable much faster retrieval of information than would be possible were it always necessary for there to be a neural “loop: through the hippocampus. A consolidation process might also allow retrieval of information from neocortical traces when it is required *without* recourse to consciousness, but the activation of this neural loop may be a signature of conscious awareness in the specific domain of memory (Moscovitch, 1995). One situation where conscious awareness

is usually engaged is in the spatial domain, where it may be helpful in updating during navigation.

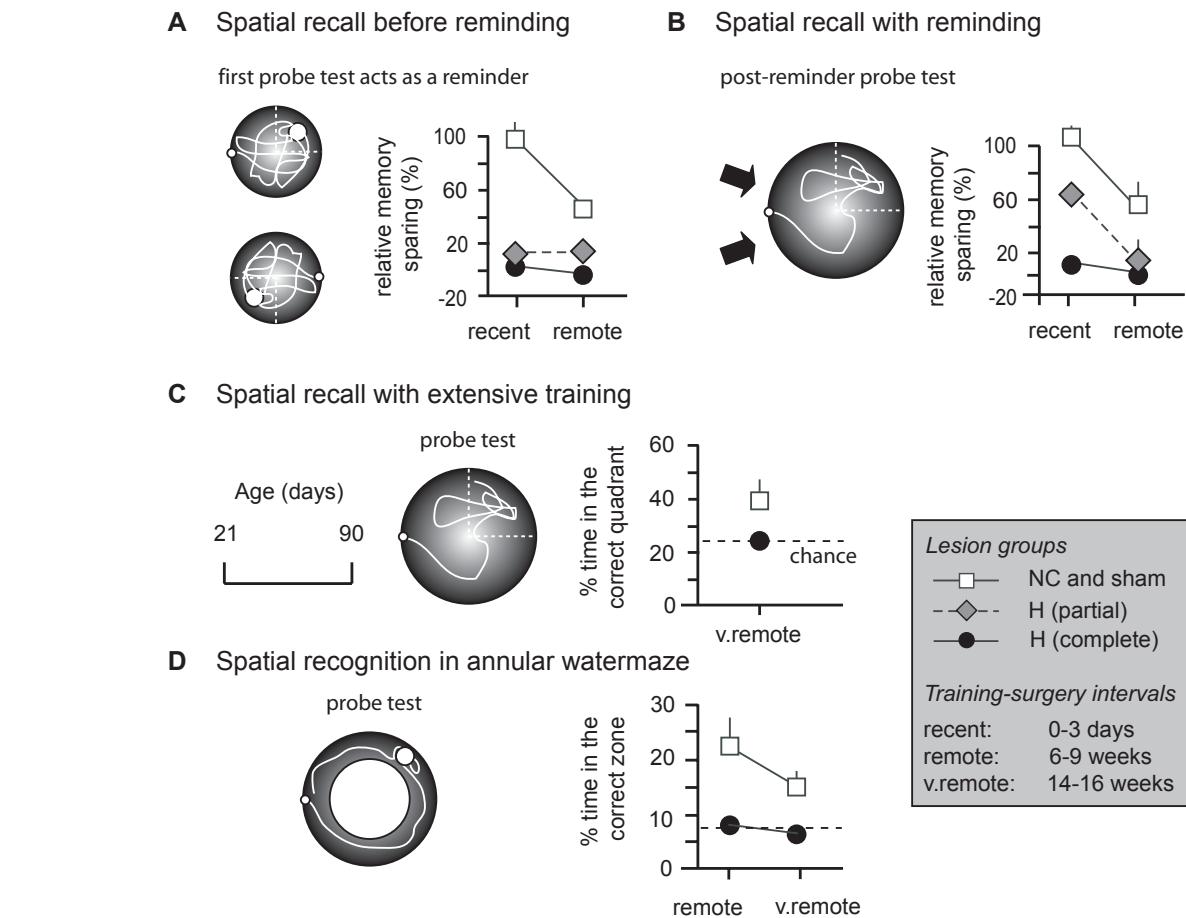

Reflecting on these putative functions of systems-level consolidation, Moscovitch wondered if memory retrieval *with* recovered consciousness might be disentangled from other features of the standard model. This led on to a series of articles in which he and Nadel proposed an alternative “multiple trace” model of memory persistence (Nadel and Moscovitch, 1997, 1998; Moscovitch and Nadel, 1998). In this model, a subset of memories is permanently mediated by corticohippocampal circuitry. Specifically, the theory holds that each reactivation of memory leads to—or at least *can* lead to—the formation of additional traces that are located at different points along the longitudinal axis of the hippocampus (anterior-posterior in humans). Temporal information is thought to be stored in the prefrontal lobe, at least in humans. Consolidation is thus a “reactivation–restorage” cycle that occurs in a punctuated manner over time, rather than as a gradual, inexorable biological process—an analogy might be drawn with the concept of “punctuated equilibrium” in evolutionary theory (Gould and Eldredge, 1977). There would then be *multiple traces* of a common past event, but these traces could entail different associations with other information that reflect their distinct provenance. Temporally graded retrograde amnesia for spatial information can then be explained by the proliferation of memory traces in the hippocampus without recourse to a neocortical consolidation process, a prediction that has been successfully modeled with a connectionist network (Nadel et al., 2000). Remote spatial memories are represented by a larger number of traces and so be more accessible than recently acquired memories. According to a later version of this model (Nadel and Bohbot, 2001; Rosenbaum et al., 2001), this multiple-trace theory applies particularly to “contextually rich” memories but not those that are context-free or semantic in character. Whether these proposals should be seen as “extensions” of the cognitive map theory or as independent ideas inspired by it is unclear. They are probably more the latter.

The declarative memory and the multiple trace theories make contrasting predictions about retrograde amnesia in the particular case of partial lesions. Unfortunately for theories of memory, the capricious nature of human brain injury results in most MTL amnesic subjects having only partial damage to the hippocampus (Rempel-Clower et al., 1996; Bayley et al., 2005b). Such patients do not discriminate the two theories. One neurological case does exist where the damage is apparently extensive yet there remains clear evidence of sparing of spatial memory from a much earlier time period in the patient’s life—patient E.P. (Teng and Squire, 1999). However, we have seen that the testing of remote memory in humans and the identification of an explicit temporal gradient is fraught with difficulty (see Chapter 12). Can animal studies of spatial memory shed light on this important theoretical issue?

Studies using the watermaze have consistently shown a flat gradient of retrograde amnesia for spatial memory when it is first tested postoperatively. In such studies, rats have typically

first been trained on a reference memory version of the task (i.e., to find a single hidden platform); then, at periods ranging from a few days to up to 3 months later, they have been subjected to large excitotoxic or radiofrequency lesioning of the hippocampal formation (Bolhuis et al., 1994; Mumby et al., 1999; Sutherland et al., 2001; Clark et al., 2004, 2005b). Subsequent to surgery, the animals have been retested in the watermaze either with the platform in its original training location, with it moved to a new location, or using probe tests (platform absent). Martin et al. (2005) used such a design with animals given partial hippocampal lesions (circa 35% sparing of either the dorsal or the ventral hippocampus) and others complete lesions (< 5% sparing). They used an Atlantis platform during training to encourage highly focused searching and better memory. An initial posttraining probe test provided no evidence of better retention of remote spatial memory, even in the group with a partial lesion of either the

**Figure 13–32.** Retrograde amnesia for spatial memory. A. An initial “pre-reminder” probe test conducted 2 weeks after sham (white), and either partial (gray) or complete (black) hippocampal lesions revealed no evidence of spared spatial memory recall in either lesioned group. This study confirms the earlier findings of Bolhuis et al. (1994) but under conditions in which a floor effect in the sham control group did not occur. (Source: After Martin et al., 2005.) B. Reminding given in the form of successive probe tests revealed some sparing of spatial memory recall in the partially

dorsal or ventral hippocampus (Fig. 13–32A). This first finding of Martin et al.’s (2005) study is inconsistent with *both* the declarative memory and the multiple-trace theories but consistent with the original statement of the cognitive map theory, subject to the proviso of there being some threshold of intact residual tissue (> 35%) necessary to mediate effective navigation.

However, in these and other studies, the performance of sham-lesioned rats in the watermaze tends to be poor after surgery, possibly reflecting a “floor” effect that masks any consolidation or multiple trace process. To address this problem, Bolhuis et al. (1994) followed up the initial probe test with retraining to unmask cryptic spatial memory traces. If anything, their “savings” data favored better relearning by *recently* lesioned groups (made 3 days after original training) than the remote groups. Rats given subiculum lesions that left the hippocampus intact were also capable of relearning to a high

lesioned group. The reminding procedure was shown not to induce relearning. (Source: After Martin et al., 2005.) C. Extensive training from an early age failed to reveal spared spatial memory in animals with complete hippocampal lesions. (Source: After Clark et al., 2005a.) D. Spatial recognition memory tested using an annular watermaze that obviates the need for hippocampal updating during navigation also failed to reveal spared spatial memory after complete hippocampal lesions. (Source: After Clark et al., 2005b.)

degree of proficiency. This is consistent with the integrity of hippocampal circuitry being important for some aspects of spatial memory storage. Mumby et al. (1999) also used retraining and a within-subjects protocol with two watermaze tasks that were trained at different time points prior to surgery. They found little evidence of spatial memory in their complete hippocampal lesion group for either of the two tasks. Sutherland et al. (2001) used both retraining and probe tests and observed a significant trend for longer training-surgery intervals to be associated with poorer retention—once again the opposite of what is predicted by the declarative memory theory. These studies reflect a consistent pattern, but the use of retraining after surgery confounded two factors: the impact of the lesion on consolidation (the focus of interest) and its impact on new learning (a separate matter).

In their comparison of partial and complete lesions, Martin et al. (2005) used a different approach: a series of rewarded probe trials at 1-hour intervals. This gradually revealed above-chance performance by the partial hippocampus-lesioned group that had undergone surgery immediately after training (i.e., their recent group). No recovery of remote memory was observed in the group for which there was a much longer 6-week interval between the end of training and surgery (Fig. 13–32B). This apparent “unmasking” of latent spatial memory was not due to any relearning during the series of probe trials, as de Hoz et al. (2004) had separately shown that the conduct of a probe trial with an Atlantis platform serves, in animals with partial lesions, only as a reminder cue. The result vindicates the interpretation drawn by Bolhuis et al. (1994) much earlier.

Noting the same problem of weak postsurgery memory, Clark et al. (2004) extended the presurgery training to as many as 80 trials, finding that it improved the performance of the sham/control group. The point of doing this is to increase the opportunity of seeing an upward consolidation function in the data (along the lines of Fig. 13–10B3). However, using large radiofrequency lesions restricted to the hippocampus, they again observed both poor memory and a completely flat gradient of retrograde amnesia in postsurgery probe tests. Another attack on the problem was suggested by the fact that patient E.P. had learned his home neighborhood as a young man. Clark et al. (2005a) therefore trained normal rats from very early in life (21 days) for a total of 392 trials over 69 days. Hippocampal and sham lesions were made at 90 days of age, and the animals were tested 2 weeks later. Once again, the complete lesion group failed to display above-chance performance and that despite the use of a reminding procedure a few days before testing (Fig. 13–32C). Undeterred, Clark et al. (2004) wondered if there was something unusual about the standard watermaze task, as other nonspatial tasks had found evidence of a temporal gradient, albeit only using a savings or choice measure (Cho et al., 1993, 1995; Ramos, 1998; Mavie et al., 2004). Accordingly, they also trained rats in an Oasis maze, in which they have to search for water in a small well located on a “desert-like” table top, and in an annular watermaze (Hollup et al., 2001) in which the animals swim in a cir-

cular corridor until they find an escape platform. The use of the annular watermaze is interesting as the need for navigational updating is minimized; the swimming rats have only to recognize a potentially safe place along the ring and slow down when they get there. However, using a single probe test, both tasks again showed a flat gradient (Fig. 13–32D).

The animals’ joy in eventually finding water in the Oasis maze cannot have been matched by any exhilaration on the part of proponents of the declarative memory theory by the outcome of this series of experiments. Clark et al. (2004) suggested that a feature that may distinguish tasks where remote spatial memory is spared (cross and radial maze tasks) compared to those where it is impaired (watermaze tasks) is that only in the latter does the expression of memory require the now-lesioned animal to recall by navigating through open space. That the hippocampus might be essential for *expressing* spatial memory, rather than storing or retrieving it, is reminiscent of Whishaw’s distinction between “getting there” (impaired by lesions) and “knowing where” (which may not always be). A processing deficit of this kind conveniently predicts that any underlying hippocampal-neocortical consolidation process would remain cryptic.

There are, however, problems with this account. First, it incorrectly predicts that remote memory should be intact in the annular watermaze because its navigational demands are minimized. The animal does not have to learn or access any navigational strategies for “getting there”—it has merely to swim in a constrained circle. Second, remember that reminder cues revealed latent spatial memory in partially lesioned animals (Martin et al., 2005). Presumably, sufficient hippocampal tissue was spared for the expression of memory. However, this latent spatial memory was in the recent-memory group, not the remote. If cryptic consolidation does occur, the effects on trace strength must therefore be substantially smaller than those of forgetting. Third, remember that different results are obtained after small partial lesions as a function of whether they are made before or after training (Moser et al., 1995; Moser and Moser, 1998b). When spatial memory is acquired by normal animals and then partial lesions are made in the hippocampus, performance is seriously compromised and needs to be relearned. This makes sense if trace storage of spatial memory is *within* the hippocampus, it being fully distributed along the longitudinal axis when created in an intact hippocampus. Relearning would be possible with a partially intact hippocampus, and this would also be enough to express the memory once retrieved.

The last twist of the consolidation story comes from the use of novel techniques. Using a behavioral training protocol similar to that of Martin et al. (2005), indirect evidence for the presence of a systems level consolidation process after watermaze training was obtained using a pharmacological approach. Riedel et al. (1999) observed that chronic reversible inactivation of the hippocampus for 1 week after training through bilateral infusion of a GluR1–5 antagonist impaired spatial memory when the animals were tested 16 days later (i.e., long after the effects of the drug had worn off). The drug

demonstrably blocked fast synaptic transmission in the hippocampus, implicating the necessity for hippocampal neural activity for some period after training if spatial memory was to persist. Riedel et al. (1999) explored the impact of delaying the “shut-down” by a few days and got the same results, but they did not examine a longer time course after training. This reversible but chronic inactivation approach is promising analytically; but even if hippocampal inactivation long after training was found to have minimal impact on remote memory, it would not mean that the neural activity required for memory persistence is necessarily a hippocampal-neocortical dialogue of the kind presumed with the “standard model.” It could also be the creation of multiple traces in the hippocampus, or some other intrahippocampal consolidation process, that requires neural activity. Reversible inactivation may not be quite the help for distinguishing the rival theories it first promised to be. A similar ambiguity pertains to the striking evidence that sectioning the direct input from layer III of the entorhinal cortex to area CA1 of the hippocampus (the temporo-ammonic tract) is essential for memory consolidation (Remondes and Schuman, 2004). When lesions were made before 7 days of watermaze training, the animals showed good probe test performance 1 day after training but poor memory 28 days later; sham-lesioned animals showed no decline. The same result was obtained when the lesions were made 1 day after the end of training. However, if the lesions were delayed until 21 days after the end of training, both the sham and temporo-ammonic tract-lesioned animals showed a continued, albeit weaker, tendency to swim in the correct quadrant 7 days later. Collectively, these three experiments are consistent with the idea that “ongoing cortical input conveyed by the temporo-ammonic path is required to consolidate long-term spatial memory” (Remondes and Schuman, 2004, p. 702), the implication being that this pathway is necessary for the hippocampal-cortical dialogue implicated in the declarative memory theory. However, this is not absolutely required by the data. It could still be that temporo-ammonic input is essential for ongoing consolidation *in* the hippocampus.

A final expression theory, as discussed by Martin et al. (2005), relates to the role of the hippocampus in the retrieval and expression of consolidated memory traces that reside in the neocortex but for which the hippocampus plays a part in their retrieval. There are a variety of possibilities. One is that the hippocampus does store information but stores only the “indices” (Teyler and DiScenna, 1986) or the “cartoons” needed to retrieve a consolidated cortical memory trace rather than detailed sensory-perceptual information (this remains in the cortex). With this view, the hippocampus might retrieve a cortical memory in a manner analogous to conducting a keyword search on an electronic document. Partial lesions would compromise the “indices” rather than the detailed sensory-perceptual memory traces and so limit the ability to retrieve cortical memory traces when a recall process is necessary. The circumstances surrounding memory retrieval and the very character of the information retrieved (Nadel and Bohbot, 2001) may determine whether the hippocampus plays a nec-

essary role in this process. Memories are widely thought to be stored in a distributed manner (i.e., their component traces are stored across different brain areas). Retrieval of the right combination of traces might be possible under circumstances in which the retrieval cues are either particularly apposite or sufficiently rich to disambiguate cortically based traces with overlapping components. However, under circumstances in which the retrieval cues do not permit easy disambiguation or where they have to be generated indirectly through a process of recovered consciousness (Moscovitch, 1995), the processing capacity of the hippocampus and its stored indices would remain essential. Disambiguation would generally be critical for context-dependent episodic memory in which a unique combination of traces corresponds to the particular event from the past that needs to be reactivated. Consistent with this idea, the expression of human episodic memory is sometimes found to be permanently affected by hippocampal damage, as noted earlier. Notwithstanding our focus on memory retrieval processes, this account is consistent with Rosenbaum et al.’s (2001) revision of the multiple trace theory. It distinguishes between context-dependent and context-free memories and suggests that only the former remain dependent on the hippocampus for our lifetime. Winocur et al. (2005) have reported data consistent with this view in a study of rats that lived in a “rodent village” for 3 months prior to explicit training on a spatial problem in the village. Posttraining hippocampal lesions had no effect on effective navigation to the correct location in the village, which they interpreted as implying the existence of a detailed “semantic” map stored in the neocortex. Rats with less experience of the village were impaired by posttraining hippocampal lesions because they presumably lacked a context-free memory of the village. Unfortunately, the lesions used in this study were partial (around 50%), allowing some use of spared hippocampal tissue in memory retrieval. Winocur et al. (2005) argued against this being of significance on the grounds of finding no correlation between lesion size and retrieval, but this is a weak argument based on only a small number of subjects with different sized lesions.

Studies of interactions and correlations between single-unit and field-potential recordings in hippocampus and neocortex during and after sleep are highly suggestive of consolidation-like processes (Siapas and Wilson, 1998; Sirota et al., 2003). Targeted molecular studies can help resolve some of the ambiguities at the mechanistic level, although not necessarily all of them, as a daunting combination of novel behavioral protocols, lesions, and molecular interventions will probably prove necessary to unravel the complexities. Frankland et al. (2001) made the intriguing observation that heterozygous  $\alpha$ CAMKII mutant mice show normal LTP in the hippocampus, decaying LTP in the cortex, and failure to consolidate both spatial and contextual information. They suggested that the instability of synaptic potentiation in the cortex could be the basis of the consolidation failure. This is an interesting idea, but it is equally consistent with the idea that effective retrieval relies on the synergy of different kinds of information permanently

stored in both hippocampus and neocortex. Frankland and Bontempi (2005) summarized these developing new lines of research using transgenic animals and IEG markers to plot the time course and regional contributions of neocortex and hippocampus to memory consolidation.

### 13.4.6 Critique

The cognitive map theory has been highly influential. The role of the hippocampus in spatial learning and memory is accepted, particularly in rodents; and such learning is widely used as an “assay” for investigating the cellular and molecular mechanisms of learning and its dysfunction in models of neurodegenerative disease. “Spatial memory” has become a keyword at international meetings, such as those of the Society for Neuroscience and the Federation of European Neuroscience Societies, and there are now laboratories all over the world investigating the neurobiological basis of allocentric spatial representation and spatial navigation. Although much of this reflects a general interest in spatial learning and memory rather than commitment to one particular theory, it is perhaps not surprising that it has been criticized as the theory “that wouldn’t die.”

However, the theory clearly has major difficulties, both conceptual and empirical. This chapter’s presentation of the theory was built around four themes—spatial representation, spatial navigation, comparative work, and studies of memory storage and consolidation—and has already included a measure of critical discussion. A few additional points should be noted in relation to these same four themes.

#### Spatial Representation, Maps, and the Geometric Module

With respect to representation, one set of problems center around whether the concept of a “cognitive map” is an explanation of anything or merely a beguiling metaphor (Healy, 1998). A map is an easily understood concept, but maps are things that people look at to extract information. Adopting this term for the neural activity of a region of the brain seems to carry with it the mental baggage that there must be some cryptic homunculus that is “looking at” the map to do likewise. In the absence of a mechanistic account of how information is extracted from the map, the explanation it offers is incomplete. With respect to the concept of cognitive mapping itself, Bennett (1996) argued that the now widespread use of the term in many different ways by investigators in ethology, psychology, and brain science is confusing and that the concept has outlived its usefulness. This feels unpersuasive. That some people use a scientific term loosely is not grounds for castigating those who use it more precisely. As Bennett (1996) himself conceded, Tolman (1948) introduced it and O’Keefe and Nadel (1978) used it explicitly in relation to the ability to represent the environment in a viewer-independent allocentric manner and to solve such problems as novel shortcuts. This definition is concise. Time and again, O’Keefe’s group

have come back to a central prediction of the theory in relation to brain activity associated with exploration and spatial novelty, most recently in showing differential activation of the human hippocampus proper when people take shortcuts in a virtual reality environment (Maguire et al., 1998; Burgess et al., 2002). Quantitative models are precise and testable, such as the boundary vector model of place cells (Hartley et al., 2000).

However, the concept of a geometric module is undergoing something of a forensic examination with experiments in rodents (Golob and Taube, 2002; McGregor et al., 2004b; Pearce et al., 2004) and humans (Wang and Spelke, 2002), raising questions about whether there is any need for a “global” representation of environmental shape, as in the study of the kite-shaped watermaze discussed earlier. Pearce’s study, part of a larger series, breaks new ground because it suggests that earlier data pointing to the existence of a global geometric module centered on the hippocampus is also consistent with a different account that sees no need for such a representation. Learning may require only a perceptual system that can distinguish long barriers from short ones (i.e., perceptual features of local cues in general) and bridge the temporal delay between turning appropriately as the animal approaches the long wall and the subsequent receipt of delayed reward. It remains to be seen where this research on local features versus boundaries and geometry will lead.

#### Successful Spatial Navigation Without the Hippocampus

A second set of difficulties for the theory is that rodents with nearly complete cell loss in the hippocampal formation can, with certain training procedures, learn allocentric spatial tasks. This is the longstanding claim of the “working memory” theory of Olton et al. (1979), who argued that spatial reference memory tasks can be learned by lesioned rats. We have seen that this claim is correct, but the rate of learning is much slower. Regardless of whether it is slower, the inescapable implication is that extrahippocampal structures can support spatial learning. This finding that the integrity of the hippocampus, or of hippocampal synaptic plasticity, is not essential for spatial reference memory is not necessarily fatal for the cognitive map theory because recent experimental and theoretical studies have established that effective spatial navigation can be realized in many ways, including strategies other than map-guided navigation. However, certain observations, such as normal probe test performance in the watermaze by rats with complete hippocampal lesions (Morris et al., 1990) must be accepted as problematic unless the theory is to descend into irrefutability. That rapid, one-trial spatial learning in the DMP task is always impaired (Steele and Morris, 1999) suggests that the integrity of the hippocampus is essential for rapid encoding of spatial information (spatial events?), but the gradual accumulation of information about spatial regularities of an environment might be information that can, albeit slowly, be encoded, stored, and retrieved in the neocortex without recourse to the hippocampus. That retrograde

amnesia is apparently always seen after both partial and complete hippocampal lesions in rats appears to be contradictory, but the initial learning in such tasks always takes place in normal animals.

In passing, it is relevant to note that knocking out the capacity to express a particular form of NMDA receptor-dependent LTP through mutation of the GluR-A receptor selectively impairs one-trial spatial working memory but not incremental spatial reference memory (Zamanillo et al., 1999; Reisel et al., 2002). The knockout is not hippocampus-specific, but a genetic rescue of the receptor mutation that appears to be largely expressed in the dorsal hippocampus (Schmitt et al., 2005) is sufficient for partially rescue of efficient spatial working memory performance. This body of work is discussed in Chapter 7. For the present, note only that it illustrates how new techniques are shedding light on what it means to classify a task as hippocampus-dependent. A mouse in which GluR-A is absent shows apparently normal fast synaptic transmission in the hippocampus but fails to show a rapidly induced form of LTP. Such an animal is like a lesioned animal in that it cannot display types of memory encoding that occur in the hippocampus; but it is more subtle than a lesioned animal, as it allows information throughput in the hippocampus, which may be essential for neocortical encoding of incremental learning.

If this is correct, one would expect that damage to certain neocortical brain areas (and not just the entorhinal cortex) would have effects on spatial navigation that are clearly not predicted by the theory. These have indeed been observed. Deficits in spatial navigation in a variety of tasks follows lesions in the posterior parietal cortex (DiMatta and Kesner, 1988a; Kesner, 1998) and the midline retrosplenial/cingulate cortex (Sutherland et al., 1988). Harker and Whishaw (2004) summarized a body of conflicting data, including strain differences, regarding involvement of the retrosplenial cortex in various spatial tasks including navigation. Aggleton and Vann (2004) concurred that retrosplenial lesions do impair allocentric spatial navigation in the watermaze, though lesion size can be a critical factor (Vann and Aggleton, 2004). Focusing on a different part of the neocortex, Kesner (2000) argued that there is parallel processing of spatial information in the hippocampus and parietal cortex, with the former more important for “spatial events” and the latter part of a neocortical “knowledge” system. This distinction echoes the episodic/semantic distinction to which we return later. It is also relevant to the issue of whether memory storage is in the hippocampus or there is some hippocampally guided consolidation process. Kesner (1998) is not alone in regarding a strictly spatial view of hippocampal function as too narrowly drawn.

### Multiple Types of Memory?

Another conceptual problem is that the simple division of learning processes into spatial versus nonspatial now appears dated. Although there have been many developments of the cognitive map theory, including its application to various

aspects of human memory, its adequacy as a general theory of multiple types of memory is limited. It has little to say about the relations between propositional (declarative) and nonpropositional forms of long-term memory (e.g., skill learning), between working and long-term memory, or, more curiously, about the nature of perceptual representations. Its proponents would argue that the theory was never intended to be a general theory of memory and cognition and that Figure 13–17 reflects their primary focus. It is a theory built around the discovery of place cells and the sensitivity of spatial navigation by rodents to various kinds of brain damage. It has imaginatively extended from these beginnings, but its place as a building block of a more general neurobiological theory remains a task for the future.

However, even within the domain of the cognitive analysis of space, there are problems with respect to the claim that spatial learning is fundamentally different from associative learning. In 1978, it was valuable to make the point that associative conditioning is generally slow and inflexible, whereas place learning can occur during one trial; but strictly behavioral studies of allocentric place learning have now revealed that spatial learning displays several qualitative characteristics of associative learning, such as “blocking” (Chamizo, 2003). Spatial learning may be associative after all.

### Integrity of the Hippocampus Is Required for Many Nonspatial Learning Tasks

If rats with hippocampal lesions can learn certain spatial tasks, a separate concern is that such lesions are now also known to affect a range of *nonspatial* tasks, including classic operant tasks with a temporal component, such as differential reinforcement of low rates of response (DRL). Although it has always been possible to construct a spatial account of DRL performance, a temporal one seems more reasonable (Rawlins, 1985). However, there are a number of other tasks, such as nonlinear discrimination learning and socially transmitted food preferences, for which a spatial account would strain credibility. Section 13.5 is a detailed examination of such tasks in the context of the “predictable ambiguity” theories for which they are relevant.

### Coda

As a last word, it is worth reflecting on the fact that the cognitive map theory—the theory that refuses to die—enjoys the security of a number of key physiological findings that are not enjoyed by the other main theory discussed so far, the declarative memory theory. The theoretical battlefield between these two theories would be very different if the discovery of other spatially responsive neurons (e.g., head-direction units, view cells, grid cells) had not occurred. All of these discoveries were made since 1978. Hippocampal neurons are not differentially active as a function of stimulus familiarity, but they clearly are responsive to an animal’s location or view of the world. This is a major if somewhat neglected obstacle to the credibility of

declarative memory theory. We have also seen a number of studies in which interventions in the induction and expression of LTP have an effect on spatial learning and retention (see Chapter 10), although the extent to which these effects are cognitively selective is not well understood. Some comfort for the declarative memory theory in the physiological domain can be derived from glucose uptake and IEG studies indicating greater neuronal activity in the hippocampus soon after learning than later, perhaps reflecting the dynamic process of memory consolidation. These observations are pertinent to the task of trying to build a neurobiological account of hippocampal function to which we return in Section 13.6.

### **13.5 Predictable Ambiguity: Configural, Relational, and Contextual Theories of Hippocampal Function**

The two major theories discussed so far command strong support and continue to be refined in the light of new findings. Neither will be discarded until a cogent alternative is widely seen to account for a larger body of data. However, numerous other theories of hippocampus function have been proposed. They include hypotheses that build on modern associative learning theories whose origins, unlike the concept of multiple memory systems, lie in the phenomenon of classical and instrumental conditioning rather than human amnesia. In one way or another, their applications to thinking about hippocampus function all have to do with dealing with the problem of “predictable ambiguity.” This phrase is intended to capture the sense that a stimulus can consistently mean one thing in one situation but something else in a different one.

Learning theory research is characterized by exacting training protocols that explore conditioning phenomena far removed from the classic account of learned salivation to the sound of a bell. As we touched on briefly in the preceding section, examples include protocols for examining whether learning occurs when an animal’s “expectations” are violated or that it alters the “associability” of stimuli or the contexts in which they occur (Rescorla and Wagner, 1972; Pearce and Hall, 1980). Such learning could include both excitatory and inhibitory associations (i.e., that a predicted event is more or less likely to happen). Beyond simple associations, there are also experience-dependent “attentional” phenomena and “occasion-setting” paradigms in which a stimulus (or more broadly an entire context) influences the retrieval of other memories quite apart from any associations in which it may also become engaged. Such phenomena have led to the suggestion that associative conditioning, far from deserving its low-level status as a “nondeclarative” form of stimulus-response “habit” learning (within declarative memory theory) or of mere “taxon” learning (in the cognitive map theory), is more complex and might offer a conceptually economical account of a variety of ostensibly cognitive phenomena. Proponents of this approach have introduced the idea that conditioning

offers insights into the way in which animals learn about “the causal texture of their environment” (Dickinson and Mackintosh, 1978). This implies that conditioning could have to do with the acquisition of knowledge that could be used inferentially (Mackintosh, 1983; Rescorla, 1988; Pearce and Bouton, 2001; Pickens and Holland, 2004) as first discussed explicitly by Dickinson (1980). These intellectual developments are relevant here because psychological processes have been identified in modern “learning theory” for which the hippocampus is a potential anatomical substrate.

Paradoxically, it has long been known that animals with hippocampal lesions are generally normal regarding simple associative conditioning tasks. These tasks involve no more than the pairing of an initially neutral stimulus (CS) with, after a delay, the presentation of reinforcement (US). The result is the gradual development of associative strength and its expression as a conditioned response (CR). In general, simple delay conditioning depends on other brain circuits. For example, hippocampal lesions are without effect in nictitating membrane (NMR) delay conditioning in which a CS starts several hundred milliseconds before and then overlaps with the presentation of a strong puff of air to the eye (US). NMR learning was shown independently by several groups (using lesion, inactivation, and unit-recording techniques) to be mediated by circuits in the spinal cord and cerebellum (Krupa et al., 1993; Hardiman et al., 1996; Beggs et al., 1999). As noted in Chapter 11, hippocampal pyramidal cells nonetheless show firing patterns during NMR conditioning that are correlated in time with the learned response (Berger et al., 1983), but this neural activity is not usually necessary for normal performance. The exception to this is when a “trace interval” is inserted between the end of the CS and the onset of US, as we saw in the discussion of the declarative memory theory; alterations in excitability are then seen in both young animals (Moyer et al., 1996) and aged animals (Moyer et al., 2000). Simple fear conditioning to a punctate CS such as a tone (in which it is sounded for a period prior to and overlapping the delivery of an aversive stimulus such as a mild electric shock) is thought to involve storage of traces in the amygdala (Davis et al., 1993; LeDoux, 2000), although others have argued that the role of the amygdala is primarily neuromodulatory (Vazdarjanova and McGaugh, 1999; McGaugh, 2000). This alternative is important because, as we saw in the discussion of late LTP (see Chapter 10), activity in the amygdala can modulate persistence of LTP in the hippocampus. These and many other studies have broadened our understanding of the role of various brain areas in learning and memory.

The hippocampus may, however, become definitively engaged in conditioning situations in which the associations into which the initially neutral CS enters are predictably inconsistent. In Section 13.2 we saw how a specific behavioral task is said to be ambiguous if there are two or more ways to solve it. A different sense of ambiguity is when the outcome of a specific CS is sometimes one US but on other occasions either another US or the absence of the first US (often abbreviated as NoUS). For example, a light and a tone may each predict the

US when presented on their own but not when presented together. How can an organism cope with this and other forms of predictable ambiguity and so behave appropriately, as many behavioral studies have shown that they can? This class of problem is called the XOR problem in the artificial intelligence and cognitive science communities (Rumelhart and McClelland, 1986) and a nonlinear task by students of the animal learning theory. The nonlinearity arises because it had been thought that CSs acquire associative strength as a function of the reinforcement with which they are linked. However, if this were all there is to learning, the net associative strength of the combined light and tone should always be higher than that acquired by either CS on its own despite the combination of CSs always being followed by nonreward. A nonlinear solution to the problem seems to be required.

Suppose, however, that the brain has a learning device that can resolve such ambiguity. It would then be possible to learn the differential outcome of single and combined stimulus presentations and so react appropriately on every occasion. The *configural-association theory* of Sutherland and Rudy (1989b; Rudy and Sutherland, 1995b) was the first of several hypotheses about hippocampal (and cortical) function that specifically addressed this kind of problem. The *relational-processing theory* (Cohen and Eichenbaum, 1993; Eichenbaum and Cohen, 2001), a development of Squire's original declarative memory theory, also tackled the issue of ambiguity. It took things further in focusing on "relationships" being encoded between stimuli (e.g., that A is better than B and that B is better than C), rather than stimulus configurations (AB, BC). It

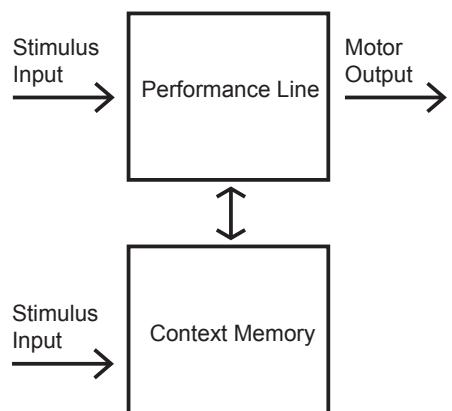

also emphasized the possibility that such stimulus relations can be "flexibly" retrieved in an appropriate way in novel situations (e.g., allowing inferences such as that A is better than C). Ideas about the involvement of the hippocampus in *contextual retrieval* (Hirsh, 1974; Good and Honey, 1991) are closely related. What we remember about a stimulus and its associations depends critically on the context in which it occurs, including the absence of an expected stimulus as occurs in the "extinction" of conditioning when a reinforcing US no longer follows a CS. Wide-ranging ideas about the contribution that context cues make to encoding and retrieval, including the notion that contexts "contain and predict rather than simply compete with explicit CSs" (Nadel and Willner, 1980, p. 218), helped spur the development of now widely used learning paradigms such as context fear conditioning. Although intellectually distinct and occasionally at loggerheads with each other, the configural-association, relational-processing, and contextual-retrieval theories have two common threads: They all set out to solve problems involving "predictable ambiguity," and they all argue that the hippocampal formation is central to achieving it.

One of the early theorists to recognize the problem was Hirsh (1974). He looked upon conditioning as a process in which stimulus input came to trigger motor output along a "performance line" as a function of simple CS-US associations (Fig. 13–33A). He argued that it is independent of the hippocampus. On the other hand, he also supposed that a separate "context memory" could somehow interact with the performance line, particularly during memory retrieval, and

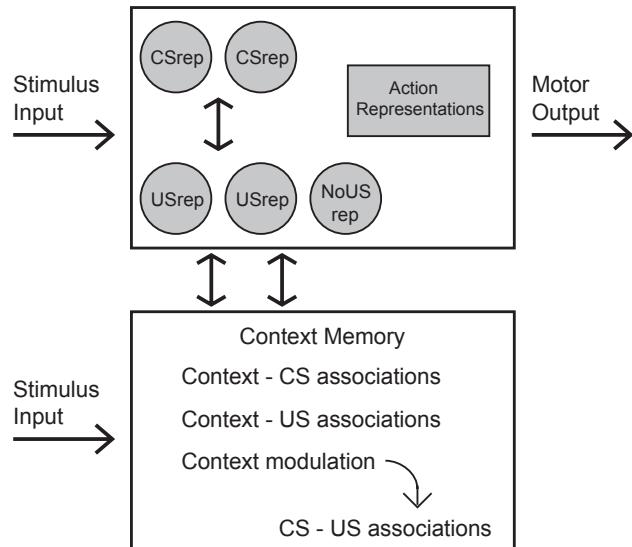

**Figure 13–33.** Coping with predictable ambiguity. A. Hirsh's model recognized a distinction between a "performance line," which stores simple CS-US relations and expresses them as conditioned responses, and a "context memory," which modulates the performance line when a CS predicts a US in one context but something

different in another. (Source: After Hirsh, 1974.) B. Modern learning theory has developed an elaborate framework that is relevant to thinking about the ways in which the hippocampus, functioning as a context memory, could modulate internal representations of associations. See text for discussion.

#### A Associative encoding and retrieval

#### B Contemporary representational framework for associative memory

so ensure *appropriate* motor output when a specific stimulus predicted reinforcement in one context but the absence of reinforcement in another. Both context memory and the process of contextual retrieval were identified as mediated by the hippocampus. Contemporary research has elaborated this framework in numerous ways (Fig. 13–33B). First, stimulus input is said to give rise to internal representations of CSs and USs that can enter into a variety of associative relations ranging from first-order associations (CSrep–Usrep where “rep” refers to an internal representation of these stimulus events), to second-order relations (CS1–CS2), and even predictions of the absence of a previously expected stimulus (CS–NoUS). These associative relations constitute “knowledge” and (somehow) give rise to goal-oriented action representations that constitute appropriate behavior (e.g., approach food) and then to motor output (the particular movements produced to fulfill an action). The concept of contextual modulation remains, but the manner in which contexts are represented and enter into associations is now recognized as quite complicated. The representations (lower part of Fig. 13–33B) may be “elemental” or “configural,” and these in turn may become associated with specific CSs or USs that occur in their presence (context-event associations). In addition to direct associations between contexts and other stimuli, contexts may also modulate the expression of other CS-US associations, such as those expressed within the knowledge system.

Several theories addressing the problems of predictable ambiguity suppose that the hippocampus is a form of configural, relational, or context memory; but they differ with respect to the precise set of processes by which such stimuli enter into or modulate other associations. A consequence of this is that the field has become somewhat baroque and impenetrable. However, it is a serious endeavor that attempts to go beyond descriptive taxonomy to a more detailed and predictive understanding of process and mechanism. The section that follows is a selective representation of this field of research.

### 13.5.1 Configural Association Theory

Learning is often complicated by ambiguity. A stimulus may signify one event in one situation and another event elsewhere. It is then a “fact” that a tone predicts food in one situation and a “fact” that it does not in another—a complication that the declarative memory theory may have recognized but offered no mechanistic way of addressing. Animals can interpret ambiguous associations such as these provided they are given sufficient additional information and a learning device sophisticated enough to do it. In a series of papers, Rudy and Sutherland (Sutherland and Rudy, 1989; Rudy and Sutherland, 1995; O'Reilly and Rudy, 2001) proposed a theory of hippocampal function, building upon earlier work with animal learning theory in which the configuring of stimuli together as fused compound CSs is the way that animals solve such problems (Rescorla, 1973). The essence of Sutherland and Rudy's and later O'Reilly's proposals are as follows (Box 13–6).

### Box 13–6 Configural Association Theory

1. A class of “nonlinear” associative problems can be solved by the process of stimulus “configuring.”
2. The hippocampus builds and stores “configural associations” between elemental stimuli (1989), serves an enabling role in their encoding and eventual storage in neocortex (1995), or helps “pattern-separate” stimuli rapidly to aid slow cortical learning (2001).

### Ambiguity, Conditioning, and the Hippocampus

Consider the case of two auditory CSs such as tones (call them A1 and A2) that, through repeated pairings, become selectively associated with two types of food (F1 and F2). The experimenter arranges matters such that when a light (L) is illuminated in the test chamber A1 signals F1 and A2 predicts F2. However, when the animals are in the dark (D), A1 is arranged to signal F2 (rather than F1) and A2 predicts F1. Rats and other animals *can* resolve this predictive ambiguity and learn “what leads to what” in each situation.

Rescorla's proposal was that animals (mentally) create stimuli that are “configural” associations between L and A1, L and A2, D and A1, and D and A2. These would be the configural cues (L+A1), (L+A2), and so on. If these configural cues are discriminable, they could enter into unambiguous associations with reinforcement without interference. Learning would otherwise obey established principles of associative learning, namely the gradual accumulation of associative strength to each configural stimulus as a function of how well the sum total of stimuli available at any one time predicts the outcome (Rescorla and Wagner, 1972; Mackintosh, 1983). The animal would have solved the problem and could express its “knowledge” of associative relations in performance.

In its original form, Sutherland and Rudy (1989) proposed that the hippocampus was the physical substrate for encoding and storing configural associations. They also proposed that the configurations could be quite arbitrary combinations of individual stimulus events (e.g., of a light and a tone) occurring together in time, one after another in sequence, or in spatial proximity. The latter aspect of this proposal neatly extended the domain of the theory to tasks such as place learning where multiple stimuli in a given context might be said to define a place. This represented something of a *volte face* for Sutherland, who had earlier argued, in keeping with cognitive map theory, that the learning of a “mapping strategy” in the watermaze was distinct from associative learning (Sutherland and Dyck, 1984). His new idea, with Rudy, was that place learning might actually be a special case of configural learning in which the individual extramaze cues around a watermaze or radial maze enter into stimulus configurations and so (somehow) guide the animal to the correct target. Data that had hitherto offered support for the spatial mapping theory could then be radically reconsidered as potentially sup-

porting the new hypothesis instead. Similarly, the supposition that the hippocampus encodes “configurations” takes the theory into territory not considered in the original version of the declarative memory theory. With that theory, the consolidated “trace strengths” of the associations between A1 and F1 and between A1 and F2 (in the example above) would be equal, and the animal would have no way of resolving the predictive ambiguity of its factual knowledge.

An important feature of the original 1989 configural association theory was that it made a number of clear-cut predictions about when deleterious effects of hippocampal lesions would and would not be observed in associative learning. This is because Sutherland and Rudy recognized that not all kinds of associative learning require configurations to be formed (simple delay conditioning being such a case), whereas others do (nonlinear problems). In short, the theory could be tested—an attractive, widely respected but always precarious feature of any good theory.

### Tests of the Original Configural Association Theory

The behavioral tasks Sutherland and Rudy considered to be valid tests are our first taste of the somewhat baroque nature of this field of research. Arguably they are problems that an animal is unlikely to face in its natural habitat, a worrying feature because it is not clear what might have been the evolutionary selection pressure to develop an “ambiguity learning module.” However, the apparent artificiality of these tasks reflects a creditable desire on the part of the theory’s architects for their hypothesis to be tested rigorously. Four types of task were studied intensively. They are called negative patterning, transverse patterning, biconditional discrimination, and feature-neutral discrimination learning (Fig. 13–34). An explanation of each follows, with reference to exemplar experiments.

With *negative patterning*, two stimuli are each paired individually with reinforcement, but the combination of the two stimuli is nonrewarded. This is annotated in Figure 13–34 as A+, B+, AB−, where A and B are individual stimulus elements, + refers to reward, and − is the absence of reward. As summarized by Rudy and Sutherland (1995), several studies from their laboratory from 1989 onward indicated that neurotoxic hippocampal lesions made in either of two ways (kainic acid plus colchicine or ibotenic acid alone) cause a deficit in negative patterning. These tasks included operant

lever-pressing tasks and a swimming task with cues hanging above potential escape locations (Alvarado and Rudy, 1995a).

This finding did not, however, prove replicable by others. Davidson et al. (1993) observed no deficit in negative patterning in animals with two types of hippocampal lesion. In Davidson et al.’s version of the task, the rats were required to press a lever several times during a tone (T+) or light (L+) for occasional reward (+). This requirement provided a more effective baseline against which to observe a decrease in the rate of responding during the nonreinforced TL− compound. They also used a posttraining transfer test with a novel clicker stimulus to check that learning of the original task did depend on the formation of a true TL configural cue. Although we cannot be certain why different outcomes were obtained in the two studies, Davidson et al. (1993) made the further observation that animals with the same kainic acid + colchicine lesions used by Alvarado and Rudy, but not those with ibotenic acid lesions, displayed disinhibited rates of operant responding during the intertrial interval between tone and light presentations. Both types of lesion are excitotoxic and should therefore spare fibers of passage, unlike older lesion techniques. However, kainic acid also produces lesions distant to the hippocampal formation, such as in the piriform and periamygdaloid cortex. This additional damage could have led to disinhibited responding, and its potential presence raises the possibility that altered motor performance rather than impaired learning contributed to the positive result in some of the earlier Rudy and Sutherland studies. An operant lever-pressing task used by McDonald et al. (1997) indicated that hippocampal lesions slowed down but did not ultimately prevent the rate of learning of a negative patterning task, and fornix lesions had no detectable effect on learning at all. Lesions of the avian hippocampus were also ineffective in impairing negative patterning in pigeons (Broadbent et al., 1999; Papadimitriou and Wynne, 1999). Bussey et al. (2000) found no deficit in a configural conditioning task (conditioned approach to a place where food was available) after radiofrequency fornix lesions or neurotoxic perirhinal/postrhinal (PRPH) lesions. All groups learned to approach in response to either an auditory tone or a brief period of darkness and to withhold approach when these two CSs were presented together. They also used posttraining transfer tests to establish that a configural solution had been used for the task, and “behavioral histology” that took the form of showing that the fornix-lesioned rats were impaired in T maze alternation and the PRPH-lesioned rats in object

**Figure 13–34.** Four tasks used to test critical predictions of the configural-association theory. The letters A, B, and so on refer to arbitrary stimuli; and the symbols + and − refer to the availability of reinforcement.

<b>A</b>	Negative patterning	<b>B</b>	Transverse patterning
	<b>A+ , B+ , AB-</b>		<b>A+B- , B+C- , C+A-</b>
<b>C</b>	Bidirectional discrimination	<b>D</b>	Feature-neutral discrimination
	<b>AB+ , CD+ , AC- , DB-</b>		<b>AC+ , C- , AB- , B+</b>

recognition memory. Overall, the available data from these and other studies on negative patterning represents, at best, only mixed support for the theory.

*Transverse patterning* fares better. It involves a series of simultaneous discrimination tasks of the form A+ versus B-, B+/C-, and C+/A- in which the stimuli A, B, and C are equally often rewarded (+) and nonrewarded (-). This set of problems, as noted by Moses and Ryan (2006) when comparing predictions of the configurational and relational theories, is akin to the children's game of "rock, paper, scissors." Alvarado and Rudy (1995b) reported that rats with hippocampal lesions could readily learn to swim toward A+ and avoid B- and to learn B+/C- when either task was presented over successive trials on its own (Fig. 13–35). However, they failed to learn the full transverse pattern when all three problems were presented together. This result is beautifully consistent with the theory provided it is the AB configurational stimulus that triggers approaches to stimulus A, the BC configuration to B, and the CA configuration to C. Unfortunately, it is also a task that may be amenable to solution without recourse to explicit configuring. This would be a "conditional solution" in which the animals learn that one stimulus (e.g., A) is correct given the presence of B, that B is correct given C, and that C is correct given A. The distinction between configurational learning and rule learning may seem subtle, but the acquisition of an "if-then" conditional rule obviates the need to form stimulus configura-

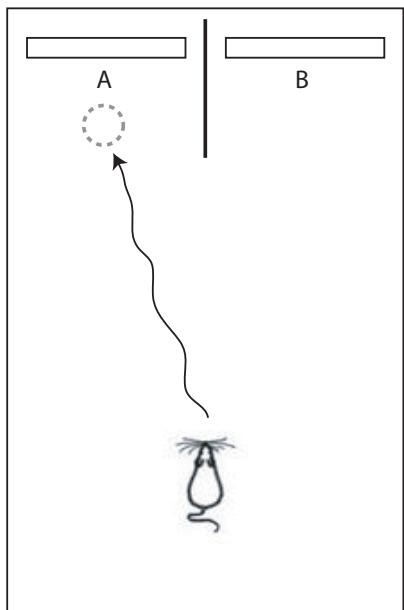

tions and may be a form of learning that depends on other brain structures (e.g., the caudate). Conditional rules are not easy for rats to learn; but with sufficient training and provided the information with which they are provided is consistent, they can do it.

Later work on transverse patterning failed to replicate the deleterious effects of hippocampal dysfunction. For example, using an operant task that made it less likely that the animals would process the cues as configurational "scenes," Bussey et al. (1998) found that fornix lesions significantly *facilitated* transverse patterning. An identified weakness of a first experiment was the relatively poor performance of sham-lesioned rats on the critical third phase when all three problems were trained together. This was addressed in a second study with all three phases trained concurrently. The sham-lesioned group was now above chance, but the trend toward a fornix lesion-induced facilitation remained. We come back to transverse patterning in the discussion (below) of relational processing theory.

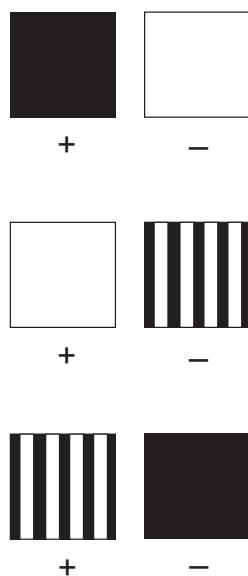

*Biconditional discrimination* tasks can also be solved using configurational cues, but unfortunately they may also be learned through the application of a conditional rule. Whishaw and Tomie (1991) trained rats to pull on strings of different widths (A, B) and different odors (C, D) in combinations that led to reward (e.g., AB+, CD+) or no reward (e.g., AC-, BD-). These pairings meant that any one elemental cue predicted

**Figure 13–35.** Transverse patterning. A. Rats were trained to swim toward hanging cue cards that were either placed in front of a possible escape location (e.g., A+) or merely hanging over the pool (e.g., B-). The spatial locations of A+ and B- would be randomized across trials. B. The stimulus patterns used for the full transverse patterning problem. C. Deficit in hippocampus-lesioned rats (H) compared to sham lesion controls. (Source: After Alvarado and Rudy, 1995b.)

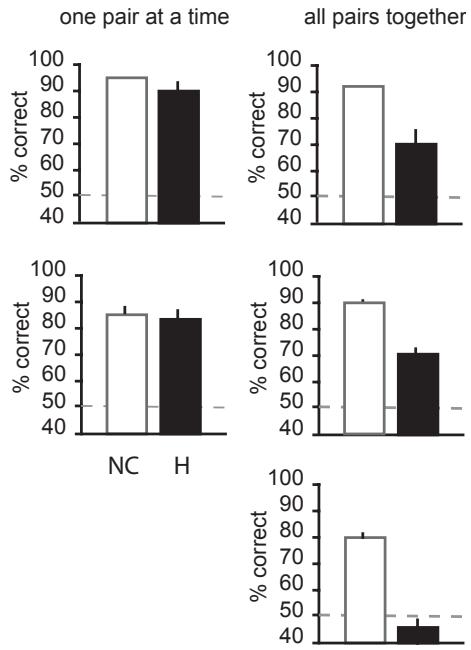

### A Apparatus

### B Stimuli

### C Performance

reward and nonreward equally often, but the creation of four configural cues would enable a solution. Here the configural-association theory fared less well: Rats with hippocampal damage and sham-lesioned animals were both able to learn to pull the correct string to get the reward. Similar negative results had also been found in a similar earlier study using primates (Saunders and Weiskrantz, 1989).

The fourth category of ambiguous problem that Sutherland and Rudy (1989) considered is the *feature-neutral discrimination task*. An explanation of the name for this protocol may help clarify what is being examined. The “feature” of the task is a particular stimulus; let us call it stimulus A (as in Fig. 13–34). In conjunction with stimulus C, the feature A signifies that a reward is available. Conditioning should lead to stimulus A acquiring some associative strength. However, in conjunction with stimulus B, feature A now signifies that a reward is *unavailable*. Stimulus A should therefore become “inhibitory.” By scheduling all four types of trial, stimulus A should remain “neutral” with respect to its scheduled association with reward (it is as often paired with reward as not) while still being the critical feature that enables the rat to learn the discrimination. Hence, it is called a feature-neutral discrimination task. As in negative patterning, no combination of elementary associations between stimuli and a reward can solve the problem, and the configural association theory uniquely predicts that rats with hippocampal lesions should fail. Unfortunately, two studies using this design have both found that rats with hippocampal lesions can learn it. In fact, Gallagher and Holland (1992) found a facilitation of some aspects of feature-neutral discrimination learning by rats with neurotoxic hippocampal lesions, a result that echoes Bussey et al.’s (1998) results on transverse patterning after fornix lesions.

Taken together, this pattern of results from the four sets of tasks provided only qualified support for the configural association theory. The results of the negative and transverse patterning tasks sometimes upheld predictions of the theory, whereas the outcome of the biconditional and feature-neutral discrimination tasks did not. It is perhaps worth reflecting further on the curious paradox that whereas a normal rat can solve these problems we ostensibly smarter humans often struggle to understand them. The struggle is nonetheless worthwhile, as understanding ambiguity and its role in learning is important. All these tasks are ones in which an implicit learning device is assumed to encode a stimulus configuration that acquires associative strength through its consistent association with reward. Ostensibly, no new principles of associative learning are involved—only a configuring device. The question therefore arises of whether this device is likely to be in the hippocampal formation. One reason to be skeptical is that the anatomical and electrophysiological data discussed in Chapters 3, 4, and 8 strongly suggest that the sensory information to which the hippocampal formation has access is *already polymodal* and *already highly processed*. Therefore, a neurobiological concern about the theory, quite apart from the inconsistencies in the behavioral data, is not whether stim-

ulus configurations are ever formed but that their construction is more likely to have taken place in the neocortex.

### Revised Theory

In response to the mixed picture of initial results, Rudy and Sutherland presented a revised theory that wisely put the configuring part of the system outside the hippocampus in neocortex. However, they still asserted that the hippocampus plays a role in learning configural associations by “selectively enhancing the salience of configural representations” (Rudy and Sutherland, 1995, p. 382). A yet later change in the theory emphasizes, in a similar vein, the role that the hippocampus could play in rapidly separating similar patterns for effective processing in the cortex (O’Reilly and Rudy, 2001). These changes were in response to observations that ambiguous tasks that could eventually be learned by animals with hippocampal damage were often learned more slowly than by controls. It was a set of changes that would rescue aspects of the theory but at the cost of making it more difficult to test definitively. In some respects, this is unfortunate because, arguably more than other theorists, Rudy and Sutherland have been rigorously honorable in demanding explicit predictions and definitive tests.

Going down with the ship is all very well, but a key issue is whether the logical structure of tasks, such as those laid out in Figure 13–34, actually constrains the way in which an animal solves any one task. The original version of the configural association theory implied that this was the case. However, when comparing negative patterning with feature-neutral discriminations and biconditional tasks, Rudy and Sutherland (1995) noted a parametric gradation across the tasks. This gradation was from negative patterning that absolutely required animals to learn to withhold responding to a configural stimulus composed of *two elements* (i.e., AB−) that are also presented alone and reinforced (A+, B+) to biconditional tasks in which none of the elements are ever presented alone and reinforced (i.e., always X with Y and either + or −). They argued that this parametric variation is important because it relates to the extent to which individual stimuli acquire associative strength during conditioning that is likely to conflict or oppose the strength that should be shown by configural stimuli. If this gradation is significant, it might be that the task with the greatest conflict would be definitively impaired by hippocampal damage, whereas that with less conflict would be least affected. To some extent, the data available in 1995 did fit this pattern.

However, one aspect not considered was the possibility that distinct CSs may not interact only by forming configural cues but in more subtle ways as well. For example, under some circumstances, one CS may modulate or “set the occasion” for the other CS to enter into a conditioned association. A good illustration of this is the *feature negative discrimination task* in which a stimulus A is reinforced on its own A+ but not reinforced when B is presented before A (i.e., B → A−). Under these circumstances, instead of an AB configural stimulus

being created (which may happen when all the stimuli are presented concurrently), B acts in a different manner, modulating whether the presentation of A retrieves a memory of the US or the absence of the US. Occasion-setting is an associative process in which one CS serves as a signal for an association between other stimuli in a hierarchical manner. Work by Holland and his colleagues indicates that hippocampal lesions can disrupt one type of negative occasion-setting (Holland et al., 1999), raising the possibility that the memory traces responsible for conditioned associations between stimuli are encoded and stored in the cortex (including configural stimuli) but can be subject to hierarchical control by stimuli processed in the hippocampus. However, an alternative interpretation remains feasible. This is that although the hippocampus is not involved in forming excitatory CS-US connections it is involved in inhibitory learning (i.e., that a particular CS does *not* lead to an otherwise expected US). Chan et al. (2001) had somewhat unfashionably defended an inhibitory view of hippocampus function. They looked on the feature negative occasion-setting task as one in which, in normal rats, a CS forms both excitatory and inhibitory associations, and the occasion-setter helps to choose between them. The disruption caused by hippocampal lesions may then be a deficit in inhibitory, rather than hierarchical, occasion-setting. The problem with this view is that there are many occasions in which hippocampal lesions have no effect on the extinction of CS-US associations—the classic test of an inhibition theory (Wilson et al., 1995).

In the further refinement of the configural framework, O'Reilly and Rudy (2001) have semantically recast the theory to refer to "conjunctive representations" rather than "configurations" and suggested that there are two kinds of conjunctive learning. One type is thought to occur incidentally or automatically, irrespective of task demands; this is the type that is rapidly learned and involves the hippocampus. The other type is slower and more deliberate, and the kind of learning that emerges as a consequence of a deliberate type of problem-solving. This new incidental versus deliberate framework is also explicit about the contribution that local circuits in the hippocampal formation make to algorithms such as "pattern separation" and "pattern completion" (in the dentate gyrus and area CA3 respectively—see Chapter 14), and to the similarities between tasks involving configurations of individual CSs with context-dependent associations. We return to issues to which these revisions of the theory are relevant in Section 13.6, together with reference to the important issue of "automaticity" in hippocampus-dependent learning.

### 13.5.2 Relational Processing Theory: Refinement of the Declarative Memory Theory

A significant feature of memory is the ability to recall facts and events in circumstances different from those in which the information was acquired in the first place. The inherent "flexibility" of this form of memory was particularly emphasized in a revision of the declarative memory theory advanced by

Cohen and Eichenbaum (1993) and later revised by them (Eichenbaum and Cohen, 2001). It has been developed further in relation to episodic memory processing (Eichenbaum, 2004), which we address later. The theory also places emphasis on the encoding of "relations" between stimuli. This is quite different from forming configurations (as just discussed), and more akin to the idea of associations between facts, such as that one fact can remind us of another. The information processing necessary for "flexible relations" is held to occur at the time of encoding but only becomes apparent when retrieval is required in circumstances different from those of the original learning. Like the original version of the declarative memory theory, this theory holds that relational processing is within the capacity of (at least) "higher" mammals, that it depends on activity in the MTL, and that the engagement of the hippocampal formation is time-limited. "Relational processing" is held to be implemented by the hippocampal formation, whereas anatomically distinct neocortical regions of the MTL mediate the processing and storage of individual stimuli. This theory led to a number of distinctive lines of experimentation that require discussion separate from those already outlined in the discussion of the declarative memory theory but to which the configural association theory is, as we shall see, also relevant. The distinctive propositions of the theory are in Box 13–7.

"Relational representations" were defined as memory representations that are "created by and can be used for comparing and contrasting individual items in memory, and weaving new items into the existing organization of memories. This form of representation maintains the compositionality of the items, that is, the encoding of items both as perceptually distinct objects and as parts of larger scale scenes and events that capture the relevant relations between them" (Cohen and Eichenbaum, 1993).

The gist of the first proposition is that the relations that humans and animals are able to store and recall go beyond the mere fact that two stimuli were experienced together in temporal contiguity—the "CS predicts US" type of association so extensively studied in conditioning paradigms. "Comparing and contrasting" implies that relations between stimuli can be more sophisticated. They may be causal, but they may also

#### Box 13–7 Relational Processing Theory

1. Declarative memory generally involves processing the relations between different items. Relational processing at encoding enables flexible access to information in situations quite different from those of the original learning.
2. Relational processing is carried out by the hippocampal formation, but storage of individual items in intermediate memory takes place in the perirhinal and parahippocampal cortex.
3. The role of the hippocampus in memory is temporary, as in the declarative memory theory.

relate to physical relations (e.g., that A is near to, or bigger than, B; as in “Versailles is near Paris”) or to abstract relations (as in “the ugly sisters were unfriendly to Cinderella”). Moreover, relations can extend beyond one-to-one pairings to elaborate networks of interconnections between facts and events—the very networks that constitute our personal understanding of the world. The theory’s proponents asserted that their view echoes William James, who described memory as an elaborated network of associations that can be applied across a broad range of situations (James, 1890). Although the circumstances or conditions of learning are not well specified in the theory, in the manner of contemporary learning theory, the emphasis on relations is clearly a step beyond reference to the “facts and events” in Squire’s (1992) original version of the declarative-memory theory. Cohen and Eichenbaum (1993) have put their finger on an important issue; and, indeed, Squire has now incorporated some of their ideas into his modern writings (e.g., Squire et al., 2004).

Whereas some types of factual information tend to be recalled in a rote-like fashion, as in a child’s recitation of arithmetic (“two-plus-two is four, four-plus-four is eight . . .”), remembering facts and events is often deductive. They may be recalled in different contexts from those in which they were originally experienced and in a manner that permits access to other perceptual features of a current situation. Indeed, certain “facts” may not have been stored at all (such as knowing the number of windows in your house, which most people work out inferentially by mentally walking through the building and counting them). The overall network of relations does not need to be present or to be recalled to access a smaller subset of facts. Flexibility also allows deductive inference. An illustrative example is inferring geographical relations. Suppose an American schoolboy living in South Carolina has learned in school that “Paris is the capital of France,” that “Madrid is the capital of Spain,” and that “France is farther north than Spain.” Based on these facts, the child should be able to infer the additional fact that “Paris is north of Madrid.” If then told that Madrid is on the same latitude as Washington, DC, he might, assuming he knows his American geography, also draw the further inference that “Paris must be north of where I live because Madrid and Washington are on the same latitude.” This illustrates how new spatial facts can be inferred even though never explicitly learned. Of course, flexibility is a hallmark of the cognitive map theory as well, but there it is held to be a specific, unique property of spatial memory. The supposition now is that flexibility includes the spatial domain but extends well beyond it to size, social relationships, and yet others. The information processing provided by the hippocampus is not domain-specific.

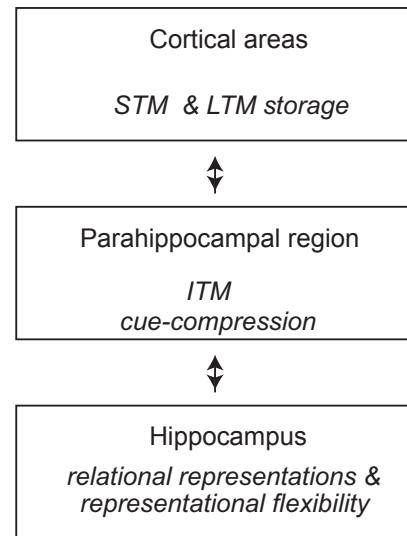

The second and third propositions of the theory concern the relation between the hippocampal formation and neocortex. Like Squire’s theory, Cohen and Eichenbaum argued that damage to the hippocampal formation causes loss of the capacity to store new explicit memories without having an effect on implicit memory (i.e., for stimulus relations of which we are *not* consciously aware). They agreed that hippocampal

lesions spare the acquisition and expression of motor, procedural, and cognitive skills. The refinement they offer is what amounts to fractionation of declarative memory into two sub-components: (1) the processing and storage in intermediate memory (ITM) of stimulus items in isolation carried out in the perirhinal and parahippocampal gyrus; and (2) the processing of stimulus relations in such a way as to enable flexible access, carried out by the hippocampal formation (Fig. 13–36). As long-term storage is held to be in other areas of association cortex, the stimulus representations in the MTL are asserted to be “compressed.” This is a metaphor taken from modern computer science; but a claim with no direct evidence to support it requires a much deeper understanding of neural representations in the hippocampal formation than we presently possess.

There are three other features to highlight. First, because spatial relations are only one of the many types of flexible relations that humans and other mammals can encode, the theory embraces some of the positive evidence hitherto held to support the cognitive map theory in an ostensibly more general theoretical position. In fact, Eichenbaum (1996) argued that spatial learning fractionates into flexible and inflexible forms, with only the former sensitive to hippocampal disruption (reminiscent of Olton’s “working memory” theory in which spatial reference memory is insensitive to such lesions). This may account for successful spatial learning by hippocampus-

**Figure 13–36.** Three functional components of the relational processing memory system: cortical-hippocampal connections showing the three main components. The cortical areas store short-term memory (STM) and long-term memory (LTM) traces of specific items; the parahippocampal region serves as intermediate memory (ITM) for specific items and does the job of cue compression. The hippocampal formation computes relational representations in a manner that enables representational flexibility.

#### Relational processing theory - processes and anatomical mediation

lesioned rats during overtraining (Morris et al., 1990) because after extended training the animals can learn discrete approach responses from each of several starting locations in the pool. However, this finding is also consistent with the hippocampus-independent “taxon” approach strategies of the cognitive map theory. Second, the theory states that the role of the hippocampus in the formation of flexible representations is time-limited. Such representations are then consolidated in the neocortex, where they can be accessed flexibly without further hippocampal input. Thus, the machinery for creating flexibility is in the hippocampus, but (somewhat clumsily) the machinery for flexible recall is in the neocortex. Third, if the hippocampal formation is damaged, stimulus items that are presented together may become fused into configurations. Associations can still be created, but the theory supposes that they are not relational but always configurational. This idea capitalizes on the same kind of data that led Rudy and Sutherland (1995a) to propose their revised theory.

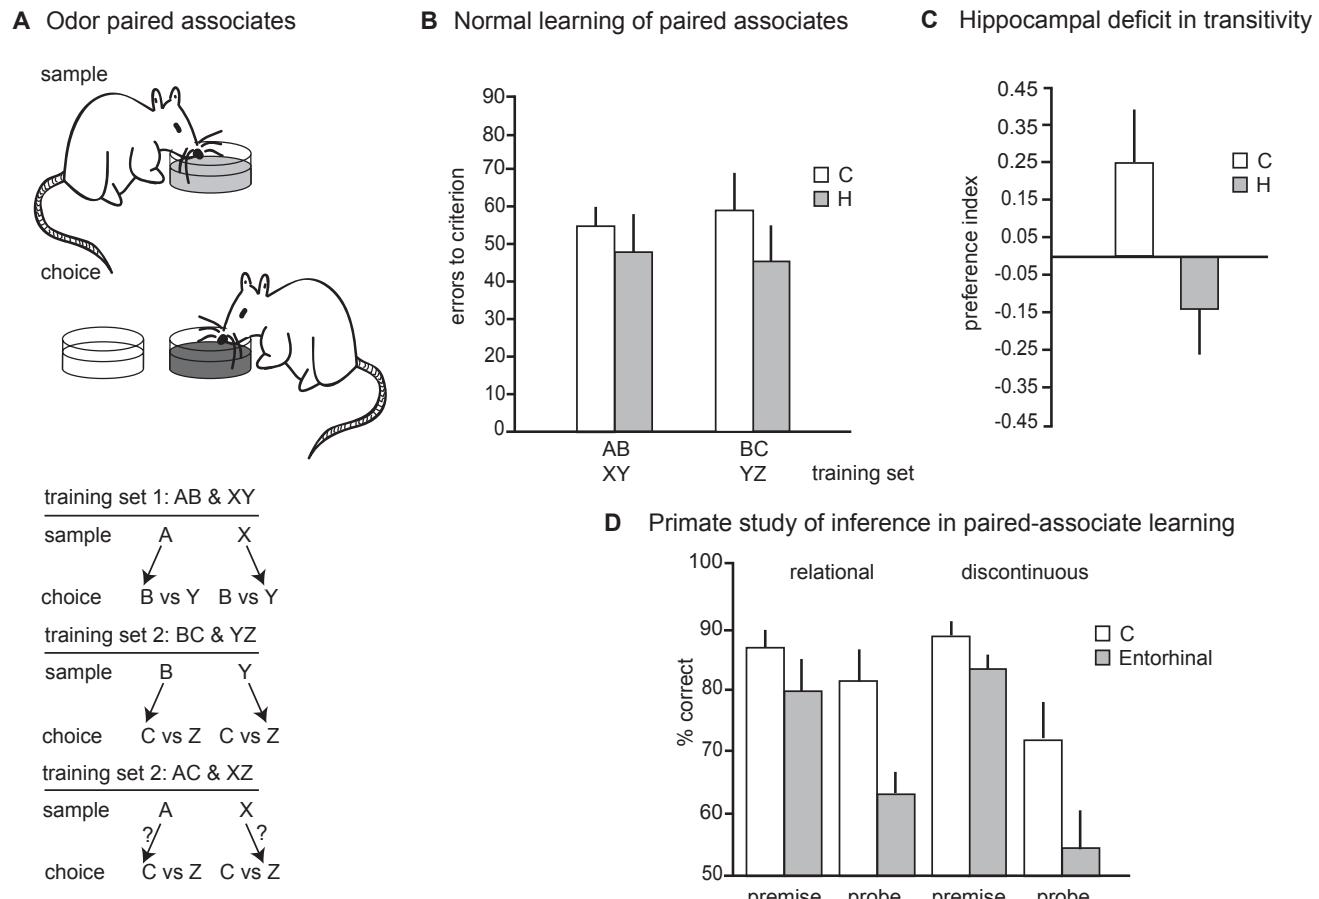

#### **Evidence for Hippocampus-dependent Relational Representations and Flexible Access**

The first study directly investigating relational processing in humans involved brain imaging using positron emission tomography (PET) (Henke et al., 1997). This study required subjects to look at slides containing a person or a house and asked them to judge the gender of the person and whether an inside or outside view of the house was being displayed or to guess whether the person was likely to live in the house or be a regular visitor to it. Only the latter instructions encouraged “comparing and contrasting” of the two pictures and so triggered relational processing. Comparison of the relative brain activation in the two conditions revealed greater activation in the right MTL during the relational condition. This finding supports the relational processing account, all the more so because the associations formed were nonspatial. Other human studies, using fMRI, have partially supported the idea that relational processing can drive hippocampal activation (Cohen et al., 1999). However, in an explicit comparison of two matched spatial and social relationship tasks, Kumaran and Maguire (2005) saw activation of the human hippocampal formation only during the spatial relation task. A network of real people, some of whom were friends (or friends of friends) and all of whom lived at various places in the same city, was identified in an initial briefing session. The main tasks to be conducted in the scanner included getting a crate of wine from one person to another (together with various control tasks). In the social version of the main task, the crate could be passed from friend to friend. In the spatial version, it was passed to the nearest neighbor. Hippocampus activation was observed when subjects were required to focus on and navigate spatially (e.g., their friend’s houses). A quite different network of brain areas was activated when subjects wandered mentally within their social network—retrieving knowledge about their friends and their relationships to each other—including the medial prefrontal cortex, insula, superior temporal sulcus, and other areas implicated in a proposed

circuitry for social cognition (Adolphs, 2003). In a further setback for the relational processing account of human hippocampal function, a sharp distinction between item and associative memory is also not fully supported by other contemporary fMRI studies, as reviewed in Chapter 12. Hippocampal activation can sometimes be seen with individual memory items, particularly when they are novel, though the novelty-driven nature of such activations is often the unusual spatial context in which a stimulus is presented and thus cryptically relational.

Animal studies have played a bigger part in driving the theory. Bunsey and Eichenbaum (1996) developed an odor-guided paired-associate learning task for rats to examine whether learned information could be used inferentially in novel testing situations. The animals could dig through food cups containing a mixture of ground rat chow and sand to secure a fruit-loop cereal reward. One of several odors was added to the sand/chow mixture so the rats’ experience of digging was associated with the odor. The animals took to the task quickly, perhaps because digging for food is as much a part of their natural foraging strategy as remembering where they are (Fig. 13–37).

Paired-associate learning tasks are most extensively used in human cognitive psychology and typically involve presentation of the first member of each pair (the so-called cue item), followed by either free recall of the second item or a two-alternative forced-choice test between two potential associates of which only one is correct. The pairs may be word pairs, words and faces, or other combinations of stimuli. Bunsey and Eichenbaum’s paired-associate training protocol for rats used the two-alternative forced-choice test. The initial training phase consisted of digging through the sample item, in which a single digging cup with a single odor was presented (e.g., cocoa = cue A), followed immediately by the two-alternative choice test in which two cups were presented and the animal’s task was to dig in the cup whose odor was to be associated with the initial cue item (e.g., coffee = cue B). That is, following cue A the animal was rewarded during the choice phase if it dug through cue B but was unrewarded if it dug through the other cup (e.g., salt = cue Y). Conversely, if the animal was presented with turmeric as a first-item cue (cue X), digging in the salt cup (cue Y) in the choice phase secured reward whereas digging through cue B (coffee) did not. Having learned in this way that A goes with B and that X goes with Y (over many training trials), a second set of paired associates was then taught in which the rats learned that odor B goes with C (not Z) and that odor Y goes with Z (not C). Sham and ibotenate hippocampus-lesioned rats learned both sets of “premise” paired associates in this way quite rapidly and at the same rate (Fig. 13–37B). An ingenious feature of the experiment was inherent in the design. The two sets of paired associates deliberately contained common elements: odors B (coffee) and Y (salt). This commonality afforded the opportunity of exploring whether rats that had learned that A goes with B (and B goes with C) could access these stimulus–stimulus representations flexibly and so reveal transitive knowledge about the relation between A and C. In a probe test

**Figure 13–37.** Flexible retrieval of learned paired-associate information. *A*, The rat approaches and digs through a “sample” trial until it gets its fruit-loop reward. A short while later, it is presented by two other scented food cups in a “two-alternative forced choice” test. The scent associated with the previous sample indicates in which of the choice cups the animal should dig to get another reward. *B*, Sham-lesioned and lesioned rats were equally capable of learning the odor-paired associations.

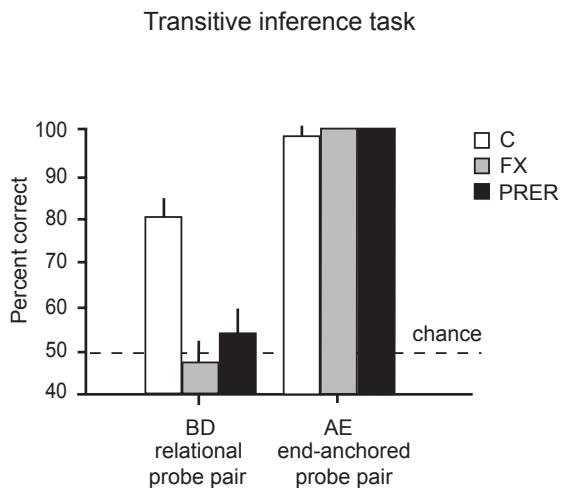

The question at issue is the nature of the relations that were encoded during this training. *C*, The test for transitivity showed that the sham rats were above chance in choosing C given A, and Z given X, whereas the hippocampus-lesioned animals could not draw these inferences. (Source: After Bunsey and Eichenbaum, 1996.) *D*, Findings from an analogous primate study revealed selective impairment on the probe but not premise choice trials after entorhinal cortex lesions. (Source: After Buckmaster et al., 2004.)

for this, the rats were first given either odor A or X as the initial single-cup cue item and then presented with a choice between cups containing odors C and Z. The striking result was that the sham-lesioned animals chose appropriately (i.e., C after A and Z after X), but hippocampus-lesioned rats did not (Fig. 13–37C).

In further experiments also using the same sand-digging method, Dusek and Eichenbaum (1997) considered the issue of hippocampal involvement in building ordered representations using a classic Piagetian seriation paradigm. It was adapted for use in work with primates by McGonigle and Chalmers (1977). Later work established that pigeons and rats could also behave “logically,” but Eichenbaum’s group was the first to explore the anatomical substrate. Sham-, fornix-, and perirhinal/entorhinal-lesioned rats were trained in a “transitive inference” task to choose odor A over odor B and then B > C, C > D, and D > E using a training protocol that began with successive trials of each discrete problem and ended with the individual problems in random sequence (see Box 13–8).

After they had mastered these four problems, the animals were presented with two other novel problems: choosing between odors B and D and between A and E. Both involved a choice between odors that had never previously been presented together, but only the former pair (B > D) required knowledge of a serial order. This is because the “probe” odors B and D had each served equally often as rewarded or as nonrewarded odors during training, whereas the “end-anchor” odors, A and E, were always positive or negative odors, respectively. Sham-lesioned rats chose both B over D and A over E, whereas rats with fornix or perirhinal/entorhinal lesions could only do the A versus E comparison (Fig. 13–38).

Work in species other than the rat has revealed mixed support for the relational processing idea. A study in pigeons revealed that they could learn the paired-associate task and successfully solve the inferential probe tests, but hippocampal lesions were without effect (Strasser et al., 2004). Using objects in a WGTA, Saunders and Weiskrantz (1989) trained monkeys on a biconditional task (like those described in the previous

**Figure 13-38.** Hippocampal participation in transitive inference. Choice performance by controls and fornix-lesioned (FX) and perirhinal/entorhinal-lesioned (PRER) groups during the two choice tests after seriation training. Both lesioned groups are at chance on the B versus D comparison, but both perform as well as controls on the A versus E end-anchored choice test. (Source: After Dusek and Eichenbaum, 1997.)

section) followed by an interrogation of what the monkeys “knew” about which object was related to which other object. The animals were trained, through a series of stages, with pairings in which each object was equally often rewarded or nonrewarded, but specific pairings were consistently rewarded (e.g., AB+, CD+) or consistently nonrewarded (AC−, BD−). Hippocampal disruption (fornix lesions or combined fornix, hippocampal, and mammillary body damage) did not affect acquisition of the task but did impair performance in the posttraining probe test of “what goes with what.” In this probe, the monkeys were confronted with three objects (A, B, C) and, having displaced A to receive a reward, got a second reward on the same trial only if they then displaced B (AB having been a rewarded pair during training). Only the con-

trols succeeded in doing this. This finding suggests that the normal controls had acquired an abstract representation of the object pairings that was more “flexible” than that acquired by the lesioned monkeys. The successful learning of the biconditional task with poor inferential probe test performance is arguably more consistent with the relational processing account than the configural-association theory.

Buckmaster et al. (2004) trained monkeys on a series of procedures intended to emphasize relational representations: a paired associate task analogous to that of the Bunsey and Eichenbaum (1996) study, a transitive inference task based on the original primate work of McGonigle and Chalmers (1977), and a novel spatial delayed recognition span procedure. They were also received training in object discrimination learning and DNMS (simple associations and recognition memory). Monkeys with large (> 90%) entorhinal lesions acquired and performed these latter tasks normally but were impaired on each of the three tasks that required relational processing. The entorhinal cortex-lesioned monkeys gradually acquired the difficult discriminations required in the paired-associate task, but acquisition was slower than normal, suggesting that a different, less flexible configural learning strategy was being used. Performance by normal monkeys in both the premise and probe trials was more than 80% correct (Buckmaster et al., 2004), but there was selective impairment on the probe trials after entorhinal cortex lesions (Fig. 13-38D). The results on the transitive inference tasks were consistent with those obtained in rats, but aberrant poor performance by one normal control monkey in this task make it difficult to draw firm conclusions. The perennial problem of the numbers of subjects used in primate studies is often quite low. The spatial span task could not be learned by the lesioned monkeys, a finding that would be consistent with the cognitive map theory were it not for the deficits in the other relational tasks that were explicitly nonspatial. These are important results, as studies of entorhinal cortex lesions had previously failed to reveal any lasting deficit in DNMTS (Leonard et al., 1995), but the commonality of the deficit here with hippocampal lesions is consistent with the proposal made in Chapter 3 that the entorhinal cortex should be viewed as a major component of the hippocampal formation.

A potential difficulty is that the transitive inference task is a classic example of a procedure in which the devil is in the detail, both conceptually and procedurally (McGonigle and Chalmers, 2003). Like other ambiguous tasks, it is a task that can be solved in several ways. Van Elzakker et al. (2003) noted at least four theoretical accounts of successful task performance and argued that a simple “excitatory stimulus value” account cannot be ruled out. This may seem surprising as, on the face of it, the novel B > D probe compares two stimuli that should be of equal excitatory stimulus value as they are equally often paired with reward and nonreward during training. However, there are some cryptic asymmetries to the training protocol that may render this assumption false. When learning D > E in the five-problem series, the pairing is with a stimulus E that is *never* reinforced. D may therefore not have

#### Box 13-8 Transitive Inference Premise Training

to acquire a very high net excitatory stimulus value before the difference between D and E crosses the threshold necessary for criterion performance. Similarly, A is always reinforced, and thus the  $A > B$  difference might also be realized despite B actually having a fairly high associative strength. Given this, the relative values of B and D may be different despite the ostensibly equal pairing with reward and nonreward. In addition, one might then expect a B versus D probe to be easier in a four-problem series ( $A > B$ ,  $B > C$ ,  $C > D$ ,  $D > E$ ) than in a five-problem series in which an  $E > F$  problem is added. Exactly these results were found by Van Elzakker et al. (2003), who therefore queried whether relational processing and inferential memory retrieval were being used to perform the task. Computational modeling by Frank et al. (2003) has taken this further, with a detailed treatment of the impact of the “end-anchors” on the associative strength of stimuli with which they are routinely paired, the role of configural representations in the performance of normal (unlesioned) animals, and the balance between effects of “pattern separation” and “pattern completion” in the task. They also queried the adequacy of a relational processing account of transitive inference and made the interesting prediction that hippocampus or dentate gyrus lesions created after training should have no effect on performance of the BD probe, in contrast to the deleterious effect on choice when made before training. This is an important prediction because, in contrast, the relational processing theory would require the hippocampus to be intact at the time of a probe test. This valuable pretraining versus post-training comparison of the configural and relational processing accounts has not yet been reported.

The lesion studies that have at least partially supported the relational processing theory of hippocampus function have been complemented by unit-recording data using similar paradigms (Wood et al., 1999). Multiple single-unit recordings were taken of CA1 pyramidal cells firing during a 1-second period just prior to a rat deciding whether to dig in a continuous recognition variant of the paradigms just described. Food cups containing sand were repeatedly presented to animals in different locations of an open arena. For trials in which the cups were scented with a novel odor (half the trials), the sand had a fruit-loop reward buried at the bottom; for trials in which the odor was repeated (i.e., no longer novel), no fruit loop was present. The rats quickly learned the logic of the situation: to dig when it was worth it and refrain from doing so when it was not. The unit-recording data taken during the Shakespearean “to dig or not to dig” decision period indicated that approximately one-third of the hippocampal cells had task-related *nonspatial* correlates. Place-specific firing was certainly seen in some cells (about another third). Of the nonspatial cells, some were associated with approach behavior, some with approaching a particular odor irrespective of its location in space, and some with whether the trial was with an odor that was familiar or novel (match/non-match)—all relations of a nonspatial character. These data indicate that the functional correlates of CA1 pyramidal cell firing may depend in part on the task a rat is being trained to perform, not just on its location in space. This is a deep idea

that requires further investigation in analytically exacting tasks. However, a follow-up study (Dudchenko et al., 2000) revealed this continuous recognition task to be insensitive to hippocampal lesions, again raising doubts about the extent to which a “relational” description of the cellular correlates is justified. The parallel to what is seen in NMR conditioning is beguiling—as if the hippocampus mischievously likes to “listen in” on things it does not have anything to do with. We later argue that this is exactly what an incidental learning system may have to do.

These experiments are taken by Eichenbaum and Cohen (2001) to indicate that: (1) rats develop a knowledge of stimulus relations that can be retrieved flexibly to guide inferences from memory; (2) hippocampal cells are responsive to such task-related attributes; and (3) the integrity of the fornix, hippocampus, and perirhinal/entorhinal cortices are essential for representing these attributes flexibly. This interpretation clearly goes beyond the domain of both the original declarative memory and cognitive map theories but leaves open whether the hippocampus is engaged in relational processing at encoding, retrieval, or both. As just noted in the contrast with a configural association account of transitive inference, making lesions before training does not distinguish these two alternatives. Reversible inactivation, using drugs that inhibit synaptic transmission cell firing, would also provide an opportunity to explore whether the hippocampus needs be active at encoding and retrieval, as it does for spatial reference memory (Riedel et al., 1999), and whether it plays a time-limited role in systems-level memory consolidation as the relational processing theory predicts. If time-limited, it would imply that “flexibility” can be displayed by neocortical circuits also, provided information is subject to both hippocampus-dependent encoding and a period of hippocampal-neocortical consolidation.

The notion of representational flexibility and its dependence on the hippocampus is also illustrated by experiments on the social transmission of food preferences using a paradigm first developed by Galef and Wigmore (1983). Two rats are put together for a short period. One of these rats, the demonstrator, is arranged to have recently eaten a novel foodstuff. The animals are then separated and, after a memory delay, the other animal, the observer, is tested with two novel foods. One novel food is the same as the one the demonstrator has eaten, and the other novel food is not. In this two-alternative forced-choice test, the observer rat shows a preference for the novel food eaten by the demonstrator over the other (Fig. 13–39A). Some social feature of the situation conquers the animal’s usual neophobia. An early series of analytical studies (Galef, 1990) had established that this social transmission of food preferences is mediated by carbon disulfide ( $CS_2$ ) in the breath of the demonstrator rat that acts a “carrier” of the smell of the food that the demonstrator has eaten. Although this social-transmission task is not obviously relational in quite the same way as the paired-associate task, it is flexible with respect to how the learned information is expressed. Information about the novel food is acquired by the observer on the breath of the demonstrator rather than through actual consumption, and

**A Odor-guided, paired associate learning**

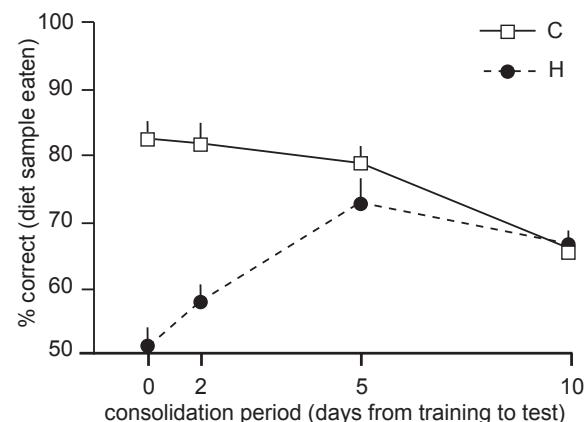

**Figure 13–39.** Social transmission of food preferences. *A*. Odor-guided paired associate learning in which information about a food odor that is safe to eat (gray food) is acquired by an “observer” rat smelling the breath of a “demonstrator” rat that has previously eaten that food. This acquired knowledge is later expressed in the

this “knowledge” is later expressed by the observer rat. Procedural learning systems in which knowledge is embedded in performance would not support such learning.

Winocur (1990) discovered that this task is sensitive to hippocampal lesions created either before or shortly after the demonstrator–observer interaction. Faster forgetting, over 6 days, was observed in the animals lesioned before training. In animals subjected to lesioning after the social transmission phase but before the preference test, a consolidation gradient was observed: Those with hippocampal lesions displayed retrograde amnesia 1 day after lesion creation, whereas those whose lesions were created 5 to 10 days later performed significantly better (Fig. 13–39B). Bunsey and Eichenbaum (1995) confirmed Winocur’s finding of faster forgetting using rats with ibotenate lesions that encompassed the hippocampus, dentate gyrus, and subiculum. Rats with more selective hippocampus + dentate lesions showed little forgetting over 24 hours, but the longer 6-day interval used in Winocur’s study was not examined and these more selective lesions were incomplete at the temporal pole. In the light of data concerning differential functions of the dorsal and ventral hippocampus, it is possible that social transmission of food preference could be one that is specifically sensitive to ventral hippocampal lesions.

#### Evidence for Functional Dissociations Between Anatomical Components of Declarative Memory: Role of the Hippocampus

One point of departure between this and Squire’s (1992) version of declarative memory theory has to do with functional dissociations between components of the MTL memory system. Squire argued against functional distinctions, except at the input stage where some differentiation between the infor-

form of a preference in a two-alternative choice test over another food (white). (Source: After Galef and Wigmore, 1983.) *B*. Retrograde amnesia for social transmission after hippocampal lesions. (Source: After Winocur, 1990.)

mation projected to the perirhinal and parahippocampal cortex is recognized (Suzuki and Amaral, 1994a,b). In contrast, the relational processing theory requires the hippocampal formation to perform a role in declarative memory distinct from that performed by the surrounding neocortical structures. The latter structures are held to be an intermediate memory store (ITM) for individual items, whereas the hippocampal formation is the “relational processor.” This modification accommodates the finding that DNMTS for trial-unique cues is impaired by neocortical damage to the perirhinal and parahippocampal gyrus but is unaffected (or only very mildly affected) by hippocampal lesions. The new findings, discussed above, support the relational processing modifications of the declarative memory theory.

One point to note in passing is that, whereas most studies of DNMTS have been conducted using visual cues and objects, olfactory cues have been used extensively in Eichenbaum’s rodent studies. Faster forgetting of olfactory cues after entorhinal lesions was first observed by Staubli et al. (1984). Otto and Eichenbaum (1992) confirmed this finding using a continuous delayed nonmatching task (cDNMT) with odors. Fornix lesions had no effect, whereas perirhinal and parahippocampal cortex lesions caused faster forgetting. Thus, for the type of information used most extensively in the studies on which the theory has been built (odors) an intermediate memory does appear to exist in the neocortical regions of the medial temporal area.

#### 13.5.3 Contextual Encoding and Retrieval

The original version of spatial mapping theory focused on how environmental landmarks of a specific context are explored and integrated into spatial maps for the purposes of navigation (O’Keefe and Nadel, 1978). However, “context” can

be important in ways other than as a space to be moved around. Memories of discrete events could include associations between an event and its context, such as the place or time at which the event happened (Nadel and Willner, 1980). Generally, a context has also to be learned about before the representation of it can enter into other associations (Fanselow, 1990), but although this representation is often spatial it need not be (Jeffery et al., 2004). It could include temporal cues, particularly during extinction of conditioned associations (Bouton, 2004); it may include feelings associated with administered drugs (Overton, 1964) or naturally occurring motivational states such as hunger or thirst (Davidson, 1993). A context may also be “cognitive” as in the mental frameworks or schema associated with particular classes of problem (Morris, 2006). The importance of context-dependent memory is well demonstrated by occasions on which it fails, such as when we embarrassingly fail to recognize a person we have recently met in a different context. Contextual encoding is clearly an effective, often automatic associative mechanism for binding events into memory.

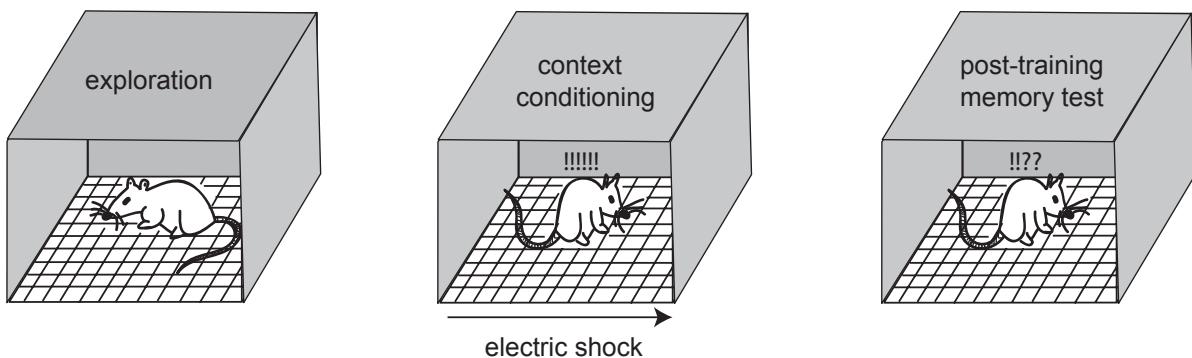

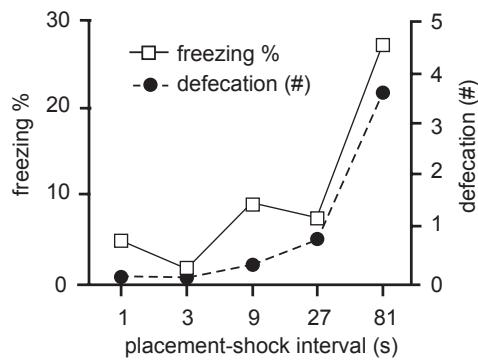

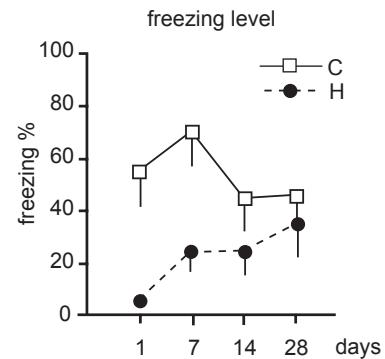

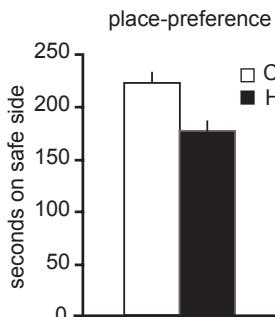

As shown in Figure 13–33B, the modulation of memory by contexts can be mediated by distinct associations and associative processes (Balsam and Tomie, 1985; Bouton and Moody, 2004). As with the formation of stimulus configurations or relational associations, contexts can influence the attention paid to a stimulus, “set the occasion” for a stimulus to predict one outcome or another, disambiguate stimuli and their predictive significance in other ways, or provide an incidental or deliberate way of organizing attended information. In general, the ability to form context-event associations is parasitic upon animals having previously developed a memory representation of the context if that is necessary (which may take time) and upon the occurrence of rapid one-trial learning (because unique events do not happen twice).

It turns out that some of the distinct aspects of contextual encoding, modulation, and recall depend on the hippocampus, but others do not. Accordingly, a simple formula such as “context-learning = hippocampus-dependent learning” is inadequate. Experiments on the role of the hippocampal formation in context-associated information processing have now developed a number of subtleties, and their discussion leads us on toward a more “episodic” account of hippocampal function.

### Context Fear Conditioning

A learning paradigm called “context fear conditioning” is now widely used to study context-event learning. It is rapidly learned (Fanselow, 1990), generally though not always hippocampus-dependent (Winocur et al., 1987; Selden et al., 1991; Gisquet-Verrier et al., 1999), and has proved ideal as a rapid assay of lesion, drug, and forebrain-specific genetic manipulations that might differentially affect short- and long-term memory for fear and the signal-transduction mechanisms engaged in its consolidation (Aiba et al., 1994; Frankland et al., 2001; Ohno et al., 2001).

Fear conditioning to a discrete stimulus is mediated by the amygdala (Davis et al., 1993; LeDoux, 2000; Maren, 2005). Whether shown as an altered startle response or somatic immobility (“freezing”), circuits interconnecting the lateral, basolateral, and central nuclei in the amygdala have been implicated in fear conditioning using lesion, pharmacological, single-unit, and LTP studies. However, the amygdala interacts with the hippocampus in certain forms of fear conditioning. The most widely used “context-freezing” task, as developed by Fanselow, involves three conceptually separate but often overlapping phases (Fig. 13–40A). First, the rat or mouse is placed into a distinctive box with a grid floor (the context) and allowed to explore it with a view to forming an integrated representation of its shape, appearance, odor, and somatosensory characteristics. This learning takes a minute or two, a fact that points to a somewhat neglected link between this form of associative conditioning and exploratory behavior. Second, a weak or intermediate-intensity electric shock is delivered to the animal through the grid floor. This may be during the same session as the initial exploration or a later one (protocols differ slightly across laboratories). In either case, the animal’s reaction to the shock may be barely detectable, it may run around for a bit, or it may immediately remain immobile. Whatever its immediate or “unconditioned” reaction to the shock, this behavior gradually gives way to sustained periods of immobility in which practically the only observable movement is breathing. This conditioned reaction (CR) is a “species-specific defense reaction” (Bolles, 1970) shown by various rodent species and is generally called “freezing.” The probability of freezing varies as a function of the number and intensity of the shocks delivered. If the initial exploratory period is not included, contextual fear conditioning does not occur (Kiernan and Westbrook, 1993), a phenomenon that Fanselow (1990) referred to as the “immediate shock effect” (Fig. 13–40B). However, when sufficient exploratory time in a context is allowed, subsequent fear conditioning occurs successfully. This learning phase ends with the animal’s return to its home cage. The third phase of testing involves returning the animal to the context at a prescribed memory interval after training (e.g., the next day). The experimenter monitors the level of freezing (Fig. 13–40C). Little freezing is seen during a postoperative memory test in rats subjected to hippocampal lesioning soon after context fear conditioning. However, the extent of freezing increases systematically as a function of the interval between context fear conditioning and the time when a hippocampal lesion is created (Kim and Fanselow, 1992). Animals that have conditioned well typically freeze for as much as 60% of a short testing session. This freezing response is only slowly forgotten over time (weeks or longer) and only extinguished by repeated context exposures in the absence of shock. Studies of the extinction of conditioned fear, including contextual fear, are currently a focus of considerable interest for their translational implications for the treatment of posttraumatic stress disorder (Cahill and McGaugh, 1996; Ressler et al., 2002; Nader, 2003).

**A** Contextual fear conditioning**B** Immediate shock effect**C** Context freezing**D** Preference for a safe context

**Figure 13–40.** Context fear conditioning. *A*. The three phases of training: context exploration, fear conditioning, and posttraining memory testing (Source: After Fanselow, 1990.) *B*. The “immediate shock effect” that reflects the absence of context fear conditioning unless sufficient time is allowed to explore the context (Source: After

Fanselow, 2000.) *C*. The extent of freezing as a function of the interval after context conditioning before a hippocampal lesion is made. (Source: Kim and Fanselow, 1992.) *D*. The impact of hippocampal lesions on place-preference as a measure of context fear. (Source: Selden et al., 1991.)

Although by far the most popular, freezing is not the only measure used to assess fear conditioning. Other measures used include the relative preference for a safe unshocked chamber compared to the conditioning chamber to which it is connected or the extent to which fear, conditioned to a discrete CS, inhibits appetitive or consummatory behavior. Selden et al. (1991) examined both the extent to which a clicker stimulus (the discrete CS) would evoke fear after pairings with shock and the extent to which an initially nonpreferred and brightly lit white chamber would be favored over a black one in which the clicker and shock had been presented (the safe and conditioning contexts, respectively). They observed a double dissociation between the effects of excitotoxic amygdala and hippocampal lesions on fear conditioning to explicit and contextual aversive cues. Amygdala lesions selectively impaired conditioning to the clicker measured by its capacity to reduce drinking (i.e., inhibition of consummatory behavior). Hippocampal lesions selectively impaired conditioning to the context measured by the proportion of time spent in the black and white chambers in a preference test (Fig. 13–40D). Independent work by other groups confirmed the double dissociation between the dependence of contextual

freezing on the integrity of the hippocampus and of tone-elicited freezing on the amygdala (Kim and Fanselow, 1992; Phillips and LeDoux, 1992). The hippocampal dependence of contextual freezing seems to be unrelated to the level of activity the animal displays in the conditioning chamber prior to shock delivery (Gewirtz et al., 2000). This lack of correlation is important, as it is known that hippocampal lesions can sometimes cause hyperactivity (e.g., during exploration of a novel environment), and the deficit in context freezing might therefore have been no more than a secondary, nonmnemonic consequence of a lesion-induced alteration in motor behavior. Two arguments marshaled by Fanselow (2000) against this possibility include the selectivity of the hippocampal lesion deficit to context but not discrete CS-associated fear and the presence of a within-subject temporal gradient of retrograde amnesia for discriminable contexts (see below). Thus, although other measures have been developed that would not be subject to the hyperactivity objection, freezing has retained its popularity, and the research field has stuck to it.

The difference between fear conditioned to a discrete CS (amygdala-dependent) and to a context (hippocampus-dependent) reflects the prior learning of the context. Fanselow

suggested that the rat must first form “an integrated mnemonic representation of the many features of the context and the rat must have this representation in active memory at the time of the shock” (Fanselow, 2000, p. 75). He likened it to a “Gestalt” memory of the environment, analogous to the spatial maps that O’Keefe and Nadel (1978) had suggested are formed during active exploration. It is therefore noteworthy that this necessary time period of exposure to a novel conditioning chamber is similar to that which Bostock et al. (1991) first reported to be necessary for rats to form a stable hippocampal firing field in a novel recording chamber. This “unified representation” of the environment then functions as an “configural” stimulus that, through classical conditioning, is associated with shock—in a manner essential identical to that implied by the configural association theory. Rudy and O'Reilly (1999) provide direct support for this view in experiments with normal rats in which they showed that preexposure to the conditioning context, but not to the individual stimulus elements that made up the context presented one after the other, facilitated later contextual fear conditioning. They also established that the extent to which fear conditioning generalizes to other contexts that had not been used for conditioning is influenced by preexposure in a manner suggestive of “pattern completion” during conditioning (see Chapter 14). Specifically, if contexts X and Y contain common elements and context Z is quite different, preexposure to context X but not to context Z facilitates generalization to context X after fear conditioning in context Y. These observations, reminiscent of Guzowski’s data obtained using the immediate early gene *Arc* (see Section 13.4) suggest that contextual freezing reflects fear elicited by a “stimulus” that is a mental entity: It is a conjunctive memory representation of the environment based on polymodal sensory information. This led Rudy to an ingenious test of his context preexposure facilitation (CPF) concept. Rats were led to expect, over a series of exposure days, that being transported in a distinctive container around the laboratory would always end in them being taken to a particular test chamber (context A). On the critical conditioning day, they were transported in the container but unexpectedly put into a distinctively *different* test chamber (context B) and given an immediate shock. Remember that immediate shock does *not* ordinarily result in context fear conditioning; and, consistent with this, no contextual fear conditioning occurred to context B. However, the rats displayed freezing when placed in context A, the context they had expected to arrive at after transport in the distinctive container but not the one in which they actually received the shock. This “CPF effect” was not observed in rats with hippocampal lesions (Rudy et al., 2002).

A complication to the story that the hippocampus is critical only for contextual fear conditioning is that several studies have shown that disruption of the ventral hippocampus (with lesions or drugs) can disrupt fear conditioning to a discrete CS such as a tone (Bast et al., 2001; Zhang et al., 2001). This may, in part, be due to the presence of direct afferents from the ventral hippocampus to the amygdala (Pitkänen et al., 2000) that ordinarily mediates CS fear conditioning. Whatever the rea-

son, a one-to-one association between hippocampal processing and context freezing is an oversimplification.

### Differential Effects of Hippocampal Lesions Before and After Fear Conditioning

The importance of exploratory learning about the context is relevant to a puzzling feature of studies examining the impact of hippocampal dysfunction. Hippocampal lesions made shortly *after* conditioning are effective in blocking contextual freezing (Kim and Fanselow, 1992; Phillips and LeDoux, 1992, 1994; Maren et al., 1997; Frankland et al., 1998), whereas those made *prior to* conditioning have varied effects (Winocur et al., 1987; Maren et al., 1997; Gisquet-Verrier et al., 1999; Maren, 2001). This dissociation with respect to the relative timing of training and the lesion is not because the lesions are incomplete (although often they are). Clearly, were they incomplete, there may be sufficient spared tissue for hippocampus-dependent learning to occur when the lesion is made prior to conditioning. That this is *not* the explanation for the differential effects of lesions made pretraining versus posttraining is because if an identical incomplete lesion is made after training a substantial deficit in context fear conditioning is still observed.

The likely explanation for the differential effect, as outlined by Maren et al. (1997), Rudy and O'Reilly (1999), and Anagnostaras et al. (2001), is that an animal with a hippocampal lesion prior to conditioning is predisposed to associate the fearful shock with some “elemental” feature of the conditioning chamber (e.g., its smell) rather than the “unified representation” that because of the lesion it is unable to form. As this type of single-stimulus classical conditioning is unaffected by hippocampal lesions, less disruption of contextual freezing is to be expected in the anterograde domain. This possibility alerts us to the importance of the exact design of the chambers in which these sorts of experiments are conducted. Different contexts are sometimes readily distinguishable in terms of an elemental feature; in other cases, they may only (or more readily) be distinguished by the set of cues that forms a single unified representation. The devil is again in the detail with respect to understanding the pattern of results, particularly in relation to the impact of genetic manipulations that, unless inducible, occur long before conditioning. As inducible, region-specific mutations are rare, we do not include a discussion here of this developing and important field but do recognize its likely importance in the years ahead.

Creating lesions after training offers the opportunity to use contextual freezing as a way of investigating the temporal gradient of retrograde amnesia. Rapid learning (during a single session) and the fact that retention is extremely robust over time are features that render the task highly suitable. Kim and Fanselow (1992) produced electrolytic hippocampal lesions in rats 1, 7, 14, or 28 days after cued and context fear conditioning. As noted above (Fig. 13–40C), a graded deficit in contextual freezing is seen as a function of the training–lesion interval, with animals given lesions 28 days after training

being indistinguishable from those that underwent sham surgery. This finding was interpreted in terms of a time-dependent consolidation process for contextual fear, consistent with declarative memory theory. Maren and Fanselow (1997) obtained similar results, but only over much a longer time interval, in animals with excitotoxic hippocampal lesions. An elegant within-subjects study by Anagnostaras et al. (1999) examined the effects of electrolytic hippocampal lesions on animals conditioned in two highly distinctive contexts with training scheduled 50 days apart. Conducted at UCLA, the two contexts were named after two famous streets in Hollywood. The "Sunset Room" was a darkened laboratory containing conditioning chambers that were triangular, had white plastic walls, and were scented with acetic acid. The "Wilshire Room" was a distinctive, well lit laboratory with conditioning chambers that were rectangular, made of aluminum and plexiglass, and scented with ammonium hydroxide. Previous work had indicated that there is little generalization between these two environments; the animals would have readily distinguished them during training and testing. The key finding was that lesions made shortly after context fear conditioning in the Sunset Room but 7 weeks after conditioning in the Wilshire Room (or vice versa) impaired later expression of the recent memory but not remote memory. "Location, location, location" is, not surprisingly—as important in Hollywood as anywhere else.

### **Contextual Control of Stimulus Significance?**

There are ways in which context can affect behavior other than by entering into associations with the US as in context freezing. One way is to modulate the effectiveness of other associations. As noted long ago by Nadel and Willner (1980), contexts can be said to "contain" events that occur within them. The relation between cue and context is then "hierarchical" rather than associative in the traditional sense. Work by Moita et al. (2003) nicely illustrates the impact of contextual cues on CA1 pyramidal cell firing during auditory fear conditioning (see Chapter 11). Place fields were first observed in the conditioning chamber prior to fear conditioning. Rapid fear conditioning then took place over a few trials in which shock was presented at the end of a white-noise CS, with a control group receiving temporally random presentations of the white noise and shock. Freezing was observed in response to the CS. In parallel, there was an increase in CA1 cell responsiveness that was specific to the place fields in the chamber where a specific cell normally fired. This suggests that the spatial representation encoded and stored during the earlier exploration can incorporate elements of the task-related fear conditioning events into its representation.

Contexts can also "set the occasion" for a particular cue having a particular significance or meaning. Good and Honey (1991) developed the first satisfactory experimental design to investigate the role of the hippocampus in such a process. Their protocol ensured that subjects became familiar with two contexts (operant conditioning chambers) and two distinct

cues (tones and clickers) and were equally reinforced in relation to both sets of cues. Rats were trained in an appetitive paradigm (collecting food pellets) in which one discrete stimulus (A) was reinforced in one context (X), whereas a second stimulus (B) was reinforced in Y. The critical test of the ability of either context to retrieve the appropriate significance of these cues was to present, for the first time, A in context Y and B in context X. The phenomenon of "context specificity" was displayed as a reduction in the appetitive responses elicited by A and B in their now "inappropriate" contexts. Rats subjected to electrolytic (Good and Honey, 1991) or neurotoxic (Honey and Good, 1993) hippocampal lesioning failed to show this reduction of conditioned responding. This failure was not because the subjects with lesions could not discriminate the two contexts; a separate experiment established that they had no difficulty in doing this when only one of the two contexts predicted the availability of reinforcement.

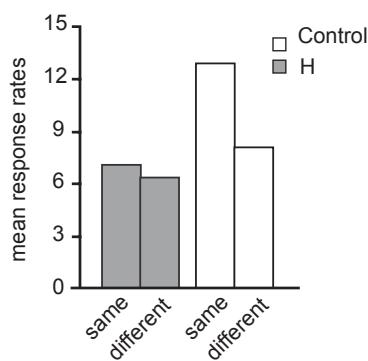

The implication appeared to be that the integrity of the hippocampus is necessary for a process associated with the contextual control of associative conditioning—associative retrieval—rather than learning a unified representation, as described by Fanselow. However, this implication is insecure for two reasons. First, remember that even the ostensibly robust deficit in contextual freezing induced by hippocampal lesions does not always occur if the lesions are produced before training as they were in the Good and Honey (1991) experiment. Second, Good and Honey's deficit in contextual retrieval has not proven easy to replicate in other laboratories. A series of experiments by Hall et al. (1996) failed to do so, and later work showed that hippocampal lesions have no effect on the rate of learning a conditional context discrimination test over a series of test sessions (McDonald et al., 1997).

Good et al. (1998) put forward the suggestion that there may be a subtle but important difference between the "incidental" processing of contextual cues (when their processing is not formally necessary to learn a task) and the "intentional" or "contingent" processing of contextual cues (when their processing is essential for learning that task). Their results indicated that when rats with hippocampal lesions were required to use context cues over several sessions to differentiate the stimulus significance of discrete cues, there was no deficit. However, when the animals were presented with a single unexpected context specificity test, with context novelty controlled, the hippocampus-lesioned group was impaired (Fig. 13–41). The possibility that there may be something critical about the hippocampus in relation to the distinction between automatic and deliberate processing is directly relevant to the conjunctive representations theory (O'Reilly and Rudy, 2001), an issue we revisit in the section of episodic memory, below.

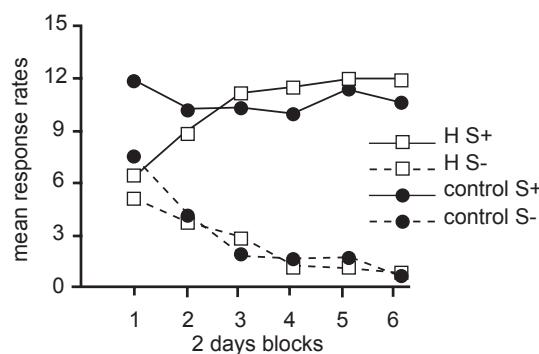

### **Hunger and Thirst as Contexts**

Patient H.M. is unable to report whether he is hungry. He does not ask for meals and, quite soon after eating, attempts to eat again if a plate of food is placed before him (Hebben et al., 1985). That he may have forgotten that it is a long time since

**A Incidental context specificity**

**B Contingent context-specificity**

**Figure 13–41.** Incidental versus contingent processing of context cues. A. When the discrete CSs predicting the availability of food in the conditioning chamber were unexpectedly presented in the other context, controls but not hippocampus-lesioned rats showed a decrease in responding. B. When the discrete CSs were repeatedly

presented in both contexts and differentially rewarded in each of them, both control and hippocampus-lesioned rats readily learned to discriminate their significance appropriately. (Source: After Good et al., 1998.)

he last ate or that he has just had a recent meal is unsurprising—yet another indication of his memory deficit—but that he has apparently no awareness of the internal state of hunger or its absence is an additional deficit. Motivational states could contribute to the contextual control of behavior.

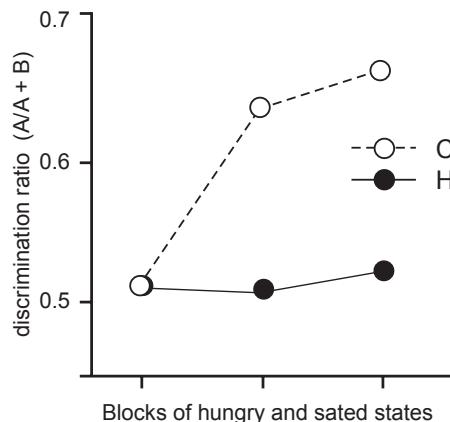

A number of animal experiments have addressed this question, with early studies using spatial tasks in which a rat was required to perform one spatial response when hungry and a different one when thirsty. Rats could learn this interesting contextual-dependent task, but any lesion-associated deficit could arise because of a failure to discriminate the motivational states, failure to use this information to retrieve the appropriate response, or failure of spatial memory itself. Davidson and Jarrard (1993) examined a nonspatial task in

which placement in an operant chamber was associated with footshock when the rats were hungry but not when nondenprived (or vice versa). An  $A/(A+B)$  type of discrimination ratio was used to measure the relative degree of conditioned freezing in the two situations, and the data in Figure 13–42A indicate that normal animals could learn this discrimination, whereas rats with neurotoxic lesions of the hippocampus and dentate gyrus could not. A later study by Kennedy and Shapiro (2004) sought to distinguish involvement of the hippocampus in learning such a discrimination and a role in contextual retrieval. Three visual distinct goal-boxes (shown graphically as black, gray, and white in Fig. 13–42B) were, across successive trials, randomly placed at the ends of the arms of a three-choice “pitchfork”-type maze and the animals’ deprivation

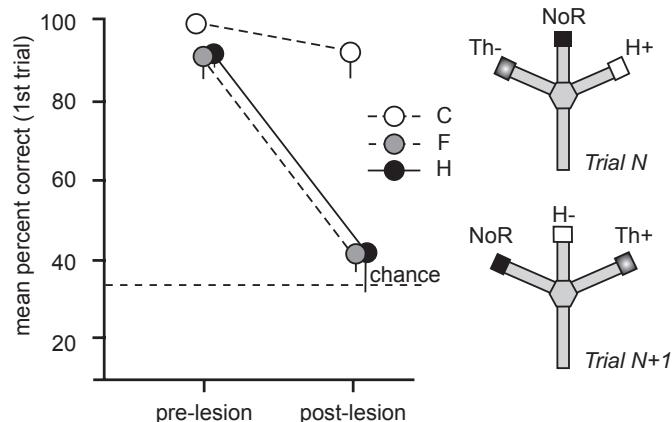

**Figure 13–42.** Motivational states as hippocampus-dependent contextual cues. A. Control but not hippocampus-lesioned rats learned to discriminate whether to be afraid in a place as a function of their state of hunger. (Source: After Davidson and Jarrard, 1993.) B. After preoperative training to choose a visually distinctive goal box to secure an appropriate reward when hungry or thirsty, rats with

fornix or hippocampal lesions were no longer able to use their deprivation state to retrieve a memory of the appropriate response. They did, however, continue to avoid the never-rewarded goal box. Goal boxes were moved randomly across trials. H+, food available to a hungry rat; NoR, never-rewarded box; Th+, water available to a thirsty rat. (Source: After Kennedy and Shapiro, 2004.)

**A Hunger as a context for fear**

**B Hunger and thirst as contexts for discrimination**

state switched between hunger and thirst on alternate days. One goal-box provided food if the animals were hungry (but not otherwise), another supplied water if they were thirsty, and the third never provided reward. Before any lesions were made, training showed that the animals could learn to make the appropriate choice as they ran the maze. After fornix lesioning or neurotoxic hippocampal lesioning, the ability to choose between the hunger and thirst boxes fell to chance, although the animals continued to avoid the goal-box that never provided reward. The sham-lesioned rats continued to perform effectively. Occasional probe trials were scheduled in which hunger was repeated across two successive days; choice behavior continued to be controlled by motivational state rather than any alternation pattern in the sham-lesioned controls. Different results in a similar task were reported by Deacon et al. (2001), but all training was postoperative and a reward was consistently available independent of motivational state. The rats with hippocampal lesions may therefore have solved the task by updating their predicted “value” of the reward (i.e., food when hungry and food when sated) using an amygdala-dependent learning process. Accordingly, it seems secure to conclude that the hippocampus is required for using internal motivational states in a contextual manner for memory retrieval.

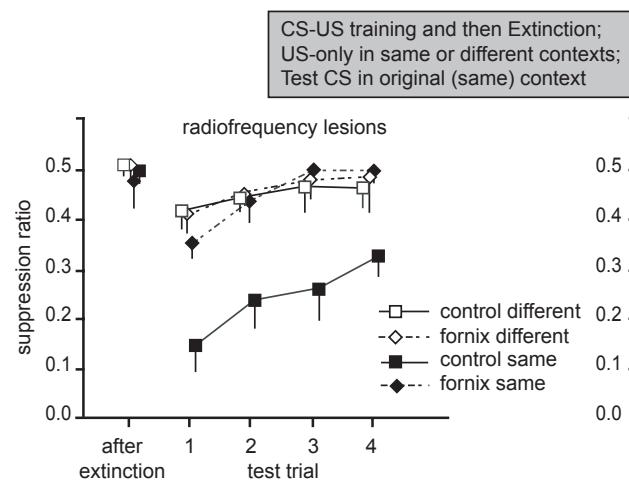

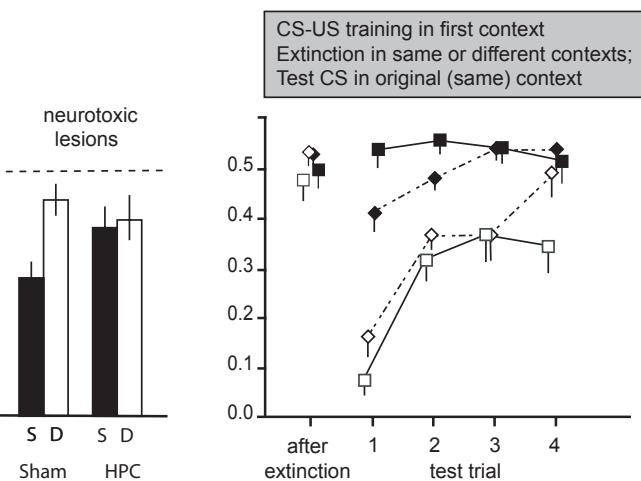

### Contextual Control of Extinction

The phenomenon of “extinction” refers to changes in learned behavior that occur when a stimulus or a response is no longer followed by the reinforcement with which it was previously associated. In the extinction of classical fear conditioning, a tone (CS) that has previously predicted the imminent arrival of shock (US) is now followed by nothing. What then happens, in terms of performance, is that the overt expression of the prior conditioning becomes weaker over successive extinction trials. An old-fashioned view of this change is that extinction is some kind of “unlearning” process, a breaking of the associative bonds between cue and consequence. However, various phenomena discovered about the determinants of extinction have led many to doubt that unlearning is what normally occurs. Extinction is more often a learning process in which contextual factors play a particularly important modulatory role—the extinction context altering what US memory is retrieved when the previously trained CS is presented (Bouton and Moody, 2004). During training the CS comes to evoke a memory representation of the US; during extinction it may acquire a memory representation of “no-US” (as in Fig. 13–33), but importantly there is no overwriting of the previous CS–US association. Which memory is retrieved in a given memory test depends on the context of testing, with the nature of the environment and how it differs from other environments, the passage of time, or other factors influencing the operative “context” as it is perceived by the animal. As Bouton and Moody put it, “the fact that extinction is more context-dependent than conditioning is consistent with the idea that the animal codes extinction as a kind of

conditional exception to the rule—one that depends on the current context” (Bouton and Moody, 2004, p. 665).

Studies by Bouton have implicated the hippocampus in certain extinction phenomena but not others. Wilson et al. (1995) using fornix lesions and Frohardt et al. (2000) using neurotoxic hippocampal lesions have provided evidence that the integrity of hippocampal function is needed for a context-processing phenomenon called “reinstatement” but is not required for another phenomenon called “renewal.” The distinction between them is important. Both are instances in which an initially conditioned and then extinguished CR recovers. Reinforcement is said to occur after independent presentations of the US in the same context as original training, with memory test consisting of CS presentations in this same context (reinforcement of the CR does not occur if the US presentations occur in a different context). In renewal of the CR, the previously trained CS is extinguished in a different context and then tested in the original training context (renewal does not occur if CS extinction occurs in the same context throughout). These experiments used the classic paradigm of conditioned suppression in which rats were first trained to press a lever for food reward in each of two contexts. They were then presented with a CS (lights turning off) on a number of occasions, this stimulus being paired with weak electric shock (US). Rats reduce their rate of appetitive responding during the CS (“conditioned suppression”), and this decline in operant responding served as a quantifiable measure of fear in much the same way as freezing. Once trained in this way, the CS was then “extinguished” by being presented several times without shock over a series of lever-pressing sessions. Rates of operant responding recovered until they were as high during the CS as in its absence (this is expressed as a “suppression ratio” calculated as CSrate/(CSrate + preCSrate), a measure that tends toward 0.5 when rates of responding have equilibrated). Reinforcement was observed as the selective recovery of the fear response to the CS (i.e., somewhat confusingly, this is a return to a *low* suppression ratio) after rats had been exposed several times to the US alone in the training context. Critically, this reinstatement effect occurred in control animals but not in subjected to fornix or neurotoxic hippocampal lesioning (Fig. 13–43A). Conversely, renewal of the CR occurred just as much in control as in lesioned rats using an ABA design in which the CS was extinguished in a different context (B) from that in which it was initially conditioned and later tested (i.e., context A) (Fig. 13–43B).

Both phenomena are context-dependent, but Bouton argued that the reason reinstatement is hippocampus-dependent, but renewal is not, is because the hippocampus is important for context–US associations but not for all forms of contextual modulation of retrieval such as positive occasion-setting or conditional rules. A strong context–US association rapidly created by the unsignaled US presentations retrieves a memory representation of the shock and, consequently, reminds the animals of the original CS–US association. That is, the re-presentation of the ostensibly extinguished CS then retrieves a memory of the US (with which it was associated

**A Reinstatement (Hippocampus-dependent)****B Renewal (Hippocampus-independent)**

**Figure 13-43.** Reinstatement and renewal after the extinction of classic fear conditioning. A. Using conditioned suppression of operant responding as a measure of conditioning, presentation of the US only in the same context as that in which CS-US conditioning had taken place “reinstated” conditioned fear in control rats but not

those that had fornix (left) or neurotoxic hippocampal (right) lesions. B. Renewal of fear to a conditioned CS was observed in both controls and fornix-lesioned groups after the CS was extinguished in a different context. (Source: After Wilson et al., 1995 and Frohardt et al., 2000.)

during training) rather than of the absence of the US (as had developed during extinction). This inferential feature of context-dependent modulation of conditioning critically involves context-US associations and thus the hippocampus. In renewal, the subject also learns a CS-US association during training and a CS-NoUS association during extinction. However, in contrast to reinstatement, there is no strong hippocampus-dependent context-US association formed. Instead, the animal’s representations of the two contexts (training and extinction) modulate whether the CS-US association or the CS-noUS association is evoked, and this modulation does not require the hippocampus. It is most likely mediated by neocortical circuits on their own. Frohardt et al. (2000) offer several reasons from the animal learning literature for recognizing renewal and reinstatement as separate context effects.

This tidy picture is complicated in two ways. First, a study by Fox and Holland, (1998) that found no effects of neurotoxic hippocampus lesions on reinstatement in an appetitively motivated task. It is possible that context-US associations in appetitive conditioning are weaker than in aversive conditioning because food also occurs in the home cage, whereas shock is specific to the testing chamber. However, a clear reinstatement effect was observed in the appetitive task, the difference being that it was just as great in the rats with hippocampal lesions. An alternative and more parsimonious explanation concerns the complication, noted earlier, of elemental versus configural/conjunctive representations of contexts. In these extinction studies, the hippocampal lesions are made prior to conditioning. We have noted that contextual fear conditioning sometimes occurs normally in such animals, as they have the opportunity of representing the context with reference to

some isolated or elemental feature of the testing chamber. One way to reduce the likelihood of this happening in animals that already have lesions is to ensure that two contexts are used in the behavioral protocol and that the critical manipulations are scheduled for only a short period (e.g., one session). The Bouton studies used two contexts that differed in quite subtle ways (e.g., the orientation of the grid bars), whereas the appetitive study by Fox and Holland did not (they used the control procedure of no US reexposure). Thus, the animals in the appetitive study of reinstatement after extinction would have been able to form an “elemental” context-US association using neocortical circuitry, and this may have been sufficient to remind the animals of which CS-US association to recall as effectively in lesioned as in normal rats.

Another problem is that the “renewal” phenomenon is sensitive to muscimol-induced reversible inactivation of the hippocampus (Corcoran and Maren, 2001, 2004; Corcoran et al., 2005). In contrast to the argument just given, Maren argued that Bouton’s use of pretraining lesions would have allowed “elemental” representation of the two contexts and thus a hippocampus-independent form of contextual-dependent renewal of extinction in the lesioned rats. His use of post-training muscimol infusions would have made it more likely that a configural representation, acquired normally during fear conditioning and extinction, would have been disrupted. However, this explanation does not seem to account for the dissociation between renewal and reinstatement observed in the permanent lesion studies. Another concern is that the spatial extent of the inhibition of hippocampal activity by the muscimol infusions was revealed in autoradiographic studies to be quite small and extended as much into cortex as it did along the longitudinal axis of the dorsal hippocampus

(Corcoran et al., 2005). If renewal is mediated by a form of contextual modulation controlled by extrahippocampal circuits (Bouton and Moody, 2004), these infusions may have disrupted a cortex-mediated component of that process also. As noted before, the use of reversible inactivation is analytically more powerful than permanent lesions, but there are technical problems to its use that should be recognized (Anagnostaras et al., 2002).

### 13.5.4 Critique

The valuable common feature of the three theories just discussed is their serious attempt to tackle the fundamental problem of dealing with ambiguity in memory. However, stepping back from the details of individual experiments, aspects of each of the ideas are problematic.

First, although it is easy to understand the selection pressure for memory systems for remembering facts and events or finding one's way around, it is not clear why mammals would have evolved a specialized neural system for solving nonlinear discrimination tasks. Ambiguity of cue significance may be a task a scientist can invent, but is it rife in nature? To be sure, there are observations indicating that monkeys execute different behavioral actions in response to distinct fear-evoking stimuli (e.g., snakes, eagles), but the stimuli from the animals and the calls then given by troop members are in no way ambiguous (Seyfarth et al., 1980). Where ambiguities do occur, they generally arise as a function of the spatiotemporal context of events and can therefore be solved without recourse to configuring. Whether an animal should freeze or flee upon hearing the sound or smell of a predator more likely depends on the relative safety of the location it presently occupies. Configuring stimuli might help solve tasks of a particular logical structure; however, for example, the occasional failure of rats with hippocampus lesions to learn transitive discrimination tasks could actually be secondary to deficits of a different kind—the inability to form relational representations or to allow a context to modulate retrieval.

Second, the relational processing theory is built around the idea that associative relations may be more abstract and more flexible than implied by traditional theories of conditioning, with their emphasis on associative strength and unlabeled associations. There are, however, aspects of the theory that seem vague. Critics such as Mackintosh (2002), prefer the precision of quantitatively precise theories of associative learning, which assert that a variety of qualitatively different associations can occur such as excitatory links, inhibitory links, and stimulus representations that set the occasion for the retrieval of others. This complexity of conditioning aside, consideration of even the simplest of associations—the pairing of a tone with shock—illustrates the problem of identifying the type of association. Is a tone–shock pairing relational or nonrelational? Can it be either depending on the training situation? In terms of the animal's phenomenal experience, the tone may come to evoke the memory representation of something painful about to happen, or it may simply assume high associative strength

that somehow triggers freezing. The speed of learning a tone–shock relationship and its ready expression in novel testing situations points to it being, by Cohen and Eichenbaum's definition, a “flexible” representation. Conversely, its slow rate of extinction suggests it is inflexible. In this and other examples, independent rules for identifying into which category an association should be classified other than observed effects of hippocampus lesions do not seem to exist. We are back to the issue that has long haunted declarative memory theories: irrefutability arising from logical circularity.

Third, both the configural and relational theories also lack detail at the level of neurobiological implementation. We are still at an early stage of thinking about how the circuitry of the hippocampal formation is used for forming or storing configural/relational associations, how it could implement the selective enhancement of the salience of configural units elsewhere in the brain, or how it could realize memory representations that would somehow afford flexibility at the time of retrieval. What are the relative roles of the dentate gyrus, CA3, and CA1 in achieving any of these tasks? How might the organization of the mossy fibers and the longitudinal associational pathway of area CA3 help implement stimulus configuring (if it does)? What role might associative LTP play in relational processing? To be fair, the relational theory has taken an important step in this direction in asserting an anatomically distinct ITM and LTM for isolated stimuli compared to relations.

Finally, fourth, ideas about contextual processing are not immune from some of the same criticisms. When is a stimulus a context and when a “discrete stimulus”? In the animal literature, a context tends to be a box. In the human literature, it is as often the color of the ink in which a word is presented. This is deeply confusing. Furthermore, how precisely can a contextual representation function in the several ways we have discussed? Why is the hippocampal formation involved in some of these aspects of contextual processing but not others? In short, how can a contextual account avoid the same charge of occasional circularity that we have leveled against the declarative memory theory? There are two strands to any answer to these questions. One is that there is a formal body of theoretical work on associative conditioning that has delineated distinct ways in which contexts can enter into associations with CSs and USs or modulate other associations, as represented in Figure 13.33B. Reinforcement and renewal are good exemplars, as their associative basis is operationally quite different, and a specific prediction could then be made about the outcome of a hippocampal lesion. Neuroscientists trying to understand mechanisms at the neural level can capitalize on this prior psychological research—as they have done with such phenomena as the immediate shock effect, the context preexposure facilitation effect, and the distinction between renewal and reinstatement.

The second strand of defense for the context ideas is the sheer plausibility and simplicity of the idea that context plays a critical role in coping with ambiguity. Events happen—at specific moments in time and space and in specific social contexts. Their meaning and significance is often context-

dependent, including semantic knowledge, just as so many aspects of our behavior. In addition, events often happen unpredictably. This simple fact requires that any system whose role is to keep track of the important events of our lives must be able to respond instantly, diverting attentional resources as required and encoding information rapidly as it happens and with reference to the context in which it occurs. This is why the distinction between incidental and contingent processing of contextual information may be important. Context processing, as O'Keefe and Nadel (1978) recognized long ago, has the potential to be one building block of a true episodic memory system. It is to that issue which we now turn.

## 13.6 Episodic Memory, Hippocampus, and Neurobiology of Rapid Context-specific Memory

The last hippocampal theory to be considered, and one in which there is growing interest, is that the hippocampal formation participates in certain aspects of *episodic memory* (in humans) and *episodic-like memory* (in animals). This idea has emerged in an integrative manner from neuropsychological studies of developmental amnesia (Vargha-Khadem et al., 1997) and work concerning scene memory, object–scene associations, and top-down control of memory processing in monkeys (Gaffan, 1994a; Miyashita, 2004). In other animals, behavioral studies of food caching by avian species (Clayton and Dickinson, 1998), studies of sequence learning in rodents (Fortin et al., 2002), single-unit correlates of prospective and retrospective memory (Wood et al., 2000; Ferbinteanu and Shapiro, 2003), pharmacological interventions affecting the encoding and retrieval of rapid paired-associate learning (Day et al., 2003), and genetic interventions targeted conditionally at specific components of hippocampal circuitry (Nakazawa et al., 2003) are all contributing to a developing perspective. That a range of approaches are converging on the same general idea indicates that the theory may be on the right lines (Box 13–9).

### 13.6.1 Concept of Episodic Memory

First introduced by Tulving (1972) and elaborated in a number of ways since (Tulving, 1983, 2004; Schacter and Tulving, 1994), episodic memory refers to the memory of a unique event and/or a temporal sequence of events that collectively comprise an episode. As originally defined, the content of episodic memory is a mental representation of “what” happened during an event, “where” it happened, and “when.” Writing in 1983, Tulving asserted that episodic memory “receives and stores information about temporally-dated episodes or events, and temporal-spatial relations among these events” (Tulving, 1983, p. 385). Thus, remembering what you did on holiday, where you went, and with whom would be an instance of episodic memory. It is contrasted with seman-

### Box 13–9

#### Hippocampus: Episodic and Episodic-like Memory

1. *Conceptual issues:* Episodic memory is the recall, by humans, of discrete events that happened at a particular place and a particular time. Such recall entails mental time travel. Episodic-like memory in animals is the memory of “what, where, and when” with respect to events.
2. *Hippocampal involvement:* The hippocampus is one of a network of brain structures that mediate the automatic encoding and retrieval of attended events and the contexts in which they occur (episodic-like memory). Distinct brain structures, including the prefrontal lobe, mediate different and more volitional aspects of this form of memory.
3. *Differential role of subcomponents:* Components of the hippocampal formation (e.g., CA1, CA3, dentate gyrus) are differentially involved in dissociable components of episodic-like memory, such as pattern separation and pattern completion.
4. *Awareness:* Episodic memory and episodic-like memory are distinguishable, as only the former requires “auto-noetic” consciousness. This cannot, at present, be studied neurobiologically. Awareness may also be an attribute of episodic-like memory in animals, but this need not be auto-noetic.

tic memory—factual knowledge—which is not bound to any temporospatial context.

Episodic memory has several important properties. First, the encoding of attended events often occurs automatically; and by virtue of this the “temporal-spatial relations” of Tulving’s definition cannot be deliberately selected or ignored. “Automaticity” implies that humans cannot normally “turn the system off” and voluntarily decide which attended events or what features of the context in which they occur are encoded (Martin et al., 1997; Morris and Frey, 1997). This paradoxically “reflexive” feature can be illustrated with reference to an example. Imagine that during a routine activity such as a shopping trip you witness a car crash. You were not expecting it to happen nor planning ahead of time to remember it. Still, what happens in front of you automatically commands your attention and it then becomes impossible *not* to encode and later remember that it happened, where it happened, and when. This inevitability of the associations formed at the time seems to be a characteristic of the brain system that processes this information. You get home and tell your family that you saw a car crash. They ask about what happened. You describe the scene of the crash, the crash itself, what happened next, and anything else that was distinctive or unusual. This is straightforward. But how strange it would be to tell your family of having seen a car crash, but then to say that you cannot remember anything about where it happened, stating only that it was “half-an-hour ago and involved two cars and a bicycle.” During ordinary discourse, the “What happened?” enquiry carries with it the implicit trilogy of “what, where, and when.”

This automatic “binding” of event, place, and time information is a characteristic of episodic memory that has neurobiological implications. It points to the need for a memory system that has anatomical access to highly processed information from all sensory modalities, is downstream of the attentional filters of the neocortex and the perceptual mechanisms for object-centered representations, and is downstream of but reciprocally connected with semantic memory. It must also be a system that stays online, can encode information rapidly, and is generally independent of volitional control. This last qualification of the automaticity property arises because some aspects of episodic memory can be volitional. For example, subjects in a neuropsychology experiment asked to learn a set of novel paired-associates or to remember a passage of prose are deliberately cooperating in a learning exercise. Their later memory of what happened is clearly an instance of episodic memory, but it occurs in the context of an intentional course of action, unlike the event of witnessing a car crash.

The “what-where-when” definition also captures a second important feature of episodic memory that marks it off from semantic memory, the other major category of declarative memory. This is the need for “mental time travel” as a part of our phenomenological experience of remembering. This concept may feel a bit fuzzy at first, but it is crucial. A person remembering an event, as distinct from merely declaring they know something, travels in their mind through time to that moment in the past when the event happened. Their experience is then one of being simultaneously *in the present* while also *reexperiencing the past*, a mental coexistence that transcends time. This is one of those psychological juxtapositions that may never have seemed paradoxical until it is pointed out: Mental time travel is a capacity of mind that we all take for granted, is apparently effortless, and yet is extraordinarily complex. Efforts to get a handle on this experimentally is sometimes done by asking subjects to make a subjective assessment of whether they “remember” or merely “know” something. We do not yet have the ability to pose such a question to animals in a neurobiological study.

Tulving (2004) made the strong claim that the capacity for mental time travel is unique to humans. Suddendorf and Corballis (1997) shared this view, arguing that animals are forever mentally trapped in the present or, as Roberts (2000) so nicely put it, they are “stuck in time.” This is a controversial claim, as biological scientists are rarely at ease with unsupported claims of human uniqueness. Like Pinker’s arguments for the uniqueness of human language (Pinker, 1994), Tulving asserted the human uniqueness of mental time travel in an arresting way. There are, he wrote, “things that bees, birds and humans all do. But there are also things that bees do but birds and humans do not. There are things that birds do that bees and humans do not. And there are things that humans do that bees and birds do not.”

A third feature of episodic memory is that the event being remembered may be one in which subjects actually participated themselves (e.g., playing in a game of football) or one that was merely observed (e.g., seeing a dangerous animal). Tulving (1983) revised his earlier definition of episodic mem-

ory by adding that the observer needed to have a particular sense of self-identity. He called it “autonoetic consciousness.” This form of self-consciousness is necessary for memories of the form “I remember scoring a goal” because such a memory entails a sense of self-identity. Opinion is divided, however, on the need for so sophisticated a form of awareness for all types of event memory. It is far from clear that one needs a sense of self-identity to recall having seen a dangerous animal, yet one can readily imagine evolutionary selection pressures that led to a brain system, present in nonhuman animals, for the effective memory of having seen a predator at a particular place and a specific time. Animals that stay that much safer by having such a memory system may or may not have a sense of self-identity. Tulving nonetheless insisted on his autonoetic consciousness criterion for “true” episodic memory, but this is impossible to apply to animals because we are unlikely ever to know whether animals have a sense of self-identity (Clayton et al., 2003b). Episodic memory may or may not be uniquely human and so may or may not reflect distinctive features of the human brain.

Given this somewhat metaphysical state of affairs, Griffiths et al. (1999) introduced the term “episodic-like” memory. This is something that can be defined behaviorally in terms of Tulving’s older 1972 definition as memory for “what, where, and when” with the autonoetic aspect finessed for the time being. Meeting even this ostensibly more modest requirement for demonstrating episodic memory remains far from easy. Considerable ingenuity is required of behavioral scientists to invent novel memory tasks with the appropriate attributes to do it successfully (Morris, 2001). Much of what is available so far, including the many hippocampus-dependent tasks discussed in this chapter are not up to the task (Hampton and Schwartz, 2004).

However, suppose that an animal model of episodic-like memory were possible. Its value would be that we would then be able to get a handle on the neurobiology of rapid, context-specific memory formation with access to the usual range of anatomical, physiological, and biochemical data necessary for making causal inferences. It could then be classified as the class of vertebrate memory that refers to unique events and for which the representational content varies in a species-specific manner. There is nothing special about such a comparative perspective. Procedural learning is just the same—the motor skills that can be learned by a bird, bee, or human vary considerably—yet Tulving would not deny that all three species have a nonpropositional form of learning that can be classified as “sensorimotor procedural skills.” By analogy, perhaps episodic-like memory may vary as a function of phylogeny with respect to both content and degree of awareness. It may have evolved in vertebrates as a “one-shot” memory because it was evolutionary adaptive to be able to encode and then later recall unique events, such as seeing an unexpected predator.

This eclectic approach opens the prospect of a neurobiological analysis provided the distinctive features of episodic-like memory can be tied down operationally. Various research groups are feeling their way toward a range of tasks that may be suitable assays. An unfortunate problem is that several such

tasks are asserted to be “episodic” in character when the classification is barely deserved. In the context of the theories that have been considered in this chapter, episodic-like memory is over and beyond being merely “declarative” and something more than a “spatial memory” because, in both cases, the memory must include information about what and when something happened as well as information about a specific location. Episodic-like memory is also more than one-trial memory. Certain emotional dispositions, such as learned fear associated with a specific stimulus, can be acquired during one trial. There may be configural or relational components of episodic memory as well, yet neither of these two categories quite captures the distinctive features of the full “episodic” concept or the possible role of the hippocampus in mediating it.

### **13.6.2 Scene Memory as a Basis for Episodic Memory and Top-down Control by the Prefrontal Cortex**

One idea about the neurobiological basis of episodic memory was Gaffan’s proposal that it was a form of scene-specific encoding (Gaffan, 1991, 1994). His hypothesis included statements about the role of hippocampal formation and related structures, but the framework is anatomically more wide-ranging (Box 13–10).

These and related ideas were developed gradually through an extensive series of experiments on Old World primates, beginning with Gaffan’s seminal study of recognition memory published in 1974 (see Section 13.3).

### **Recognition Memory, Associative Memory, and Scene Memory**

The distinction between recognition and association (Gaffan, 1974) was, in certain respects, a forerunner of Mishkin’s distinction between memory and habit (Mishkin, 1982). However, later work by Gaffan and his colleagues overturned

the idea that fornix lesions leave associative memory unaffected following a series of ingenious experiments reported in somewhat impenetrable papers published during the early 1980s. The insight buried within this work was a new set of ideas about what it means to say that an animal has learned an “association.” The traditional view was that associations were, to all intents and purposes, conditional reflexes or autonomous “habits,” but Gaffan’s studies and modern animal learning theory have considerably enriched our view of associative learning.

Inspired in part by the work of the animal learning theorist (Capaldi, 1971), Gaffan explored tasks in which an object might lead to food the first time it was seen but not the next time it was presented (Gaffan et al., 1984). That is, reward was available when the object was novel but not when it was familiar. Normal monkeys could learn this type of task, correctly reaching for the “other” object of a pair in two-alternative choice tests as quickly as in a simple association task. This novelty association task is sensitive to fornix lesions. The implication was that certain types of rapidly acquired “associations” between an object and reward are not autonomous habits at all; they are bits of stored “knowledge.” Gaffan went on to suggest that the type of actions a monkey is required to perform during an association task may be critical to whether a fornix lesion that partially disconnects the hippocampus from anterior parts of the brain has a deleterious effect (Gaffan, 1983). However, this hypothesis, although supported by studies suggesting that spatially directed actions are sensitive to fornix transection (Rupniak and Gaffan, 1987), failed to attract general support.

A turning point that led to a key insight about episodic-like memory was the outcome of a study on conditional learning (Gaffan and Harrison, 1989). Monkeys were trained to reach for one of two objects (A or B), such that A was correct when the animals were facing one way in the laboratory room, but B was correct when they were facing in the other direction. This task was relatively easy for control animals to learn, but a severe deficit occurred after fornix lesioning. Interestingly, the deficit was not a general problem of conditional learning because there was no deficit if the objects were presented on trays of different colors with object A correct on an orange tray but B correct on a white tray. From a strictly logical perspective, the two tasks are identical, but they were differentially sensitive to fornix lesions. Gaffan suspected that it might have something to do with the spatial organization of the “scene” before the animal. When the monkey had to face in different directions, the scene before him changed even though many elements of it were still there (e.g., the window). When the monkey looked at objects on trays of different colors, however, the global scene was unchanged despite the minor change of a specific element in it. A third experiment contrasted “scenes” with “places.” To compare them, a new set of monkeys was trained to reach for one of five objects as a function of their place in the room. The places were chosen to be as visually different from one another as possible so location rather than the spatial arrangement of the scene would differentiate the places (e.g., in front of bookshelves), by the

#### **Box 13–10 “Scene Memory” Basis of Episodic Memory**

1. *Part of a circuit:* The hippocampus is part of a circuit that includes the fornix, mammillary bodies, and anteror thalamus (the Delay-Brion circuit), which collectively encodes events with respect to the spatially organized scenes in which they occur.
2. *Spatial basis:* There is a spatial component to episodic memory (“scene-encoding”) that is neuropsychologically dissociable from place memory per se and from spatial navigation.
3. *Anatomical dissociation of function:* The functions of the Delay-Brion circuit are also dissociable from the roles in memory played by the frontal lobe and the medial temporal lobe (which it connects), including the amygdala and perirhinal cortex.

door, by the window). Surprisingly, no fornix lesion deficit was seen. Accordingly, Gaffan argued for a distinction between places and scenes, arguing that a fornix lesion disrupts some aspect of scene encoding or the capacity of scene information to set the occasion for other stimuli to be rewarded or nonrewarded. This analysis was a forerunner of Aggleton and Brown's later description of hippocampal memory as involving the spatial organization of familiar objects (Aggleton and Brown, 1999). The elegance of Gaffan and Harrison's (1989) classic paper is marred only by a minor confounding between the selectivity of the deficit and the change from two scenes to five places, with a fornix lesion impairment in the two scenes experiment but no such effect in the five places experiment. However, subsequent work went on to establish the sensitivity of scene memory to fornix transection in monkeys that were *not* moved from place to place.

The emphasis on scenes rather than places is a subtle but important way in which Gaffan's hypothesis differs from the cognitive map theory. What is important is not *where* the monkey is itself located but *what he is looking at*. Later unit-recording work by Rolls revealing the existence of "view cells" in the hippocampus (Robertson et al., 1998) raised the possibility that fornix transection disrupts a view-specific physiological process that is implemented in or, at least projected to, the hippocampus. Gaffan, being apparently uninterested in localization of function as a scientific goal, was noncommittal about what aspect of cognitive function is mediated within the hippocampus itself—perhaps uncertain that it would map onto any psychologically defined category. His interest has generally been restricted to whether damage to area X disrupts some psychological process or, in disconnection studies, that conjoint unilateral damage to area X and contralateral damage to area Y does likewise (e.g., Easton et al., 2001). Thus, despite the extensive use of lesions as a tool to dissociate putative memory systems and a detailed specification of relevant primate neuroanatomy, the "scene-processing" theory does not identify the episodic system as located in one or more structures. The closest Gaffan's theory comes to anatomical localization is with reference to the Delay-Brion circuit, a group of structures that includes the hippocampal formation as well as the fornix, mammillary bodies, and anterior thalamus. This emphasis on the anterior connections of the hippocampal formation, not least the connectivity with the prefrontal lobe (Browning et al., 2005), is strikingly different from the perspective offered in the declarative memory theory, where the emphasis is much more on posterior neocortical connections (as in Chapter 3). Gaffan's ideas can be said to be forward-looking.

Subsequent experiments have elaborated and developed the idea of scene-specific memory as the essential basis of episodic-like memory. Before describing them, two points should be noted. First, the hypothesis captures an important phenomenological feature of episodic memory—our ability to remember the context in which an event occurred. This is relevant to many memory tasks given to humans and animals where the description provided by the experimenter can all

too easily ignore features of the surrounding scene because they do not seem relevant to the solution of the task. Recognition memory is, once again, a case in point. Although the surrounding features of the testing apparatus (the WGTA or computer touchscreen) may not help the monkey remember whether object X or image Y was seen most recently, an incidental and noncontingent memory of the context may still be important. Normal animals automatically form object–context associations, and the context may then act as a retrieval cue or as an element of the remembered visual scene. This was, it should be remembered, the basis of Nadel's concern about removing monkeys from a WGTA during long memory delays in some of the primate studies of recognition memory (Nadel, 1995).

The second point to note is methodological. The first scene-encoding study (Gaffan and Harrison, 1989) and other studies conducted around the same time involved moving the transport cage containing the monkey to change the scene around the animal. This procedural burden, coupled with the laborious nature of training monkeys by hand in WGTAs, encouraged the Oxford laboratory to be pioneers in the development of automated stimulus presentation systems. Automated testing was introduced by the National Institutes of Health (NIH) group around the same time (Murray et al., 1993), following innovative developments of T. Aigner, and later by a San Diego group to test monkeys at very short memory delays in DNMTS (Alvarez et al., 1994). Horel's group also developed systems that used slide projectors under computer control. The development of touchscreen technology was partly a matter of convenience, but it was also to have an impact on Gaffan's developing theoretical ideas. He began by using laser disks to show a large number of scenes to monkeys (e.g., scenes from a film) and later digital graphics software to generate a nearly infinite variety of abstract designs as scenes (typically of colored circles, ellipses, and typographical characters of different sizes).

### **Scene Memory, Place Memory, and Object-in-Place Memory Are Sensitive to Fornix Lesions**

In one study, monkeys were shown scene after scene from George Lucas's film "Raiders of the Lost Ark" (Gaffan, 1992). Although we may wonder what they made of it, their task was to remember which scenes were associated with reward and which were not.\* A highly significant deficit in the rate of learning was observed in fornix-lesioned monkeys. This result is important because it suggests that scene learning and object discrimination learning may be quite different. From a strictly

\*An unpublished study by Nicholas Humphrey should be mentioned in passing. He showed cartoon movies to monkeys on a television screen. To test whether there was any understanding of what was happening, he allowed the animals to choose between seeing the film run normally or in the reverse direction. Although the scenes the animals saw were visually similar, only the normal movie "made sense." The monkeys preferred the regular film.

logical point of view, learning the reward significance of a set of scenes is identical to concurrent object discrimination learning in a WGTA. We saw earlier that concurrent discrimination tasks are sensitive to MTL lesions when multiple trials of each pair of objects are given each day but not when only one trial of each object is given per day (Malamut et al., 1984). However, somewhat paradoxically, when several hundred scenes are presented each day, each for no more than one or a few trials, a clear deficit is observed with a fornix lesion that typically produces only mild amnesia in humans and little or no deficit in many classic primate declarative memory tasks. Gaffan's finding of a positive effect of fornix lesions therefore supports his case that there may be something special about scene processing in the Delay-Brion circuit compared to merely discriminating objects.

Computer-generated abstract scenes provided another way to compare three conditions: place memory, object memory and object-in-place memory (Gaffan, 1994a). In the object-in-place task, for example, the correct response for the monkey is to reach out and touch the one object of a pair that always occupies a particular position in a unique background of abstract colors and shapes (Fig. 13–44A). The use of the term "object" is slightly misleading because, in practice, the monkeys are often required to reach toward nothing more than alpha-numeric characters on the screen. However, work by Buckley and Gaffan (1998b) showed that monkeys are very good at equating objects seen on a computer screen with real three-dimensional objects they can handle and pick up. In a series of experiments using such abstract scenes, a central finding has been that hippocampal, fornix, mammillary body, or anterior thalamic lesions each cause a deficit in recalling scenes learned preoperatively and in learning new scenes (Fig. 13–44B). The reasons for arguing that the Delay-Brion structures form a circuit responsible for this type of memory are (1) lesions to each structure individually cause a learning

impairment of comparable magnitude; and (2) adding a fornix lesion to a preexisting mammillary body lesion does not exacerbate the deficit. It therefore seems likely that these structures make their contribution to processing in a serial manner. Later studies have gone on to implicate the entorhinal and perirhinal cortex in object-in-place memory as well (Gaffan and Parker, 1996; Murray et al., 1998; Easton and Gaffan, 2000; Charles et al., 2004b).

A possible weakness is that although described as an "animal model of episodic memory" there is nothing very "event-like" in remembering which of two alpha-numeric characters is rewarded with food within particular scenes. The task could be learned semantically and stored as a "fact" rather than as an episode. There is also no "recall" element to the task. The cues are always provided on the computer screen, and the animal can recognize them rather than bring them to mind. To be sure, learning is remarkably rapid such that, in experienced monkeys, it takes only two to five trials to learn each object-in-place task. At that speed of learning—clearly much faster than traditional visual discrimination tasks—the animal is remembering correctly what to do on the basis of only one or at most a few trials. However, the episodic character of the task, like paired-associate learning in humans, is being inferred more from the sheer speed of learning than its formal logic. It does not absolutely require memory of "what, where, and when."

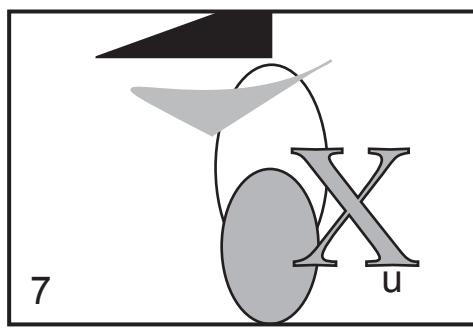

#### **Memory Functions of the Temporal Lobe, Delay-Brion Circuit, and Prefrontal Cortex**

The proposal that the hippocampus is part of the Delay-Brion circuit and that this circuit has a highly specialized role in memory is only one aspect of Gaffan's wider ideas about multiple types of memory mediated by circuits interconnecting the temporal and frontal lobes. His scene-specific theory of episodic memory differs from the declarative memory

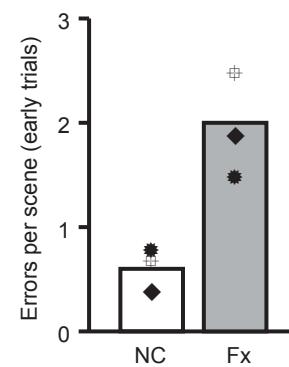

**Figure 13–44.** Scene-encoding as a component of episodic memory. A. The monkey faces a computer screen that typically consists of a number of randomly placed shapes and alpha-numeric characters. The task is to reach for one object (e.g., the number 7 in the bottom-left corner) against one background and for another object

(e.g., the letter u in the right-hand side) when the presented against a different background scene (not shown). B. Monkeys soon learn these types of problem rapidly, whereas fornix-lesioned animals show a clear deficit. (Source: After Gaffan, 1994.)

**A. Greyscaled display of 'object-in-place' task**

**B. Mean performance during learning**

theory in two major respects: First, it regards hippocampus-dependent scene memory as one of several qualitatively distinct propositional memory systems. Like the position taken by Horel a generation ago (Horel, 1978b, 1994), Gaffan therefore takes exception to the concept of a monolithic MTL memory system (Gaffan, 2002). Second, unlike both the declarative memory and relational processing theories, there is apparently no explicit consolidation mechanism. Gaffan believed that the Delay-Brion circuit is important for memory encoding and memory retrieval, even if retrieval is not required until months after original training, but it is non-committal on sites of storage. The perspective on the role of the MTL in memory is difficult to pin down. This is because the dissociations that have emerged from his experiments (using a variety of tasks and both bilateral and crossed unilateral lesion techniques) are generally described only in terms of the “necessity of a given area/pathway for a given task.” No statement of what cognitive operations are carried out by each structure in the temporal lobe has been presented, nor statements about the nature of different memory systems, their rules of operation, or the type(s) of information on which they operate. Even for the best studied part of the system, the Delay-Brion circuit, there is no statement of the presumably distinct contributions to scene-specific episodic encoding and recall made by the four distinct structures of the circuit. This is puzzling because the local circuitry, numbers of cells, and extrinsic connections of the mammillary body differ radically from those of the hippocampus. Even if Gaffan is correct that they work together serially to enable a common function, it would be helpful to unpack this statement by outlining their distinct contributions to that “common function.” Electrophysiological studies may be helpful here.

These points may seem unduly harsh criticisms. However, the picture that is emerging from Gaffan’s seminal work is that he envisages a widespread but loose hierarchy of cortical areas involved in memory (Murray et al., 2005). The middle and inferior temporal gyri have the job of analyzing visual object features, such as shape and color. The most anterior neocortical region, the perirhinal cortex, associates these object features with nonvisual features of objects (e.g., reward significance) to form perceptual representations of unique individual objects (Buckley and Gaffan, 1998a). Information about unique objects processed in the perirhinal cortex is put together, in circuits involving the hippocampus, with spatial information to form representations of unique complex scenes (Murray et al., 2005). Finally, the entire system has important functional connections with the prefrontal lobe.

By way of a coda, it should be noted that Gaffan’s emphasis on networks for memory processing has points of similarity to Miyashita’s distinction between “automatic” and “active” retrieval of information (Miyashita, 2004). Although Miyashita accepted the idea of an MTL memory system, he also identified a “semantic” associational system in area 36 of the limbic cortex and the important role of “top-down” connections from the prefrontal cortex in guiding the intentional or active retrieval of information from these systems.

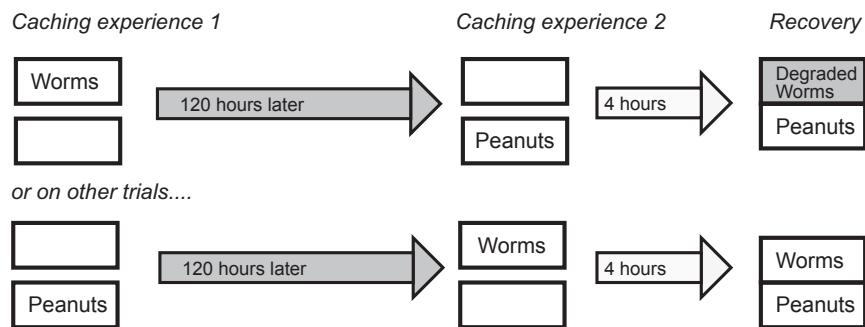

Miyashita’s analysis extended beyond the domain of episodic memory to paired-associate learning following his identification of neocortical “pair-coding” neurons that fire differentially as a function of the association that binds two stimuli together (Sakai and Miyashita, 1991). His suggestion is that automatic retrieval of episodic or semantic information requires no more than activation in the MTL or area 36, respectively, but effortful retrieval also involves a top-down signal from the prefrontal lobe. Two main lines of evidence from animal studies support this idea. First, the latency at which unit-recording signals are observed during automatic retrieval is shortest in the most medial structures and spreads backward from the hippocampus (for episodic information) and from area 36 (for semantic information) to area TE where neurons are gradually recruited that provide a fuller representation of remembered information, be it an event or a fact. Second, during active retrieval, neurons in the inferotemporal cortex received categorical rather than stimulus-specific information from the frontal cortex to help guide the effortful process of memory searching (Tomita et al., 1999). Miyashita saw the challenge ahead as being “to understand the hierarchical interactions between multiple cortical areas” (Miyashita, 2004, p. 435) in the expression of memory. Notwithstanding differences of approach and detail, Gaffan’s perspective was similar.

### **13.6.3 What, Where, and When: Studies of Food-caching and Sequence Learning**

#### **Food Caching by Corvids as a Model of “What, Where, and When”**

A different approach to thinking about the recollection of past experience was taken by Clayton and her colleagues, who conducted a series of studies examining food caching and recovery by a corvid species, the Californian scrub-jay. Clayton and Dickinson (1998) allowed adult hand-raised scrub jays to cache food items in sand-filled ice-cube trays surrounded by trial-unique arrays of distinctive visual objects (Lego bricks). The two food items were (1) preferred but perishable wax moth larvae and (2) less-preferred but nonperishable peanuts, each of which were in plentiful supply in bowls at the time of caching. During two successive caching periods separated by an interval of 120 hours, the birds transported and then cached wax moths on one side of the caching tray and peanuts on the other, with each side being covered by a Perspex strip during the caching of the other food item (Fig. 13–45A,B). These caching periods constituted the opportunity for the animals to encode into memory what food item was being cached where and when. Recovery was permitted either 4 or 124 hours later with both sides of the ice-cube tray uncovered and available. Over a series of pretraining trials extending over several weeks, with the visual arrangement of Lego bricks and the assignment of tray sides for the two foods randomly changed on each trial, birds in the “degrade” group had the opportunity to learn that wax moths recovered after 4 hours

### A Experimental Design for Training Trials

### B Scrub-jay retrieving food caches

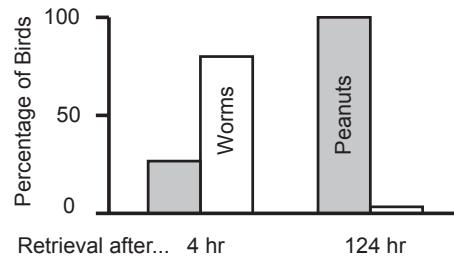

**Figure 13–45.** Memory for what, where, and when in California scrub-jays. A. Experimental design for the training trials in which the birds in the “degrade” condition (shown) had the opportunity to learn that wax-moths become unpalatable after a period of 4 days. B. California scrub-jay performing the task. C. Results from

are tasty and worth eating, whereas those retrieved after 124 hours are not. Birds assigned to a separate “replenish” control group always found fresh wax worms at recovery whether it occurred at the short or the long recovery interval. The main finding of this ingenious study was that in nonrewarded probe tests in which neither food was actually available (thereby preventing any olfactory or visual cues to guide search location) the scrub-jays in the degrade group searched preferentially for wax moths when recovery occurred 4 hours after caching but switched their search to peanuts when recovery did not occur until 124 hours had elapsed (Fig. 13–45C). This switchover was not shown by the birds in the “replenish” condition but partially shown by birds in a third, “pilfer,” group in which the preferred wax worms were missing after a 124-hour delay. This pattern of results implies that, at recovery and using free recall, the birds can recollect what food item was stored where and, at least in some sense, how long ago.

In addition to careful controls, such as nonrewarded probe tests, there are several innovations in this experimental approach. The use of food caching is helpful as it ensures the animal is attentive and engaged in the task at the time of memory encoding; the act of caching is not, however, a requirement for the formation of episodic-like memory. The use of very long memory intervals over hours and days ensures that memory retrieval is outside the range over which interval timing mechanisms, mediated by short-term memory, can operate (Hampton and Schwartz, 2004). The use of

the “degrade” group showing proportions of birds making their first pecks to the wax-moth or peanut side of the caching tray. (Source: After Clayton and Dickinson, 1998. Photograph courtesy of N. Clayton.)

free recall at cache recovery obviates the use of a familiarity strategy that has been so problematic in studies of recognition memory. Clayton and Dickinson’s claim that their initial study provides “the first conclusive behavioral evidence of ‘episodic-like’ memory in animals other than humans” (Clayton and Dickinson, 1998, p. 274) was vindicated by later studies in which a number of detailed issues were taken further (Clayton et al., 2001). In one of the studies, scrub-jays were allowed to cache preferred crickets (rather than wax moths) and less-preferred peanuts (Clayton et al., 2003a). After caching but before recovery, the birds were taught that the crickets, which used to remain edible for at least 3 days, now degraded rapidly and became inedible. During cache recovery, the birds now avoided the crickets and sought out the less preferred peanuts. Thus, the birds seem to be able to apply information retrospectively at the time of retrieval to guide their choice of food item. Other studies have investigated prospective aspects of food caching with the scrub-jays (Emery and Clayton, 2001) and refined the criteria for identifying mental time travel in animals (Clayton et al., 2003b).

### Sequence-dependent and Context-dependent Object-Place Memory in Rats

The scrub-jays are not suitable subjects for neurobiological studies, particularly because these studies use hand-raised birds to ensure control of the caching experience. Unfortu-

nately, efforts to demonstrate “what, where, and when” in other species, particularly laboratory animals such as rats, have not been successful so far. This has led some to question whether animals can undertake mental time travel (Roberts, 2000). Others have raised the possibility that the “when” component should be thought about in other ways, such as with reference to the context in which they occur or their sequence of occurrence. Both sequence and context sometimes act as mental surrogates for the experience of time.

With respect to context, which we have already discussed extensively (see Section 13.5), Eacott made the interesting argument that when asked about “when” an event happened people often work out where they were at the time and then use the retrieved contextual information to remember events. In this mental exercise, there is not necessarily any mental time travel as such (Eacott et al., 2005). Based on this thought, she has developed a modification of Ennaceur’s novel object recognition (NOR) task for rats in which context, place, and object can be a triad of associations. That is, the rat has to remember whether a specific object was in a specific location in a particular context. Using this task, she reported that fornix lesions disrupt recollection of the what–where–where triad while, somewhat surprisingly, appearing not to affect a simpler what–where task (Eacott and Gaffan, 2005). This is a challenging result being, on the face of it, very different from the extensive results reported by Gaffan’s group using object-in-place memory. However, given the importance of testing numerous memory delays in NOR tasks before claiming selectivity (Clark and Martin, 2005), it would be valuable for various memory delays to be investigated in her task. On a conceptual level also, that people sometimes cannot remember time and use the surrogate of context does not imply that they always do so, nor does it undermine the central importance of mental time travel to “true” episodic memory.

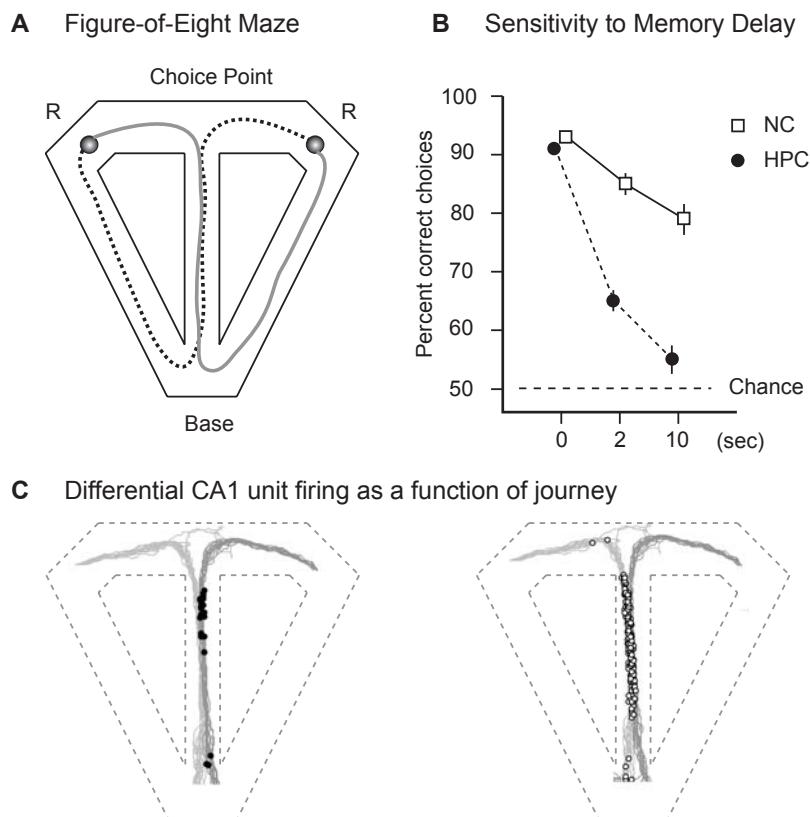

With respect to memory for the sequence of events, Honey et al. (1998) showed that rats with hippocampal lesions were less able than sham-lesioned animals to notice any change in the order of two sequentially presented stimuli during an orienting task. In another study, Fortin et al. (2002) showed that rats could remember some information about the sequence in which a series of distinctive odors was presented. Cups of sand through which rats could dig to find food (like the paired-associate and transitive inference experiments of Section 13.5) were presented at 2.5-minute intervals. Common household odors were mixed into the sand to determine its smell, with different novel sequences of odors given during each series of trials. For a given sequence, call it A-B-C-D-E, the animals were later tested for whether they could remember that sand odor A came before odor C, B before D, and so on; they were also tested for whether odors A–E were familiar compared to other novel odors. The results showed that whereas the sham-lesioned animals could perform above chance on both the sequence and recognition components of these tests, the rats with radiofrequency-induced hippocampal lesions could remember the individual odors but not the sequential information. A follow-up study by Agster et al. (2002) indicated

that rats with hippocampal lesions could eventually acquire some sequential information about repeated sequences with extended training but never well enough to disambiguate overlapping sequences. That the hippocampus could be involved in rapidly learning sequences has also been the subject of modeling studies focusing on the recurrent associative network organization of area CA3 (Jensen and Lisman, 1996; Levy, 1996). Nakazawa’s observation that mice with a knock-out of the NMDA receptor specific to area CA3 are poor at “one-shot” learning but successfully master a spatial reference memory task (Nakazawa et al., 2003) represents partial support for this view, but it would be interesting if such mice could also be shown to be poor at learning explicit sequences of information. Given these findings, Eichenbaum (2004) extended his relational processing theory into the episodic domain by arguing that the hippocampus is also the neural substrate for mediating the sequential organization of memory. In his view, the mediation of memory for time can often be achieved by reference to memory of the order in which items occurred rather than some absolute memory of the time at which they were initially presented.

In a complementary approach to thinking about sequential aspects of events, single-unit recording studies in rats have indicated that hippocampal pyramidal cells can sometimes mediate more than “place” information. Chapter 11 documented the extensive evidence for the spatial sensitivity of single-units in rodents, including place cells, theta units, head-direction cells, and grid cells. However, we have already seen that a growing body of evidence indicates that CA1 and CA3 pyramidal cells may have cognitive and behavioral correlates that extend beyond the domain of space (Eichenbaum et al., 1999; Wood et al., 1999; Jeffery, 2003).

Wood et al. (2000) recorded hippocampal complex-spike neurons in rats running a figure-of-eight maze in which, after moving through the common stem of the maze, the animals had to alternate between turning left or right to secure reward (Fig. 13–46). A high proportion of the cells (up to 67%) with place fields on the stem fired differentially as the rat traversed the common stem on left-turn and right-turn trials, even when potentially confounding variations in running speed and exact heading direction were taken into account. Other cells fired similarly on both trial types (i.e., were place cells), and other factors contributed to the firing determinants of the remaining cells. They argued that hippocampal representations, as represented by cell firing, encoded information about other nonspatial features of specific memory episodes. An earlier study had also found evidence of patterns of nonspatial firing correlates in an olfactory nonmatching task (Wood et al., 1999). CA1 cell firing was related consistently to perceptual, behavioral, or cognitive events, irrespective of the location where these events occurred.

Ferbinteanu and Shapiro (2003) went on to disentangle factors that could be responsible for journey sensitivity, showing that CA1 complex-spike cells certainly display “retrospective coding” and possibly also “prospective coding.” They used a hippocampus-dependent plus maze task (Packard and

**Figure 13-46.** Task-dependent modulation of CA1 pyramidal cell firing. *A*. Figure-of-eight maze as used by Wood et al. (2000) to establish additional properties of complex-spike cells than just place and direction sensitivity. The dotted and continuous lines refer to alternating traverses through the central stem as the animal runs the maze, receiving a reward (*R*) soon after each alternating choice. *B*. Choice performance of normal and hippocampus-lesioned animals

as a function of an imposed delay before entering the stem of the maze. *C*. Differential firing as a function of whether the rat has come from the left side of the maze and is about to turn right (filled symbols) or has come from the right side and is about to turn left (open symbols). (Source: After Wood et al., 2000 and courtesy of James Ainge.)

McGaugh, 1996) in which the start arms of the maze were switched between north and south within a block of trials, and the goal arm switched from east to west between blocks of trials. In this way, the animals could make one of four kinds of journey: from north to either east or west and from south to either east or west. Thus, in traversing the east arm up to the goal, the rats could have come either from north or from south. During recording studies, many “pure” place cells were observed, as described by Wood et al. (2000), but differential cell firing in the east and west arms was also observed, depending on whether entry was from the north or south arms, reflecting journey-sensitive “retrospective coding.” “Prospective coding” is also claimed in the paper but accepting that it is slightly problematic because the recordings were then compared across blocks of trials in which the reward location had been switched. Although unlikely, this goal reversal might itself alter the firing properties of the cells, a complication that does not arise with retrospective coding in which reward location is fixed and recordings are taken from within a single block of trials in which some journeys began in the north and others in the south. One way in which this confounding might be addressed is through the use of two

rewards (e.g., different flavors of food) at the east and west arms of the plus maze, respectively. Then, through cueing of the animals with a “pre-taste” of one or other food reward in the start box, it might be possible to secure recordings within a block of trials in which the animals turned toward the east when cued with flavor 1 (from either north or south) and turned to the west when cued with flavor 2. Evidence for prospective coding uncontaminated by the use of a reversal schedule might then be obtained.

What do these unit-recording findings imply for hippocampal involvement in episodic-like memory? With respect to neurobiological mechanisms mediating the “what-where-when” trilogy, it is clearly necessary for place representations to be supplemented by temporal or sequence information (time-tagging or relative order) and by representations of objects that are to be found at each place. These new studies of the correlates of hippocampal cells raise the possibility that at least “when” and “where” might both be represented in population vectors of such cell firing. To date, the data are limited to short time periods (seconds) and to the simplest descriptors of sequence (e.g., south-before-east is encoded by cells different from those representing north-before-east).

### 13.6.4 Problem of Awareness

Experiments with animals that lay claim to revealing a “recollective” component of memory should somehow discriminate explicit and implicit processing. We should try to face up to the formidable problem of understanding the neurobiology of “awareness.” Following Gaffan’s work, “asking” a monkey if it saw a specific image on a computer screen 40 minutes ago is now routine. Another example is the seminal work on “blindsight” in monkeys (Cowey and Stoerig, 1995) that was discussed earlier (Fig. 13–13). The discovery of “mirror neurons” in primates (Rizzolatti and Craighero, 2004) further extends our appreciation of a possible neurobiology of animal awareness, as do Iriki’s studies of tool use (Maravita and Iriki, 2004). These are telling examples because they are precisely the kinds of phenomenon that an honorable and scholarly skeptic who asserts the importance of language to awareness, such as Macphail (1998), might have predicted to be impossible to demonstrate in animals.

To be sure, cogent arguments have been put forward to suggest that we may never know whether any animal can ever be said to possess “autonoetic” consciousness or engage in mental time travel and that seeking true episodic memory in animals is therefore a forlorn exercise (Suddendorf and Busby, 2003). However, there is value in taking a positive view of the possibility of identifying aspects of memory awareness in animals using behavioral criteria (Clayton et al., 2003b). Language may not be central to its expression, a sense of the self may not be required, and new behavioral protocols will hopefully continue to reveal more about animal awareness and the role, if any, of the hippocampus in it. In this way, the problem of awareness is being broken down into bite-sized chunks at which experimentalists can nibble away. We have already seen (Fig. 13–14) that monkeys can reveal an awareness of whether they can remember (Hampton, 2001). Can animals also display quantitative characteristics of memory that parallel those shown by humans when they are using recollection or familiarity to solve a recognition task? Can they do one-trial cued recall? For each of these, we can go on to ask whether performance is affected by hippocampal dysfunction.

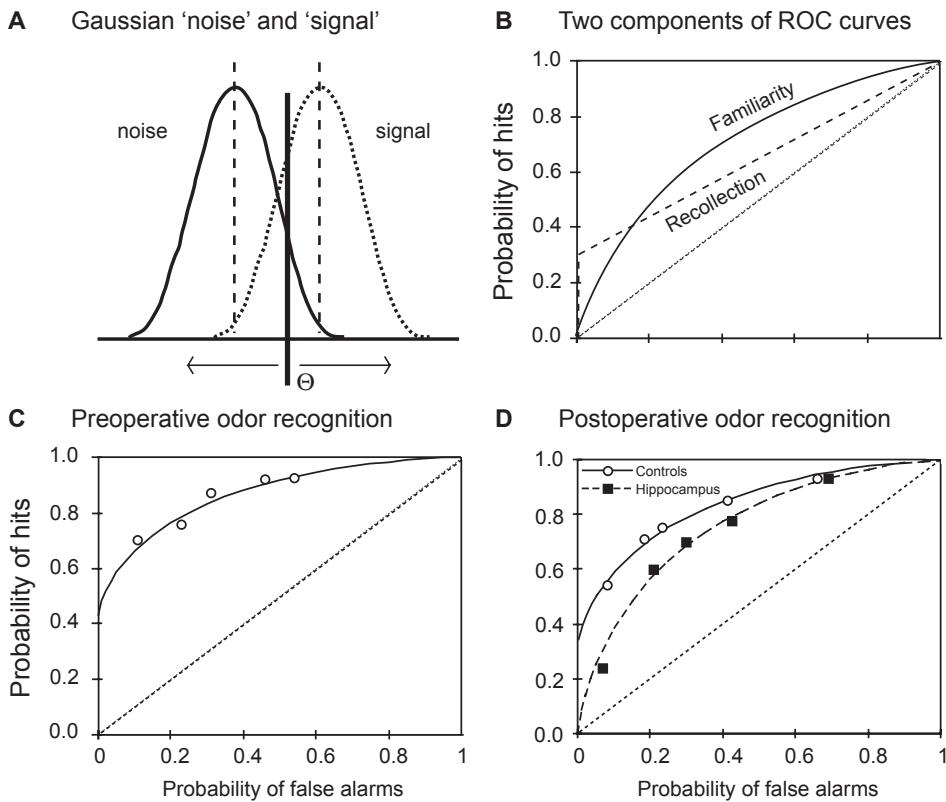

#### Recollection, Familiarity, and Region of Interest Curves

Studies examining the hippocampal contribution to the phenomenological experience of memory have also been inspired by developments in cognitive psychology. Fortin et al. (2004) exploited a quantitative approach for distinguishing the two components of dual-process theories of recognition memory—recollection and familiarity—that was developed during the 1990s by Yonelinas (2001). His approach, discussed in Chapter 12, involved plotting graphs called receiver operating characteristic (ROC) curves, which are an important part of the signal-detection theory (Tanner and Swets, 1954). Two sets of probability functions, usually Gaussian, are plotted that vary as a function of cost and benefit: “hits” and “false alarms.”

Hits are recorded when a subject *correctly* identifies a previously presented stimulus (i.e., a signal); false alarms are recorded when the subject *incorrectly* identifies a stimulus as seen before when it had not in fact been presented earlier (i.e., noise). The range of conditions involves systematic variation of relative value, that is, the costs and benefits of correctly reporting hits and mistakenly making false alarms. If the cost of missing a correct stimulus is high and that of making a false alarm is low, subjects adjust their reporting criterion in the direction of reporting hits (i.e., to the right of the graphs in Figure 13–47A.) Conversely, if the risks associated with incorrect memory are high (as in eye-witness testimony), then subjects shift their response criterion downward (i.e., to the left in the graphs).

How can this seemingly overcomplicated way of thinking about memory performance be helpful? Yonelinas’s important contribution was to recognize that the divergence from the diagonal can take two forms. It may be *symmetrical* or *asymmetrical*. In the former case,  $p$  (hit) initially rises faster than  $p$  (false alarm) until both reach 0.5, and then the increase in  $p$  (false alarm) catches up. This creates a symmetrical ROC curve and reflects the familiarity component of recognition (curved line in Fig. 13–47B). In the latter case,  $p$  (hit) rises rapidly at low values of  $p$  (false alarm), an asymmetry thought to be due to the second component of recognition memory—recollection (dotted line in Fig. 13–47B). This component operates as a threshold process in which items and their spatiotemporal context are either recollected (above threshold) or not recollected (below threshold). There is no gradation of subjective familiarity as occurs in other components of recognition memory. Like pregnancy, there are no half-measures.

Fortin et al. (2004) have now successfully established that ROC curves for recognition memory can also be plotted for rats. This was done taking advantage of their spectacular memory for odors, using a continuous recognition task in which the rats had to dig in sand wells for reward when the odor of the adulterated sand was novel and refrain from doing so when it was familiar (and then search elsewhere for reward). Wood et al. (1999) had previously shown that this is a task that displays a number of hippocampal unit correlates. Costs and benefits were manipulated by altering the height of the sand wells (making digging easier or more difficult) and the size of the reward the animals got when they dug successfully (from one-fourth of a pellet to three pellets of food reward). Their findings indicate that when normal rats were tested 30 minutes after exposure to a “list” of odors (analogous to a list of words in a human recognition experiment), the ROC curve was asymmetrical (Fig. 13–47C). When half the rats were then subjected to hippocampal lesioning, the ROC curve became symmetrical (Figure 13.47D). Together with other data in this study, it seems that recognition memory in rats complies with dual-process models of recognition memory in humans and that hippocampal lesions may remove the “recollection” component of this memory. The task of realizing a neurobiological understanding of episodic and episodic-like memory and the nature of hippocampal involve-

**Figure 13-47.** Receiver operating characteristic (ROC) analysis of recognition memory in the rat. *A*, Hypothetical Gaussian functions plotting the probability of “signal” and “noise” during memory of a prior event. The receiver operates at various points along the x-axis and can so make estimates of what constitutes a “hit” (i.e., a true signal) and what constitutes a “false-alarm” (i.e., from the noise distribution but claimed to be a memory). The threshold  $\theta$  can be adjusted up or down the x-axis to enable a more conservative (to

the right) or more risky (to the left) detection policy, as described in the text. *B*, Quantitative analysis of ROC functions reveals a linear recollection component and a symmetrical familiarity component of memory. The sum of the two components is a curved but asymmetrical function. *C*, Normal rats show asymmetrical function in odor recognition memory. *D*, After hippocampal lesions, rats show a symmetrical ROC function. ment in it seems no longer quite as forlorn an enterprise as once it did. It is to one developing theory of this type that we now turn.

### 13.6.5 Elements of a Neurobiological Theory of the Role of the Hippocampus in Episodic-like Memory

It is premature but not inappropriate to end this chapter with an attempt to tie several strands together. The focus in this chapter has been on the major historical contribution that animal lesioning studies over the past 30 years have made to our understanding of hippocampal function. Modern work has greatly expanded the levels of analysis at which neuroscientists think about function and has been converging on the idea of a role in the automatic aspects of episodic-like memory. There has been little discussion so far of the specific role hippocampal synaptic plasticity might play in this process or how the cell biological determinants of that plasticity fit with neuropsychological ideas about memory consolidation. Given the shift toward more interdisciplinary approaches in neuroscience, it is fitting to end on this note.

### Automatic Recording and Retrieval of Attended Experience

One neurobiological theory of hippocampal function does attempt to specify a role for synaptic plasticity in memory formation (Morris et al., 2003). This theory supposes that hippocampal memory can, like other forms of memory, be divided into four processes: encoding, storage, consolidation, and retrieval. A key aspect of the neurobiological approach is the assertion that activity-dependent synaptic plasticity (e.g., LTP) is critical for encoding and the intermediate storage of memory traces in the hippocampus that correspond to the “indices” or “pointers” to cortical regions where detailed perceptual information is temporarily stored (as discussed in Section 13.3). These hippocampal indices are cartoons that bind event information to the context in which they occur. A novel feature of the theory is that these index memory traces decay rapidly but are sometimes rendered more persistent by the process of cellular consolidation. That is, LTP is actually something of a misnomer as many, perhaps most, memories of events captured online are soon lost. Protein synthesis-independent E-LTP is more of a system for creating the

“potential” for memory with synaptic tagging at the time of E-LTP induction (see Chapter 10) playing a part in determining what traces are rendered more persistent. The rapid “snapshot” creation of a temporary event-context index involves synaptic potentiation at a large number of synapses across parts of the hippocampal network (probably in CA1 and CA3). Tags set automatically at the time of an event, irrespective of how trivial that event may be, can capture the products of the somatic or dendritic synthesis of plasticity proteins set in train by events before, during, or even after an event to be remembered. This capturing process renders the temporary indices in the hippocampus more permanent and thus allows sufficient time for systems-level consolidation to occur. This two-stage process of consolidation serves as a “protective filter” in the sense that rapidly decaying index traces do not last long enough to guide neocortical consolidation; and thus events that are *not* subject to cellular consolidation in the hippocampus do not become represented in a persistent manner in the cortex. Although hippocampal synaptic plasticity is critical for encoding and its expression subject to intrahippocampal cellular consolidation, the theory also asserts that it is not involved in memory retrieval. It is also unlikely to be involved in the widely discussed systems-level consolidation process that depends on hippocampus–neocortex interactions, although it does not preclude the possibility that neocortical synaptic plasticity is critical. More formally, the propositions of this developing theory are presented in Box 13–11.

### **Box 13–11**

#### **Neurobiological Theory of Hippocampal Function**

1. Some animals have episodic-like memory, and the hippocampal formation is one group of brain structures that can encode and retrieve such memories.
2. Activity-dependent, associative, NMDA receptor-dependent synaptic plasticity in the hippocampus is the primary neural mechanism responsible for inducing temporary encoding and storage of hippocampal “indices” of rapidly acquired event-context memories. The detailed perceptual information associated with events is represented in the cortex.
3. An essential feature of cellular consolidation processes to which these index traces are subject is the interaction between local “synaptic tags” (set by glutamatergic activation), and diffusely targeted “plasticity proteins” (which can be triggered by heterosynaptic activation of neuro-modulatory and glutamatergic inputs).
4. Systems-level consolidation requires both hippocampus and neocortical neural activity and is therefore not solely time-dependent although certainly a process that takes time. It does not require hippocampal plasticity but may engage mechanisms of neocortical plasticity.
5. The hippocampal formation is one of a number of brain regions that detects novelty, and its neural activity alters in ways that enable a representation of novel events to be encoded rapidly online.

This framework builds unashamedly on the functional/neuropsychological theories discussed earlier in the chapter, but it also makes a number of novel predictions, including some counterintuitive predictions, at other levels of analysis. Some examples of the shoulders on which it stands and these predictions are as follows. From a neuropsychological perspective, it recognizes that events happen in particular places at particular times, and their later recall generally includes the memory of where and when an event occurred (Gaffan, 1994b; Clayton et al., 2001). Thus, event encoding is necessarily associative and “contextual” in character, a point emphasized in several functional theories (e.g., cognitive mapping, configural associative, relational). Many events cannot be anticipated, occur only once, and may contain distinct features that, in sequence, form short episodes—a point about episodic memory emphasized by Eichenbaum (2004). It is vital that traces representing information about such episodes are encoded and stored in real time (as they happen), a process that Frey and Morris characterized as the “automatic recording of attended experience” (Morris and Frey, 1997). Not all events are remembered for any length of time, and to do so is not only unnecessary but might also saturate the storage capacity of relevant areas of the brain. Moser et al. (1998) exploited this feature of hippocampal memory in their contribution to studies examining the functional significance of hippocampal LTP (see Chapter 10). With respect to the level of representational detail, it is also unclear whether the hippocampus need receive, via its extrinsic afferents, detailed sensory/perceptual information pertaining to individual objects or events. The networks and local circuits for detailed perceptual processing are in the cortex. Rather, all it needs to remember events and the sequence in which they occur is binding information about the locations in the neocortex where this detail is processed and temporarily encoded—a point about hippocampus–neocortex interactions discussed in Chapter 3. Later processing, guided by these indices, determines whether the temporary neocortical encoding becomes permanent. This view of hippocampal memory processing capitalizes on the advances made in other theories; and, like them, it implies that the hippocampus is far from being an island. Realizing its functions *absolutely* requires the synergistic activity of other brain areas both upstream and downstream. This is therefore a framework that, unlike some others (McClelland et al., 1995), implies that the cortex must be able to encode information rapidly online. The view here is not only that the cortex can do this but that it loses information rapidly unless new connections are stabilized by systems-level consolidation. In this sense, consolidation is permissive rather than instructive.

The next step of this framework takes us farther into the neurobiological domain. If events are to be encoded, there must exist physiological mechanisms for capturing events as they happen and encoding traces that could later enable retrieval of event or event-associated information. A prominent candidate for the neural substrate of event memory is hippocampal NMDA receptor-dependent synaptic plasticity, so-called Hebbian plasticity. Such plasticity, as revealed by the

physiological phenomenon of LTP, exhibits many properties that are suitable for a role in memory formation (Bliss and Collingridge, 1993; Martin et al., 2000), and a growing body of evidence offers support for this view (see Chapter 10). Index memory traces are achieved by an alteration in the connectivity between neurons such that retrieval cues, expressed as patterns of neural activity, are able to induce new patterns of neural activity that are one part of the substrate of “memories” of prior events.

Another strand relates to the persistence of such traces. A key supposition is that, notwithstanding the fantastic storage capacity of the brain, there is no need to store everything permanently, and the system is absolutely not evolved to do so. Indeed, most memories fade and are lost. Of those that persist, retrieval processes contribute to their accessibility such that “forgetting” is a dual function of trace decay and retrieval failure. If most automatically encoded event memories are temporary, there must be psychological processes and neural mechanisms for selecting the subset of traces that are to be rendered longer lasting or even permanent, such as the emotional significance of the event to be remembered or, more interestingly, the significance of *other* events happening close together in time or space. Experiments on “behavioral tagging” are needed to explore the predictions of the synaptic tagging framework in the context of real memory (see Chapter 10, Section 10.10). There is also evidence that the persistence of memory can also be determined by the relevance of ongoing events to the existing knowledge structures and interests of the person witnessing them (Bartlett, 1932; Bransford and Johnson, 1972; Bransford, 1979), an idea long known in educational circles but that has had curiously little impact on neuroscience until recently (Maguire et al., 1999). Mediating these psychological processes of persistence are two neuronal mechanisms of memory consolidation: (1) cellular consolidation mechanisms, which include the synthesis and synaptic capture of plasticity proteins that stabilize memory traces at the level of the individual synapse in neurons (Goelet et al., 1986; Frey and Morris, 1998; Sweatt, 2003); and (2) systems-level consolidation mechanisms, as discussed in previous sections of this chapter, which reflect a dynamic interaction between populations of neurons in the hippocampus and neocortex (Dudai and Morris, 2001). These forms of consolidation are distinct but also interdependent. This interdependence arises because cellular consolidation enables memory indices in hippocampus to last long enough for the slower systems-level consolidation process to work and thus for their time courses to dovetail.

The defining functional characteristics of associative networks such as the hippocampus are believed by several theorists to include distributed representations, interleaved storage across multiple synapses, and associative retrieval. These processes enable patterns of activity to be stored as a matrix of synaptic changes and retrieval to be “completed” from partial fragments of the original input (Marr, 1971; McNaughton and Morris, 1987; Paulsen and Moser, 1998; Nakazawa et al., 2002). Several factors determine the operating characteristics

and storage capacity of such networks. One of them, connectivity density (i.e., the number of connections per cell), provides an anatomical basis for understanding an important feature of the relation between hippocampus and neocortex (McNaughton et al., 2003). Specifically, the average connectivity in the cortex is, in general, too low to support the encoding of arbitrary associations (Rolls and Treves, 1998). The cortical mantle contains on the order of  $10^{10}$  neurons, but each cortical principal neuron receives only about  $10^4$  connections. Thus, the average connection probability in cortex is only 1:10<sup>6</sup>. To overcome this apparent biological limitation, mammals seem to have evolved an arrangement whereby distributed associative memory between items represented in different sensory modalities can be accomplished through indirect associations mediated by a hierarchical organization (McNaughton et al., 2003). In such a scheme, neocortical modules at the base of the hierarchy are reciprocally connected via modifiable synapses with one or more hippocampal modules at the apex. The hippocampal modules include CA3 as well as the dentate hilus, both characterized by high internal connectivity as well as modifiable synapses. In CA3, each pyramidal cell is contacted by ~4% of the pyramidal cells of the same subfield (Amaral, 1990), implying that most CA3 pyramidal cells are connected via two or three synaptic steps (Rolls and Treves, 1998). This high degree of internal recurrent connectivity is probably sufficient to allow autoassociation, or association among individual elements of a patterned input (Marr, 1971). Activity patterns reflecting sensory detail in neocortical modules may generate a unique identifying index in such a network (Teyler and DiScenna, 1987). This high-level hippocampal trace index is no longer “sensory” in any strict sense but is stored associatively with other indices and the output fed back to neocortical modules via modifiable synapses. Activation of a cortical pattern (e.g., a specific flavor of food) could then result in activation of its index in the hippocampus. In turn, this enables retrieval of associated indices and thence the complementary pattern in the other cortical modules (e.g., where the food is found). Indirect associations enable memory retrieval between cortical modules that are too sparsely connected to do this directly.

This principle of indirect association in memory places high demands on the synaptic storage capacity of the hippocampus that, as noted briefly above, is otherwise in danger of becoming saturated. Once saturated, learning can no longer proceed effectively (McNaughton and Barnes, 1986; Moser et al., 1998). There are several ways in which this burden may be limited. One, as already noted, is via rapid decay of a high proportion of the traces that are automatically encoded online (a property of E-LTP). Heterosynaptic depression may also serve a normalizing function and so increase effective storage capacity (Willshaw and Dayan, 1990). A third way to limit the rate of use of storage space, also an element of the present theoretical ideas, would be to ensure that what is stored in the hippocampus is only a cartoon, with the full sensory/perceptual details encoded in the cortex. The fourth way—the process of systems-level memory consolidation itself—would

be to enable hippocampal associations that are strongly and/or repeatedly recalled, such as those representing environmental regularities, to trigger the development and stabilization of low-level intermodular connections in the neocortex. It is these connections that could later enable cortical retrieval in the absence of neural activity in the hippocampus. To work, it is vital that the intermodular connections that develop are appropriate to the associations represented. This requires the gradual interleaving of appropriate connections (McClelland et al., 1995), perhaps during sleep (McNaughton et al., 2003). Interestingly, the rate of consolidation may not be strictly time-dependent. Rather, the process may be “cladistic,” with the rate of consolidation affected by the frequency with which hippocampal indices are reactivated. It may also depend on an activated neocortical schema to receive the new information.

The last step to be considered relates to the detection of novelty and acting on it. If the hippocampus is critical for building context representations and encoding events in relation to them, it is likely that its neural activity reflects changes to the environment. This is not a new idea, as Gray (1982), Vinogradova (1995), and more recently Gray (2000) have extensively discussed possible “comparator” functions of the hippocampus. Novelty detection is by no means unique to the hippocampus, it being a process required in several cognitive systems; but evidence in favor of a hippocampal contribution has come from many experiments on different forms of novelty detection, including the studies of exploratory behavior in which rats examine objects and landmarks in simple arenas (see Section 13.4). The misplace cells of O’Keefe (1976) and the more recent observations of neural firing in response to the movement of a hidden escape platform in a watermaze (Fyhn et al., 2002) also suggest that the hippocampus, perhaps acting in concert with neuromodulatory systems, detects and represent changes in the conjunction of objects and their locations. Several cells fired vigorously at the new platform location, despite previously having been silent. Others that fired in different locations around the maze continued to do so after platform relocation, arguing against spatial remapping. The new activity was paralleled by reduced discharge in a subset of simultaneously recorded interneurons. The pattern of activity largely returned toward its original configuration as the rat learned the new location. However, a few of the newly recruited neurons remained active. This persistent firing may reflect facilitated synaptic plasticity during the temporary reduction in inhibition (Wigstrom and Gustafsson, 1983; Paulsen and Moser, 1998). NMDA receptor-dependent LTP may be necessary for these permanent modifications in firing patterns when novel events occur in a familiar environment.

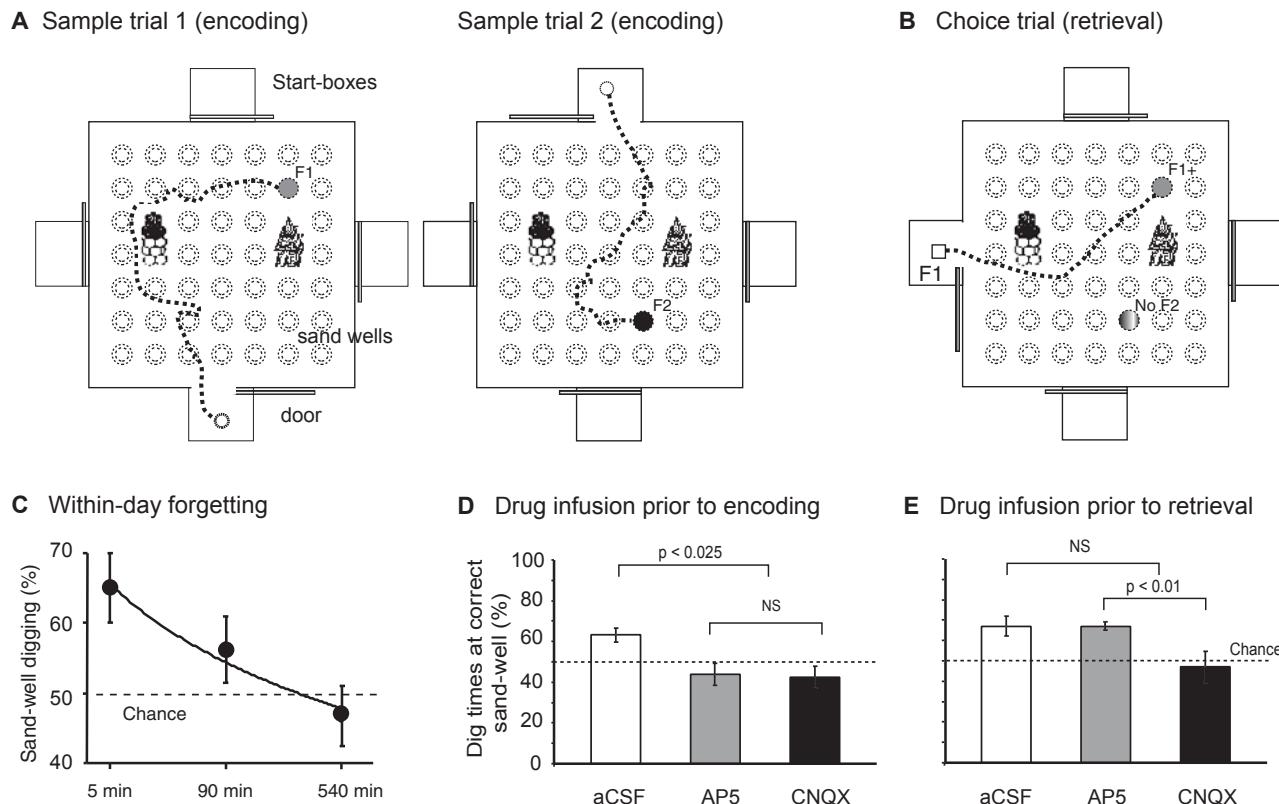

### Hippocampal Synaptic Plasticity, Neural Activity, and Rapid Paired-associate Learning

Day et al. (2003) developed a one-trial paired-associate task in which rats were trained to recall in which of two locations a particular flavor of rat chow was to be found in a large “event

arena” (Fig. 13–48). In each of two sample trials on each day a few minutes apart, rats left the start box to find a single open sand well where they could dig for a flavored food. No choices were required on this sample trial, and there was nothing in the procedure that would have required the animals to engage a contingent learning mechanism. The animals merely ran out into the arena, found a sand well, dug in it, and found food. This constituted one “event.” The two sample trials did, however, use two locations and two foods. This gave the animals the opportunity of automatically encoding—in one trial for each sandwell—that one flavor of chow was at one location and another flavor at another (Fig. 13–48A). They therefore had two “events” prior to the daily choice trial, which was started 5 to 20 minutes later. It began by giving the rats one of the two flavors to eat in the start box (their recall cue). A short while later, they were allowed to enter the arena where they now found two sand wells (Fig. 13–48B). On choice trials during training, going to the location associated with the flavor cue was rewarded with more of that same flavor. Nonrewarded probe trials were also run. Up to 30 locations and flavors were paired in novel combinations at the rate of two pairs per day. The results obtained with this “what–where” paradigm provided evidence that rats are capable of a limited form of episodic-like memory—and in a species more amenable to neurobiological study than the scrub-jays used by Clayton. The protocol lacks the dimension of time (the “when” element), which is a concern; but it shares with the avian food-caching paradigms that recall is required rather than recognition, and this represents a step forward from the object-in-place tasks used by Gaffan.

Day et al. (2003) also established that the one-trial encoding of such paired associates lasted no longer than 60 minutes before recall performance dropped to chance (Fig. 13–48C). Nonrewarded probe trials established that there was a preference for digging at the cued location despite the limited nature of the “event” that had uniquely taken place there that day. Encoding was sensitive to the acute intrahippocampal infusion of an NMDA receptor antagonist (D-AP5) without any effect on retrieval (Fig. 13–48D,E), whereas retrieval was insensitive to the AMPA receptor antagonist CNQX (Fig. 13–48E). These pharmacological observations were made by timing the infusions to be either just before or just after the encoding trial. That a difference between encoding and retrieval was obtained when the dorsal hippocampus was infused with D-AP5 indicates that the mere presence of the drug has no effect on memory retrieval, but it definitively blocks encoding. It seems more likely, and is in keeping with physiological studies revealing its importance for associative LTP, that an NMDA receptor-dependent mechanism in the hippocampus is involved in encoding the paired associate of an event and its location into memory in such a manner that the reactivation of one member of the pair can retrieve the memory of the other.

The “event arena” has the potential to serve as a flexible test bed for examining the neurobiology of rapid associative memory of the kind that may underlie human episodic mem-

**Figure 13-48.** Cued recall of the location of a single event. *A*, The 1.6 m<sup>2</sup> “event arena” made of plexiglass consisted of 49 sand wells, 2 intramaze landmarks, and 4 start boxes. On sample trial 1, the door to a start box is drawn back, and the rat runs out into the arena (dotted line) where it displays occasional lateral head movements to find food 1 at the single open well. Sample trial 2 is to a different food (F2) at a different location. *B*, The cued-recall choice trial begins with presentation of either of the two sample trial foods in the start box (food F1 is shown) followed by the rat being rewarded

selectively for digging at the sand well containing this same food. *C*, Rapid decay of event-place memory over the course of the day. *D, E*, Nonrewarded probe trials show that the animals preferentially digs in the sand well appropriate to the cue flavor given in the start box. Memory encoding in this task is sensitive to blockade of NMDA receptors (*D*), whereas memory expression requires only fast synaptic transmission via AMPA receptors (*E*). (Source: After Day et al., 2003.)

ory (what, where, and when). However, there are several features of behavioral performance in this task that need to be clarified and improved. First, the temporal component has yet been addressed, though it may be possible to use the surrogate of contextual specificity. Second, no hippocampal lesion study has yet been reported, and there is the difficulty that the drugs used may be directly affecting only one component of the what-where-when triad, such as the spatial component. That is, the drugs’ apparent impact on associative encoding or retrieval could be misleading. Studies of one-trial spatial memory in the event arena have helped clarify this point (Bast et al., 2005). Third, alterations in the protocol to look at the concurrent training of multiple places and flavors, analogous to learning a list of object–place pairs, are also underway. Conducted in the spatial domain, such a study would cast light on how multiple spatial associates could become integrated into “spatial schema” that might be constructed and stored in the neocortex. Preliminary data from such a study by Tse, Kakeyama and Langston (personal communication) indicates that such spatial schema can be gradually acquired over

several weeks; and once fully encoded and stored, new information can be added to the schema rapidly. If the schema can be shown to be neocortical, which preliminary evidence indicates they are, such a study may offer some handle on whether neocortical storage of information in a hippocampus-dependent learning task can be achieved during a single trial. This would provide vindication for the unusual prediction of this neurobiological theory that cortical learning is sometimes just as fast as hippocampal learning. Fourth, it would also be valuable to complement lesion and inactivation studies with physiological studies investigating whether there is differential c-fos or Arc activation in the hippocampus during this task, and if it is possible to identify neural representations of cued recall using ensemble single-unit recording. The latter would be a formidable undertaking but a valuable one, as it might reveal anticipatory components of place-specific unit firing driven by the task demands in which a flavor cue evokes a memory of a place. This would be a logical extension of the concepts of prospective and retrospective coding introduced by Ferbinteanu and Shapiro (2003).

### Storage of Spatial/Contextual Information Outside the Hippocampus?

An important milestone in the understanding of spatial cognition was the discovery that most pyramidal cells in the hippocampus exhibit location-specific activity and that the activity of such place cells is influenced by the training history of the animal (see Chapter 11). The predominantly spatial nature of hippocampal neuronal activity led to the proposal that place cells form a distributed map-like representation of the spatial environment that an animal uses for efficient navigation (O’Keefe and Nadel, 1978). When a rat is exposed to a new environment, pyramidal cells develop distinct firing fields within a few minutes (Hill, 1978; Wilson and McNaughton, 1993b). The place fields then remain stable for weeks or more if the environment is constant (Thompson and Best, 1990; Lever et al., 2002), as predicted if these cells contribute to a particular spatial memory.

It is commonly believed that the development of hippocampal firing patterns, like hippocampal memory, might depend on LTP at hippocampal excitatory synapses. Several studies have investigated the contribution of LTP to spatial firing in hippocampal pyramidal cells. Surprisingly, interventions that abolish hippocampal LTP have only subtle effects on place fields. For example, place-specific firing fields develop normally in rats treated systemically with an NMDA receptor antagonist at a dose that prevents new LTP in the hippocampus (Kentros et al., 1998). Despite blockade of the NMDA receptor, place fields can be maintained between consecutive test sessions in the same environment for at least 1.5 hours. They do, however, show instability across days. Place fields recorded in CA1 in mice with mutations of NMDA receptors in either CA3 or CA1 are somewhat less distinct than in control mice under certain conditions; but in contrast to the pharmacological findings, firing fields remain stable across repeated tests on the same day once they have been established (McHugh et al., 1996; Nakazawa et al., 2002). Similar results were obtained when LTP was blocked by interference with  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase II (Rotenberg et al., 1996) or protein kinase A (Rotenberg et al., 1996). However, these interventions did decrease the long-term stability of the place fields, as measured 24 hours after the initial exposure to the environment. Together, these studies suggest that NMDA receptor activation may not be necessary for the development or initial maintenance of place-related activity in hippocampal neurons, although it may contribute to the fine-tuning of place fields and aspects of the long-term stabilization of spatial representations (see Chapter 11). The latter function could involve the neocortex as well as the hippocampus.

The development of place fields during NMDA receptor blockade or other forms of disruption of LTP is consistent with several lines of work suggesting that spatial information can be generated and stored upstream of the hippocampus. First, location-specific firing is already expressed in the superficial layers of the entorhinal cortex (Quirk et al., 1992; Frank et al., 2000; Fyhn et al., 2004; Hafting et al., 2005). The fact

that most principal cells in entorhinal cortex exhibit view-independent spatial modulation suggests that, by this stage, a fundamental spatial computation may already have been made. It is also possible, however, that spatial firing in superficial entorhinal neurons depends on spatial input from cells in deep layers, which in turn may rely on associative computations in afferent hippocampal structures. The manner in which entorhinal cells code space remains unclear, but that they do helps to understand why pyramidal cells in CA1 exhibit spatial firing both after selective lesions of the dentate gyrus (McNaughton et al., 1989) and after disconnection of CA1 from CA3 (Brun et al., 2002). In CA3-lesioned animals, CA1 pyramidal neurons receive cortical input only via direct connections from the entorhinal cortex. The presence of place fields in these preparations suggests that direct entorhinal–hippocampal circuitry has significant capacity for transforming weak location-modulated signals from superficial layers of the entorhinal cortex into accurate spatial firing in CA1. Several simple filter mechanisms could accomplish such a transformation. For example, firing rates of perforant path fibers to CA1 could be thresholded by feedforward inhibition, such that only the highest afferent firing rates (i.e., those in the center of the entorhinal place field), are able to drive postsynaptic neurons in the hippocampus. Alternatively, single excitatory postsynaptic potentials (EPSPs) in distal pyramidal cell dendrites of CA1 may often not be sufficient to trigger somatic action potentials in these cells; reliable discharge may require summation of EPSPs (i.e., high afferent firing rates (Golding and Spruston, 1998; Golding et al., 2002).

It is important to note that the computation and storage of positional information outside the hippocampus does not preclude long-term storage of some spatial information (or the indices of such information) in the hippocampus. Indeed, the internal recurrent connectivity of hippocampal area CA3 makes the region highly suitable for storage of just these types of patterned “cartoons,” at least for an intermediate period of time and perhaps longer in some cases. Other results suggest that plasticity in associational synapses of CA3 is necessary for successful “snapshot” encoding of spatial information in a manner that later allows recall with partial cues (Nakazawa et al., 2002). Longitudinal axon collaterals in CA3 may be important for successful retrieval of such information, as memory retention may be impaired by a single transversely oriented cut through the dorsal CA3 region of each hippocampus (Steffenach et al., 2002).

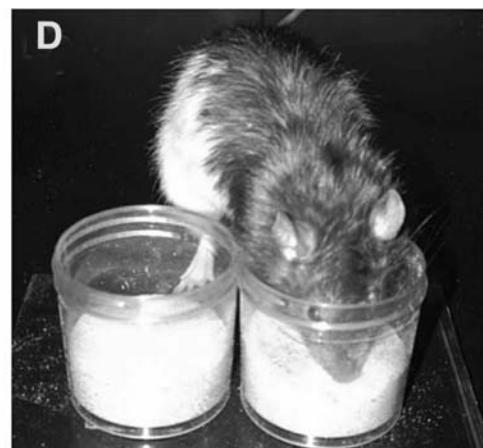

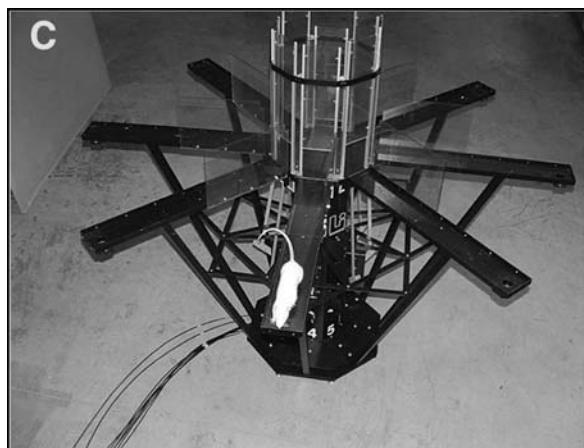

### A Last Word

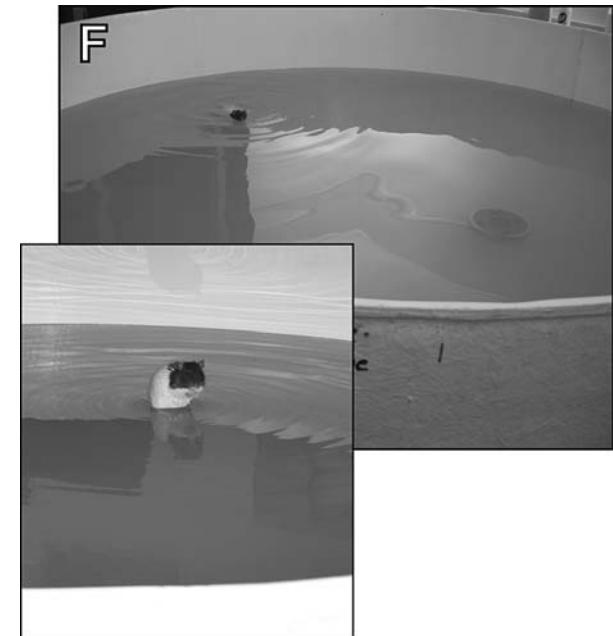

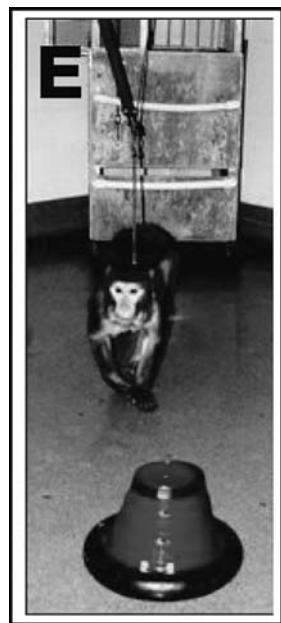

It remains to be seen how this and other neurobiological theories of episodic-like memory (Hasselmo et al., 2002; McNaughton et al., 2003; Nakazawa et al., 2004; Buzsaki, 2005; Hasselmo and Howard, 2005) will handle the growing body of data that point to a specific role for the hippocampus in at least aspects of “episodic-like” memory. The approach just described builds on the neuropsychological framework developed in this chapter. It accepts that understanding the neuroanatomical basis of recognizing a previously seen stimulus

is an important foundation stone of declarative memory (see Section 13.3) but asserts that there is more to memory than this (as, indeed, declarative memory theory has long recognized). It also accepts that hippocampal cells agree that space is special but argues that they can do more than encode spatial information and calls into question the supposition that allocentric spatial memory is fundamentally different from other forms of associative memory (see Section 13.4). It tries to take on board the somewhat impenetrable developments in contemporary animal learning theory and the progress that has been made in understanding predictable ambiguity (see Section 13.5). Perhaps most difficult of all, it is part of an international effort seeking to integrate functional and mechanistic ideas about rapid, one-trial, context-specific learning. This task requires an exquisite understanding of hippocampal neuroanatomy, including that of the myriad inhibitory interneurons and the local circuits of which they are a part that surely make a major contribution to the information processing “algorithms” computed in the hippocampus. Cell biological approaches will also prove increasingly valuable when

thinking about the problems of trace stabilization and memory consolidation. A major obstacle ahead is understanding better how information is “represented” as patterns of neural activity, and progress in unraveling the physiology of hippocampal neurons will aid in that formidable task (see Chapters 5 and 6). In this research program, a wide range of behavioral tasks with animals will continue to play a key part in unraveling the functions and neural mechanisms of the hippocampal formation. This chapter has drawn on data derived from primate experiments investigating recognition memory and object-in-place memory and from rats running in radial mazes, digging in odorized sand wells for food, or swimming in watermazes; and it has touched on new behavioral techniques to investigate episodic-like memory. It is fitting to acknowledge and celebrate the contribution that laboratory animals have made to this effort (Fig. 13–49, see color insert). Progress is being made in tackling the mysteries of the hippocampal “memory machine.” The challenges ahead are as formidable as have been the achievements in characterizing its role in memory over the past three decades.

**Figure 13–49.** Examples of common behavioral tasks used to study hippocampal function in animals. A. Classic Wisconsin General Testing Apparatus for macaque monkeys. B. Screen shot of modern “touchscreen” display. C. Radial maze foraging task for rats, shown with doors. D. Rat making a choice in a two-pot olfactory discrimination task. Only one odor is familiar or may be cued by another odor in a paired-associate manner.

**Figure 13–49.** (Continued) *E*. Foraging monkey exploring objects in a laboratory. *F*. Watermaze. Rat swimming in a large 2-m pool trying to find a hidden escape platform under the water surface (just visible on the right). *Inset* (below). The rat is on the platform, rearing and working out his location. *G*. Scrub-jay in an episodic-like

“what-where-when” memory task in which it caches various foods in an ice-cube tray and then retrieves them selectively later. *H*. Paired-associate event arena task for rats. Different foods are found at specific locations (e.g., one shown) in the apparatus.

## ACKNOWLEDGMENTS

I am grateful to many people for their help in preparing this chapter. In addition to my co-editors of this book, Mark Baxter (Oxford University) read a draft of the entire manuscript and offered numerous comments and criticisms. Tobias Bast, Stephen Martin (University of Edinburgh and other members of the Laboratory for Cognitive Neuroscience), Edvard Moser and May-Britt Moser (Center for the Biology of Memory, Trondheim), and Craig Stark (Johns Hopkins) also read large parts and directed me to additional literature. I am grateful to Helen Knight, Marie Pezze, and Carolyn Smith for collecting material for and assisting with many of the figures. I am also grateful to many neuroscience colleagues around the world who provided material for the figures or advice of other kinds (including Jamie Ainge, Verner Bingman, Norbert Fortin, John

Guzowski, Lucia Jacobs, Len Jarrard, Kazu Nakazawa, and Simon Rempel). Patrick Spoooner helped with many aspects of the computing. I apologize to yet others who helped but whom I have not mentioned. Finally, one institution should not be forgotten. I am eternally grateful to the UK Medical Research Council without whose support throughout my career this work would not have been possible.

# Computational Models of the Spatial and Mnemonic Functions of the Hippocampus

## 14.1 Overview

Some of the most striking data relating cognitive behavior to neuronal firing, damage, or metabolic activity in the brain concerns the hippocampus. The use of computational models has been invaluable for exploring the link between neurons and behavior, enabling hypothetical mechanisms to be defined precisely and examined quantitatively. Here I review many of these models, including models of spatial functions, models of more general associative mnemonic functions, models that stress feedforward processing through the hippocampal system, and those stressing recurrent processing within it. I review the spatial models first, as they are most firmly rooted in the known electrophysiology of the region. These models cover both the representation of the animal's spatial location and orientation and the use of this information in spatial navigation. The models of mnemonic function, specifically associative or episodic memory, follow from Marr's seminal 1971 model. I use this model as a generic framework in which to consider the various subsequent developments to it. Finally, I review those models attempting to bring together the spatial and mnemonic functions of the hippocampus.

## 14.2 Introduction

There have been many attempts to understand and quantify the contribution of the hippocampus to cognitive behavior. In this chapter I focus on models of the link between the cognitive ability of the animal and the action of individual cells and synapses. As reviewed in Chapter 13, lesion studies in a variety of mammals (including humans) have implicated the hippocampus in spatial navigation, whereas human neuropsychology has most notably implicated it in episodic or declarative memory (see Chapter 12). In addition to these

data a vast body of knowledge has been collected regarding the neural representation of the spatial location and orientation of freely moving rats (see Chapter 11). Hypotheses regarding the function of the hippocampus have traditionally been expressed in words. However, it is often possible to interpret verbal descriptions in more than one way, or to change their interpretation retrospectively to suit the facts. In addition, it can be difficult to tell whether the proposed explanation would actually work as described and, if so, difficult to make unambiguous quantitative predictions that can be used to test it. These problems become even more acute when hypotheses address the question of how a putative function arises from the cooperative behavior of large numbers of neurons and synapses. One way around this is to express such a hypothesis in terms of equations or computer simulations, referred to as a computational model. An advantage of this approach is that all of the parameter values and assumptions necessary to generate the behavior concerned need to be made explicit; another is that the operation of the model is unambiguously specified. These advantages mean that computational modeling has an important role to play in the progress of scientific understanding, most importantly in its interaction with experimental investigation: by predicting critical experiments, undergoing revision to reflect their results, and predicting new ones. They are not a panacea for all ills; and interpretation of a model, the way it works, and the values of its parameters can still be changed or disputed. At the most basic level a computational model can serve as an existence of proof of the behavior that can result from a proposed mechanism, but more generally it can serve to define a theoretical understanding and provide a powerful framework within which the nature of a theory relating brain to behavior can be understood.

Examples of potential insights into the function of the nervous system that would not have been fully understood, and in some cases even suspected, without computational modeling include the relation of voltage-dependent ion chan-

nels to the propagation of action potentials (Hodgkin and Huxley, 1952); the possible relation of the pattern of firing of dopamine neurons during conditioning experiments to the process of learning from trial and error (interpretable via the Rescorla-Wagner law and subsequent computational models of “reinforcement learning”) (e.g., Shultz et al., 1997); the relation of partially shifting gain field responses in parietal cortex and optimal integration of multiple cues (made clear by computational understanding of the way attractor networks can perform this function) (e.g., Deneve et al., 2001); and the effect of genetic knockout of *N*-methyl-D-aspartate (NMDA) receptors in hippocampal region CA3 on the robustness of both the mouse’s spatial memory and the firing of its place cells when a subset of environmental landmarks are removed (interpretable as “pattern completion” in a model of CA3 acting as an attractor network) (Marr, 1971; Nakazawa et al., 2002) (see Section 14.3.3 and 14.5.3).

Computational modeling of the hippocampus has followed two largely independent streams over the years: one seeking to explain a general role in associative memory and the other focusing on its role in spatial navigation. Models usually start from as detailed a biophysical level as is useful for the level of the hypothesis they seek to investigate. Although many models reviewed here involve detailed simulation of cellular and synaptic electrophysiology, the aim of this chapter is to explain the neural bases of spatial and mnemonic behavior—something that is made easier by focusing on the simplest level of description capturing the likely functional consequences of cellular and synaptic events (e.g., whether an action potential was fired). Thus, the activity (firing rate) of a neuron is simply viewed as a monotonic function of the amount by which the net input to it exceeds some threshold value. The net input to a neuron is the sum of the activity of each neuron connected to it weighted by the strength of the connection (occasionally inhibitory inputs are modeled as a divisive term in the net input rather than a subtractive term, see Figure 14–10, later). “Learning” corresponds to modification of the connection strengths. Most commonly learning is of a “Hebbian” nature (Hebb, 1949) such that simultaneous pre- and post-connection activity leads to increased connection strength and is often used in explicit analogy to synaptic processes such as long-term potentiation (LTP) (see Chapter 10) (see Box 14–1). Other concepts are explained as and where necessary. Readers interested in neural computation more generally should see the relevant literature (e.g., McClelland and Rumelhart, 1986; Rumelhart and McClelland, 1986; Hertz et al., 1990; Dayan and Abbott, 2002).

Because the anatomy of the region is similar in rats, primates, and humans, it seems sensible to start with the computational functions of the hippocampal region in the rat and then consider how these functions might have been adapted during evolution. This has the advantage of applying the most detailed electrophysiological constraints at the outset. Accordingly, in this chapter I concentrate initially on neural models starting from the reliable and well understood body of data regarding place cells and the neural representation of

space, drawing mostly on experimental data collected in rats. I next consider models of the use of spatial representations in guiding behavior. Together, models of the representation of location and orientation from sensory input and models of how these representations are used to guide behavior provide one of the best examples of quantitative understanding of the links between perception, cognition, and action and between cells and systems and behavior. The second half of the chapter concerns attempts to model the more general role of the human hippocampus in memory for personal experience. The chapter concludes with consideration of the models that attempt to reconcile these two streams of research (spatial and mnemonic). As we shall see, the role of the recurrent collaterals in area CA3 of the hippocampus maintains a common point of contact between these models: In both the spatial and episodic memory frameworks they are assumed to perform an associative memory function.

### 14.3 Hippocampus and Spatial Representation

This section addresses the representation of spatial location and orientation. Models of the representation of location embodied by the firing of place cells are considered first. These models take two often equivalent forms: those relying predominantly on feedforward connections to capture the data and those relying predominantly on the recurrent connections in CA3. It is not only the firing rates of place cells that encode location but also the time of firing relative to the ongoing theta rhythm on the electroencephalogram (EEG) (O’Keefe and Recce, 1993). Both of these aspects of firing have been the subjects of extensive computational modeling. The representation of the animal’s orientation embodied by the head-direction (HD) cells is equally striking; and the nature of this signal, considered in the remainder of this section, has also been investigated by computational modeling in more recent years. Finally, the discovery of grid cells’ (Hafting et al., 2005) has provided a new focus, reviewed by McNaughton et al. (2006).

#### 14.3.1 Representing Spatial Location and Orientation: Data

A rich set of experimental data has been gathered on the neural representation of spatial behavior found in and around the hippocampus. Here I briefly summarize the results with the greatest relevance to the models described below (see Chapter 11 for more details). The firing of place cells in the hippocampi of freely moving rats encodes the location of the animal, each cell firing when the animal is within a particular portion of its environment (the “place field”). Cells with similar responses have also been observed in primates (Hori et al., 2003; Ludvig et al., 2004) including humans (Ekstrom et al., 2003). In open environments through which the rat can move freely, firing rates are not influenced by the animal’s orientation, whereas in environments in which movement direction

**Box 14-1****Learning via Synaptic Modification: Hebbian Learning Rules**

In the simplest type of neural network model, the firing rate, or “activity,” of a neuron ( $a$ ) is simply a function (the “transfer function”  $f$ ) of the net current coming into the neuron, which in turn is simply a weighted sum of the firing rates ( $u_i$ ) of the neurons connecting to it. That is:  $a = f(\sum_i w_i u_i)$ , often written as:  $a = f(\underline{w} \cdot \underline{u})$ , where  $\underline{w}$  is the vector of connection “weights” modeling the strengths (e.g., net synaptic efficacy) of connections from the input neurons, and the dot is the vector dot product. With the simplest, linear, transfer function, the activation is given by:

$$a = \underline{w} \cdot \underline{u} \quad (1)$$

In such networks, “learning” corresponds to modification of the connection weights  $\underline{w}$ . Below I discuss some of the Hebbian learning rules mentioned in the rest of the chapter, and their effects, following the discussion in Dayan and Abbott (2002), where further details can be found.

A learning rule directly implementing Hebb’s (1949) postulate of coincident firing leading to increased coupling between neurons describes the change in connection weights in terms of the product of pre- and post-synaptic firing rates:

$$\tau \frac{dw_i}{dt} = au_i \text{ or } \tau \frac{d\underline{w}}{dt} = a\underline{u} \quad (2)$$

where  $\tau$  gives the rate of change of connection weights with time. When this rule is applied to a “training set” of  $n$  example input patterns of activity  $\underline{u}^\mu$ , each presented for an equal duration over a total time  $T$ , we can integrate equation 2 to see the total change in  $\underline{w}$ :

$$\underline{w} \rightarrow \underline{w} + \frac{T}{\tau} \sum_{\mu} a^{\mu} \underline{u}^{\mu} \quad (3)$$

where  $a^{\mu} = \underline{w} \cdot \underline{u}^{\mu}$  from equation 1. If the connection weights are updated only after presentation of all of the input patterns, we can say:

$$\underline{w} \rightarrow \underline{w} + \frac{T}{\tau} \sum_{\mu} (\underline{w} \cdot \underline{u}^{\mu}) \underline{u}^{\mu} = \underline{w} + \frac{nT}{\tau} Q \cdot \underline{w} \quad (4)$$

where  $Q$  is the correlation matrix of the input patterns ( $Q = \langle \underline{u} \underline{u} \rangle$ , where  $\langle \rangle$  denotes the average over input patterns, and  $\underline{u} \underline{u}$  is the outer product of  $\underline{u}$  with itself). Thus, simple Hebbian learning rules are also known as correlation-based learning rules. Inspection of equation 4 indicates that the weight vector  $\underline{w}$ , if plotted in the same space as the input vectors  $\underline{u}^{\mu}$ , eventually follows the principal eigenvector of the correlation matrix; that is, it will lie along the direction from the origin to the mean input pattern ( $\langle \underline{u} \rangle$ ) or, if  $\langle \underline{u} \rangle$  is at the origin, along the first principal component of the set of input patterns. However, this learning rule is not stable: Large weights produce large output activations, which produce large increases in weights and so on. More formally, it can be seen from the dot product of  $\underline{w}$  in equation 2 that the length of the weight vector increases whenever the output neuron is active:

$$\frac{d |\underline{w}|^2}{dt} = 2\underline{w} \cdot \frac{d\underline{w}}{dt} = \frac{2a\underline{w} \cdot \underline{u}}{\tau} = \frac{2a^2}{\tau} \quad (5)$$

One way to introduce balance into the learning rule is to allow for a connection weight to increase or to decrease according to the levels of pre- and postconnection activity, by analogy with long-term potentiation and depression (LTP and LTD) (see Chapter 10). In this way equation 2 could become

$$\tau \frac{d\underline{w}}{dt} = (a - \theta) \underline{u}, \text{ or } \tau \frac{d\underline{w}}{dt} = a(\underline{u} - \varphi) \quad (6)$$

where either a postsynaptic threshold or a set of presynaptic thresholds are applied to determine the sense and size of weight changes (respectively:  $\theta$  is the level postsynaptic activity must surpass for the connection to increase rather than decrease; or  $\varphi$ , which is the vector of activity levels each input neuron must surpass). The most obvious choice of threshold for the pre- or postsynaptic neuron is its average activity over the training set. In this case, following a similar derivation to equation 4, both versions produce the same learning rule:

$$\underline{w} \rightarrow \underline{w} + \frac{nT}{\tau} C \cdot \underline{w} \quad (7)$$

(Continued)

**Box 14-1****Learning via Synaptic Modification: Hebbian Learning Rules (Continued)**

where  $C$  is the covariance matrix of the input patterns:  $C = \langle(\underline{u}-\langle\underline{u}\rangle)^2\rangle = \langle\underline{u}\underline{u}\rangle - \langle\underline{u}\rangle^2 = \langle(\underline{u}-\langle\underline{u}\rangle)\underline{u}\rangle$ . These learning rules are also known as covariance rules. Inspection of equation 7 indicates that the weight vector will eventually follow the principal eigenvector of the covariance matrix (i.e., it will lie along the direction of the first principal component of the set of input patterns). It should be noted that these rules are also not stable; in this case  $d w^2/dt$  is proportional to the variance ( $\langle a^2 \rangle - \langle a \rangle^2$ ) of the output activity over the training set.

The BCM learning rule, derived from experimental investigation of visual cortical plasticity (Bienenstock et al., 1982), proposes that:

$$\tau \frac{dw}{dt} = a\underline{u}(a - \theta(a)) \quad (8)$$

This requires both pre- and postsynaptic activity for modification of a connection weight (unlike the rules in equation 6), and also involves a sliding postsynaptic threshold ( $\theta(a)$ ), which varies with postsynaptic activity. So long as the postsynaptic threshold increases as a power of  $a > 1$  (typically following a time-averaged estimate of  $a^2$ ), it can ensure stability of the learning rule: effectively increasing the threshold to an overactive output neuron so connection weights to it tend to be reduced.

The other common way in which Hebbian learning rules are stabilized—e.g., in Rumelhart and Zipser's (1986) “competitive learning” algorithm—is to use divisive normalization: explicitly constraining the length of the weight vector to remain constant during learning by dividing all weights by  $|\underline{w}|$ . Although this is a nonlocal operation, because synaptic strengths must be altered according to the state of other, distant synapses, a similar effect can be achieved by the local learning rule of Oja (1982):

$$\tau \frac{dw}{dt} = a\underline{u} - \beta a^2 \underline{w} \quad (9)$$

An analysis similar to equation 5 shows that  $|\underline{w}|^2$  tends to a value  $1/\beta$  under repeated application of this rule.

As well as being stable, the BCM and normalized Hebbian learning rules involve competition between connections: Increasing some of the connection weights onto a neuron leads to a decrease in the others. Under the BCM rule, this occurs because of increased activity leading to a higher postsynaptic threshold and thus an increased incidence of LTD versus LTP. With normalization it occurs directly owing to the increase in the length of the weight vector. These learning rules tend to allow a neuron to become tuned to respond to specific patterns of input activation (see text). There is at least some evidence for competitive interaction between synapses such that increasing the strengths of one set of synapses leads to a decrease in the strengths of others so as to normalize the total synaptic strength onto the neuron (Royer and Pare, 2003). Note however, that recent evidence of the dependence of synaptic plasticity on the precise timing of pre- and postsynaptic activity (see Chapter 10) changes the likely nature of learning rules based on LTP and LTD, as in the effects of temporal asymmetry noted in Section 14.4.3.

is constrained (e.g., linear tracks, eight-arm mazes) firing is strongly modulated by the rat's direction of motion (see Chapter 11). The orientation of the place cell representation is controlled by “distal” cues at or beyond the edge of the environment (O'Keefe and Conway, 1978; Muller and Kubie, 1987) but not by those within it (Cressant et al., 1997). A place cell's spatially localized firing appears to be robust to the removal of subsets of cues and indeed removal of all of the controlling visual cues while the rat remains in the environment (Muller and Kubie, 1987; O'Keefe and Speakman, 1987), although remaining uncontrolled cues may be important in these cases (Save et al., 2000).

The complementary representation of orientation independent of location is found in “head direction cells” (HDCs) in the mammillary bodies, anterior thalamic nuclei, and dor-

sal presubiculum (Taube et al., 1990). The HDCs code for head direction within an environment, each firing whenever the animal's head points in a specific direction, independently of the animal's location. The orientation of the head direction representation is controlled by distal visual cues in the same way as the place cell representation. The overall orientation of both place and HDC representations may be disrupted by disorientation (rotating the rat in a covered container); and when both have been recorded simultaneously, both representations have remained in register with each other (Knierim et al., 1995). Interestingly, hints that an expanded representation of neurons responding to specific combinations of place and direction have been found in the presubiculum (Sharp, 1996; Cacucci et al., 2004). A third type of representation, “grid cells,” has now been found in dorsomedial entorhinal cortex

(Hafting et al., 2005). Each grid cell fires in a set of locations which is laid out on a hexagonal grid. The intriguing properties of these cells are summarized at the end of Section 14.3.3. However, at the time of this writing they have not yet been fully incorporated into models of hippocampal function and so are not a focus of this chapter.

Beyond the clear encoding of spatial location and orientation in the firing rates of these neurons, the picture becomes slightly more complex. Initial experiments in which place cells were recorded in environments of different shape (Muller and Kubie, 1987) reported completely different patterns of firing in the two environments (“remapping”). A place cell active in one environment might fire in an unrelated location in the second environment or might be silent. In other experiments, perhaps involving less complete changes to the environment or less extensive pretraining in the various environments, parametric changes in the pattern of firing were observed (e.g., O’Keefe and Burgess, 1996). Interestingly, although the firing rate of place cells can be shown to encode the animal’s location within a given environment (e.g., Wilson and McNaughton, 1993), the times at which they fire relative to the theta rhythm encodes additional information (see Chapter 11) (O’Keefe and Recce, 1993; Skaggs et al., 1996; Jensen and Lisman, 2000).

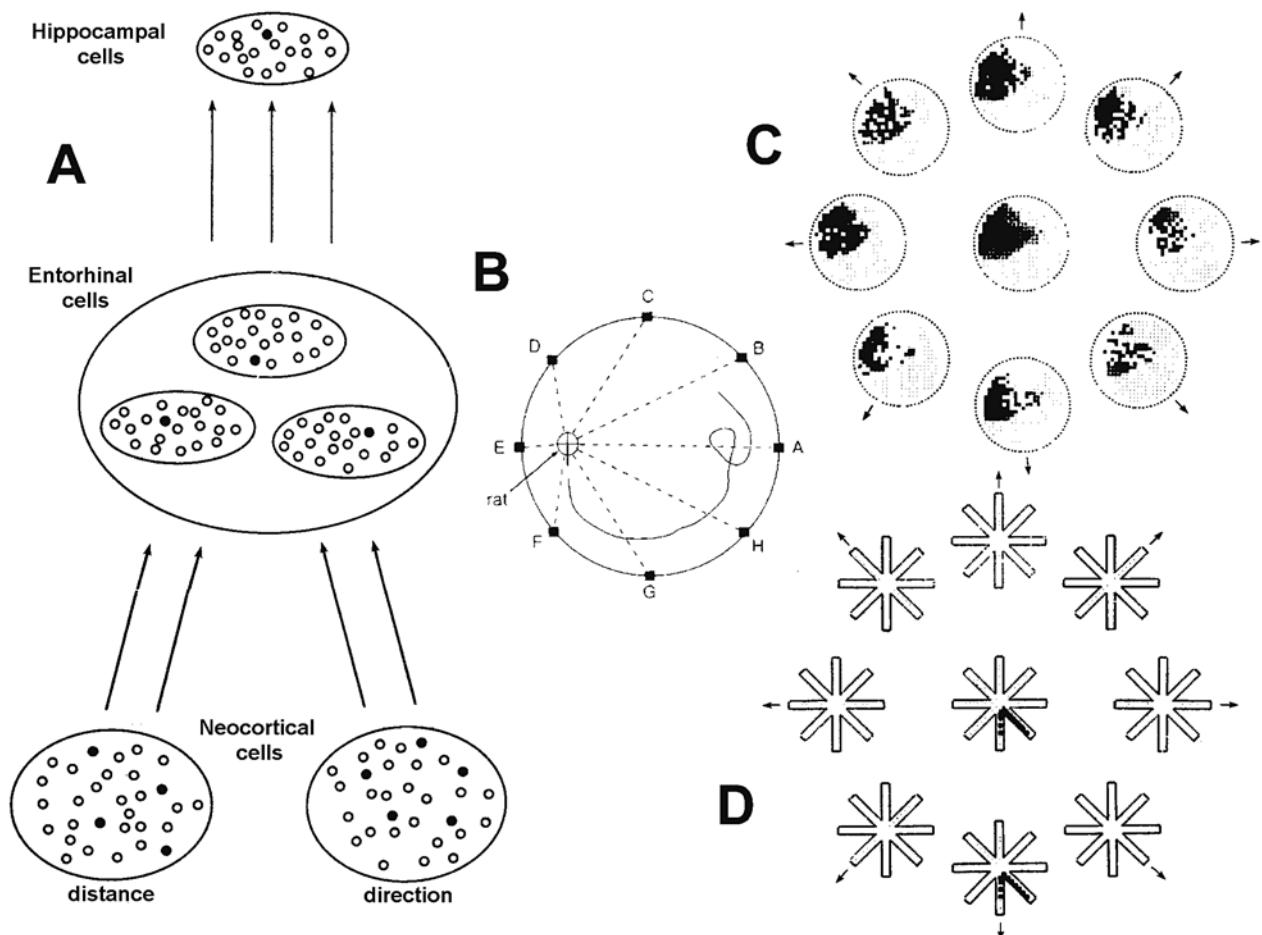

### 14.3.2 Representing Spatial Location: Feedforward Models

Computational modeling of place cell firing began with Zipser’s (1985) model. In this model, sensory details of the environment feedforward to landmark detectors and thence to place cells. Landmark detectors are neurons specific to a specific place cell and to a specific aspect of the sensory scene (a “location parameter”). The output of these detectors is proportional to the match between the stored state of a location parameter and its currently perceived state. A place cell’s activity corresponds to a thresholded sum of the strengths of the matches it receives from several landmark detectors. Interestingly, the most obvious location parameter—distance from a landmark—was rejected in favor of measures that scale with environmental size, such as the retinal angle between two landmarks, on the basis of a misinterpretation of Muller and Kubie’s (1987) experiment. In this experiment, a significant but small number of place fields were shown to expand following a doubling in the linear size of the environment. However, this expansion corresponded to, at most, approximate doubling of the place field in area rather than the quadrupling predicted if everything scaled up proportionately. Furthermore, in many cells the expansion often appeared to be along only one environmental dimension rather than both. The model captures some of the motility of place fields in the presence of manipulations of environmental cues and some of their robustness to the removal of subsets of cues and (incorrectly) produces a place field that scales up proportionately with environmental expansion.

Sharp (1991) followed in the same vein of feedforward modeling of the response of place cells to sensory input from

the environment but with the incorporation of an element of “competitive learning” (Rumelhart and Zipser, 1986). Briefly, this involves neurons arranged in groups dominated by lateral inhibition such that only the neuron with the greatest input can fire. Normalized Hebbian learning is then applied (i.e., increasing the strengths of connections between simultaneously active neurons while decreasing the others so the overall strength of connections to a neuron does not change (see Box 14–1). This results in specific neurons coming to represent specific patterns of input, with each neuron responding to a particular pattern or patterns similar to it. Sharp’s model envisaged two types of sensory input regarding each distal cue: one representing its distance from the rat and the other representing both its distance from the rat and its direction relative to the rat’s heading. This sensory input passed forward to a layer of entorhinal cortical cells and thence to a layer of place cells (Fig. 14–1). Competitive learning at each layer causes the entorhinal and place cells to learn to respond selectively to the pattern of sensory input present in a particular portion of the environment, and it produces reasonable robustness to cue removal. The successive layers of competition produce sharper tuning to position and greater robustness to cue removal in place cells than entorhinal cells. Due to the use of distance-related inputs, expansion of the environment produces results that are qualitatively similar to those of Muller and Kubie’s (1987) experiment. The most interesting aspect of this model concerns the directional modulation of place cell firing. In the model, place cell firing is initially directionally modulated owing to the partially directional sensory inputs. During random exploration through an open environment, competitive learning allows a given place cell to learn to respond to the sensory inputs occurring for different orientations at the place field, producing nondirectional firing. By contrast, this does not occur during constrained motion (i.e., back and forth in a single direction). This provides a good, simple model of the directionality of place cell firing, although a more detailed look at directionality data indicates that, if anything, place fields in open environments are initially nondirectional and become directional as a result of experience. For alternative models see Blum and Abbott (1996), Brunel and Trullier (1998) and Kali and Dayan (2000), discussed below.

In an attempt to derive the form of the sensory input to the place cells, O’Keefe and Burgess (1996) systematically varied the shape and size of the rat’s environment while recording from the same cells. The patterns of firing across environments included place fields that stretched or became bimodal when the environment expanded. These patterns were not consistent with those obtained in previous models of place fields depending on the relative locations of discrete landmarks from the rat (e.g., Zipser, 1985) but, rather, indicated continuous dependence on environmental boundaries. Specifically, place fields were viewed as a thresholded linear sum of inputs tuned to respond to the presence of a boundary at a given distance along a given allocentric direction (i.e., independent of the orientation of the rat and probably

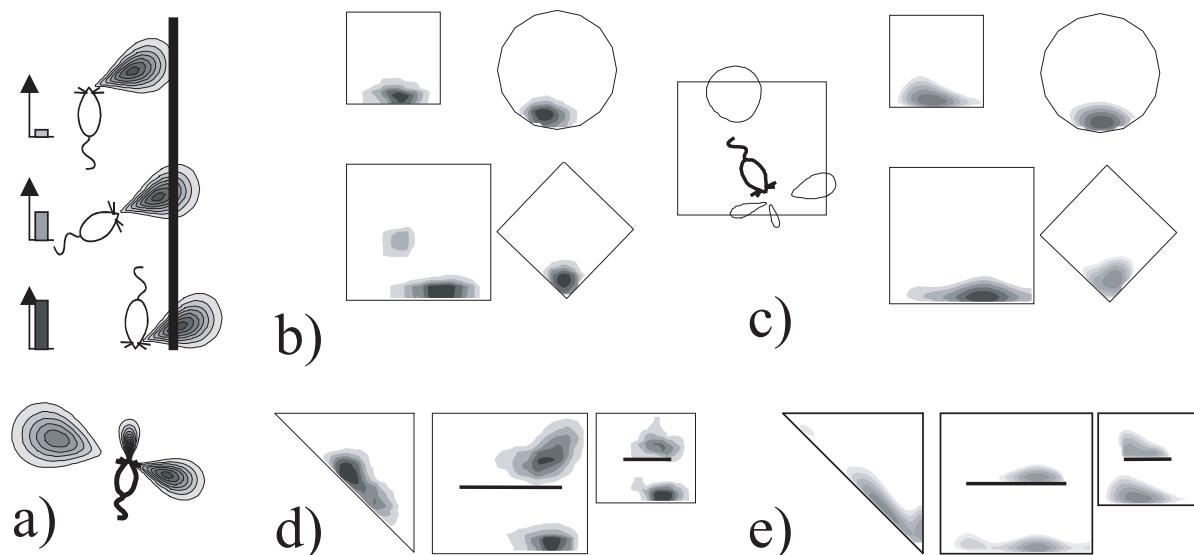

**Figure 14-1.** Sharp's (1991) model of place cell firing in response to sensory input. *A*, Two groups of neocortical cells respond to the distance or (egocentric) direction of specific cues as the rat moves in a cylinder (shown in *B*, cues marked by letters). Competitive learning in successive layers of entorhinal cells and place cells leads, after exploration, to spatially tuned firing that is robust to removal of subsets of cues. *C*, If exploration is unconstrained, as

in an open cylinder, place cell firing is only weakly modulated by the heading direction of the animal (overall place field shown in center, firing fields at each of eight heading direction shown around the edge). *D*, If exploration is constrained to specific directions of movement, as on a radial arm maze, place cell firing is strongly modulated by the heading direction. (Source: Adapted from Sharp, 1991.)

determined relative to the head-direction system; see below) (Fig. 14-2). These hypothetical inputs were termed “boundary vector cells.” By fitting a place cell’s firing pattern across several environmental shapes, the model can predict its firing pattern in an environment of novel shape (Hartley et al., 2000). In an experiment complementary to the variation of environmental shape, Fenton et al. (2000) parametrically varied the position of two cue cards around the edge of a cylindrical environment. Although each card alone can control the overall orientation of the recorded place fields, inconsistent movement of both (i.e., moving them closer together or apart) produces inhomogeneous parametric movement of the place fields such that their movement depends on their location. The added complexity of the cue cards acting as both identifiable boundaries and directional cues can be incorporated into the boundary vector cell model by assuming that inconsistent cue-card movement warps the representation of head direction, and boundary vector cells become sensitive to variations in texture after sufficient exposure (Burgess and Hartley, 2002).

One phenomenon not addressed by the above models is the “remapping” of place cell representations across different environments. This remapping can be both partial and incremental over time (e.g., Bostock et al., 1991; Skaggs and McNaughton, 1998; Lever et al., 2002), with the eventual creation of stable but distinct patterns of firing in the two environments. The factors influencing the speed and completeness of remapping are not currently well understood, but one common change in an individual place cell is to continue to fire in the environment in which it fires most strongly and to stop firing in the other. This aspect of remapping was addressed by Fuhs and Touretzky (2000) in a model of learning in the perforant path projection from entorhinal cortex to place cells in CA3. They found that the usual learning rules relating synaptic modification to the product of pre- and postsynaptic activity (i.e., Hebbian learning) or to its covariance were unable to reproduce this behavior. In the case of Hebbian learning, a place cell with strong firing in one environment and weak firing in the other strengthens its firing in both environments. In

**Figure 14-2.** Model of the geometrical influence on place fields (Hartley et al., 2000), assuming a stable directional reference frame. Place fields are composed from thresholded linear sums of the firing rates of boundary vector cells (BVCs). *a*. Above: Each BVC has a Gaussian tuned response to the presence of a boundary at a given distance and bearing from the rat (independent of its orientation). Below: The sharpness of tuning of a BVC decreases as the distance to which it is tuned increases. The only free parameters of a BVC are the distance and direction of the peak response.

the case of covariance learning, exposure to the second environment tends to lead to loss of the place cell representation of the first environment. By contrast, the BCM (Bienenstock-Cooper-Munro) learning rule (Bienenstock et al., 1982) (see Box 14-1), which explicitly makes the direction of synaptic modification dependent on the strength of the postsynaptic activity, did produce the desired result: strong firing remaining stable and weak firing reducing with experience. This type of learning can also capture the way place fields become more coherent with time and the temporal dynamics of their response to the introduction of a barrier into the environment (Barry et al., 2006).

Evidence of experience-dependent change in place cell firing also comes from experiments by Mehta et al. (1997, 2000). They found that, over the first few runs through a CA1 place field on a linear track, the spatial distribution of firing changes from roughly symmetrical to slightly asymmetrical, caused by additional firing at low rates earlier on the track. They suggest that this change results from the known temporal asymmetry of LTP (which is greater when presynaptic activity precedes postsynaptic activity than vice versa) acting on the CA3 to CA1 pathway (see Chapter 10). Other models have implicated the recurrent connections in CA3 as responsible for this effect. Interestingly, the phase shift seen in place cell firing (see Section 14.3.1 for data and Section 14.3.5 for models) (see also Chapter 11) acts to increase this effect of temporal asymmetry in LTP, causing place cells with fields early on the path to fire before those with fields later along the path during each theta cycle. The apparently unrelated effect of the remapping

*b*. Place fields recorded from the same cell in four environments of different shape or orientation relative to distal cues. *c*. Simulation of the place fields in *b* by the best fitting set of four BVCs constrained to be in orthogonal directions (BVCs shown on the left, simulated fields on the right). The simulated cell can now be used to predict firing in novel situations. Real and predicted data from three novel environments are shown in *d* and *e*, respectively, showing good qualitative agreement. (Source: Adapted from Burgess and Hartley, 2002.)

of place cell representations across different environments has also been ascribed to the effects of the recurrent connections in CA3. Models stressing these connections are the subject of the next section.

#### 14.3.3 Representing Spatial Location and Orientation: Feedback Models

The long-range recurrent connections between pyramidal cells in area CA3 of the hippocampus have long been interpreted as enabling this region to work as an autoassociative neural network (e.g., Marr, 1971; Hopfield, 1982; Amit, 1989). This type of network is most often used to provide a content-addressable memory, a subject explored in Section 14.5 (see Box 14-2). In this section I consider the role played by recurrent collaterals in the spatial representations of place and HD cells. Interestingly, direct experimental evidence for an associative function for CA3 has emerged recently, with indications that the NMDA receptors in this region are involved in making both the place fields and the rat's spatial memory robust to cue removal (Nakazawa et al., 2002). In parallel, attractor dynamics have been found in the place cell representation of two environments of different shape after fast remapping caused by exposure to the two environmental shapes made of different materials (Wills et al., 2005). In these representations, in contrast to those that have not fast-remapped (Leutgeb et al., 2005), the two shapes act as attractors: all place cells in intermediate shaped environments coherently returning to one or other representation.

**Box 14–2****Attractors in Memory, Neural Coding, and Path Integration****POINT ATTRACTORS AND MEMORY**

A network of recurrently connected neurons can be arranged so a finite number of discrete patterns of activation across the neurons are stable states, or “attractors.” This means that any pattern of activation similar enough to one of these attractors will evolve into the attractor pattern under the dynamics of the network. These patterns of activation are “stored” in the network in the sense that they are “retrieved” from any similar enough initial pattern. Such networks are also referred to as “autoassociative” networks, and are an example of a “content-addressable” memory in that a pattern of activity is retrieved by a pattern of similar content, rather than, say, an unrelated index term or the address of a storage location.

In one of the simplest models (Hopfield, 1982), the activity of neuron  $i$  is modeled as  $a_i = \pm 1$ . Connections between neurons  $i$  and  $j$  are symmetrical, with synaptic “weight”  $w_{ij} = w_{ji}$ . The dynamics of the network are given by:  $a_i(t+1) = \text{sign}(\sum_j w_{ij} a_j(t))$ , such that the “energy” or Lyapunov function of the network:

$$E \propto - \sum_{ij} w_{ij} a_i a_j$$

can only reduce. If connection weights undergo a form of Hebbian learning when the to-be-stored patterns of activation ( $a^\mu$ , say) are present, such that  $w_{ij} \propto \sum_\mu a_i^\mu a_j^\mu$ , these representations become attractors so long as the number of stored patterns is not too large (less than around  $0.14N$ , where  $N$  is the number of neurons, in this case). That is, a similar enough pattern of activation converges onto the stored pattern under the dynamics of the network (Cohen and Grossberg, 1983). This situation is often visualized by imagining how the “energy” of the network varies as a function of the networks’ “state”  $\underline{a}$  ( $= (a_1, a_2, \dots, a_N)$ )—the attractor states being local minima of the energy surface to which nearby states evolve under the network’s dynamics (Fig. 14–3A). Similar behavior is also shown by more biologically realistic models (Amit, 1992; Treves and Rolls, 1992; McClelland et al., 1995) (Fig. 14–10).

**LINE ATTRACTORS AND NEURAL CODING**

The value of a continuous variable (or “stimulus”) often seems to be represented in the firing rates of a population of neurons, each of which is tuned to respond preferentially to a single “preferred” value. For example, head-direction cells can be thought of in this way, with  $s$  representing the rat’s heading. The pattern of activation of the population is often visualized by imagining the neurons arranged so their location reflects their preferred values: showing a smooth bump of activity across the neurons peaked at the actual value of the stimulus. However, if the firing rates are noisy it is difficult to estimate the precise value of the stimulus. The presence of recurrent connections between neurons, arranged so that the weight of the connection between each pair is simply a decreasing function of the difference in their preferred values (or physical separation when arranged as above), can help by ensuring that the firing pattern takes the shape of a smooth bump<sup>1</sup> (Fig. 14–3B). With the appropriate choice of recurrent connections, such a network can perform optimal decoding (Latham et al., 2003), including the situation where the representation is formed from different, unreliable sources of information (Deneve et al., 2001).

The patterns of activation comprising a smooth bump can be thought of as a line in the  $N$  dimensional state space  $\underline{a}$  ( $= (a_1, a_2, \dots, a_N)$ ) of the network. Each point on the line corresponds to a different estimate of  $s$  (referred to as  $\hat{s}$ ). Conversely, all of the possible noisy patterns of activation that end up producing the same  $\hat{s}$  lie on an  $N-1$  dimensional subspace within which the action of the recurrent connections corresponds to convergence onto the line (Fig. 14–3C). An important aspect of these networks is that, although the recurrent connections ensure that patterns of activation move onto the line attractor, movement along it, corresponding to changing  $\hat{s}$ , is not affected by the recurrent connections (because the connections between a pair of neurons depends only on the *difference* in their preferred values, not what those preferred values are).

**LINE ATTRACTORS AND PATH INTEGRATION**

Because the (symmetrical) recurrent connections provide no resistance to the motion of the bump of activity along the line attractor, its position is easily moved by asymmetrical connections from each neuron to neighbors farther along the line (Skaggs et al., 1995; Zhang, 1996).

<sup>1</sup> These patterns have low “energy” as activation is concentrated in nearby neurons, which have the strongest interconnections.

The greater the size of the asymmetrical connections—which should correspond to the spatial derivative of the symmetrical connections for the bump to move without changing shape (Zhang, 1996)—compared to the symmetrical ones, the faster the movement of the bump (Figs. 14–3 to 14–5). Thus, if the strength of the asymmetrical connections is proportional to angular velocity, the location of the bump of activity in a ring of head direction cells tracks the head direction of the animal—performing angular “path integration.” For a more detailed model, see Redish et al. (1996).

As noted by Zhang (1996) and McNaughton et al. (1996), the angular path integration models of head direction cell firing can be extended to path integration models of place cell firing. In this case, the place cells are imagined as a two-dimensional array, so the location of each neuron corresponds to the location of its place field in the environment (Fig. 14–6). Again, symmetrical connections decreasing in strength with the physical separation of the pre- and postsynaptic neurons can ensure that neural activity forms a single-peaked bump over the array. Asymmetrical connections from each neuron to its neighbors along a given direction causes the bump to shift in that direction (Figs. 14–3 and 14–4). In this case, to perform path integration of position, the strength of the asymmetrical connections between a pair of neurons displaced in a given direction needs to be proportional to the velocity of the rat in that direction. See Samsonovich and McNaughton (1997) for a more detailed model and Droulez and Berthoz (1991) and Dominey and Arbib (1992) for the origins of this type of model.

### **Continuous Attractor Models of Head Direction Cells**

The simplest examples of the use of continuous attractors (see Box 14–2) to model spatial representations come from models of the representation of head direction rather than location. In many respects the literature on head-direction cells (HDCs) is much more straightforward than that on place cells. The overall orientation of the head-direction representation can be controlled by sensory cues in a way similar to that of the place cell representation. Unlike the place cells, however, there have been no reports to date of HDCs changing their preferred orientations relative to each other. Even when the rat is disoriented or is in a symmetrical environment without polarizing cues, the preferred directions of simultaneously recorded HDCs remain in synchrony—if they rotate, all rotate together. For this reason all models of the head-direction system follow the same basic mechanism of a one-dimensional continuous attractor, or “line attractor” (Skaggs et al., 1995; Zhang, 1996) from which the two-dimensional continuous attractor models of place cells developed (Figs. 14–3 to 14–6) (see Box 14–2).

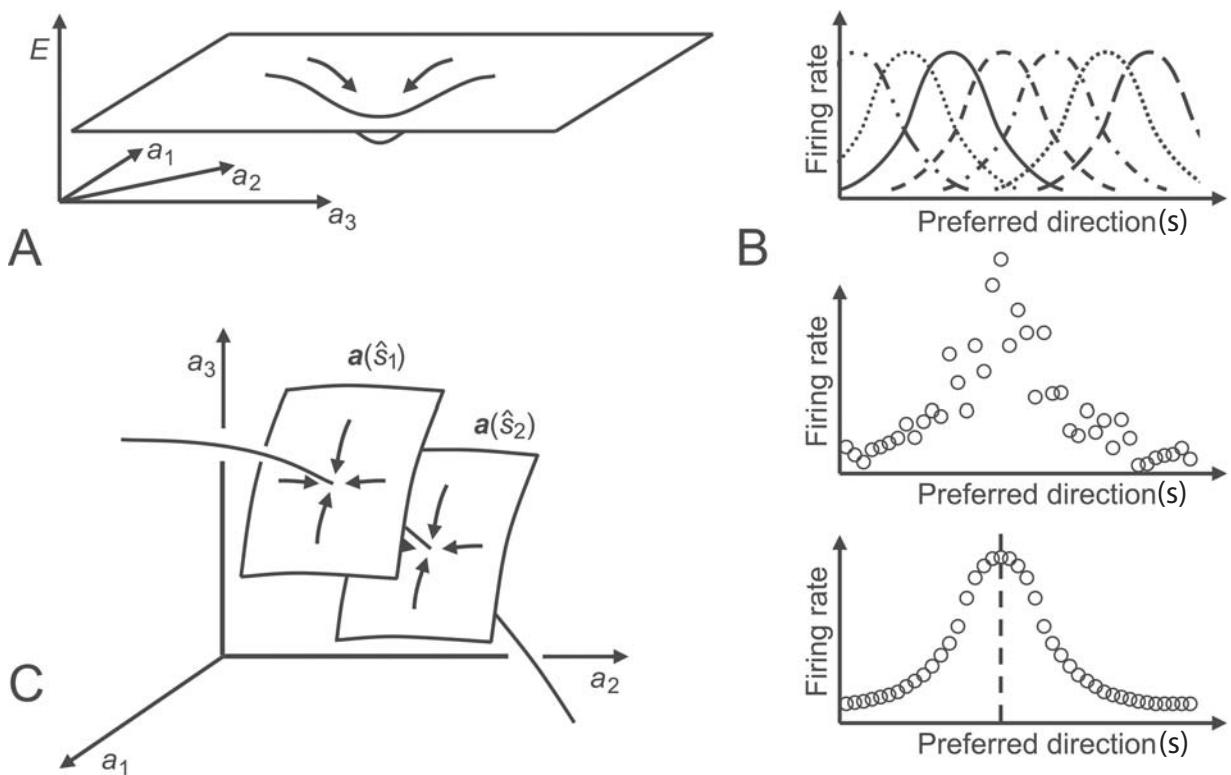

If HDCs are imagined laid out in a ring with each cell’s location corresponding to its preferred direction and each is connected to its neighbors (see Box 14–2), activity is smoothly peaked at the current heading direction. Skaggs et al.’s model contains two more rings of cells, with each cell receiving connections from the corresponding HDC. One ring is composed of “left rotation” cells, which project back to the HDCs to the left (anticlockwise) of their location; the other ring is composed of “right rotation” cells, which project back to HDCs to the right (clockwise) of their location. The left rotation cells corresponding to the current heading direction are activated when the rat is turning left because of inputs from the vestibular system as well as the HDCs, causing the HDC activation to move leftward. In addition to these cells, the HDCs receive

input from “sensory cells” (“visual cells” in Fig. 14–5) and so can be associated with those sensory inputs appearing at a stable bearing during exploration of a new environment. These sensory inputs subsequently prevent the cumulative errors that would otherwise occur in the integration of angular velocity.

This basic model has been implemented and extended in various ways, developing in hand with our knowledge of the operation of the head-direction system. This is now thought to involve a circuit from the mammillary bodies (MBs) to anterior thalamic nuclei (ATN) to dorsal presubiculum (PS). In this circuit, cells in the MBs code for head direction further in the future (60–70 ms) than those in the ATN (20–30 ms), whereas those in the PS code for current or past head direction (0 to –10 ms) (Blair and Sharp, 1995; Blair et al., 1998; Taube, 1998; Taube and Müller, 1998) (see Chapter 11). Various of the additional detailed properties of these systems, such as time advances and asymmetrical responses during turning, have been modeled more recently (e.g., Touretzky and Redish, 1996; Blair et al., 1997; Goodridge and Touretzky, 2000). However, here I focus on the hippocampus, and return to models of location.

### **Continuous Attractor Models of Place Cells**

Samsonovich and McNaughton (1997) produced a detailed model of the place cell representation as a continuous attractor, following Zhang (1996). In this model, the recurrent connections in CA3 are preconfigured to provide several continuous attractor representations of location (termed “charts”). Each chart involves a different set of place cells, the relative positions of whose place fields are predetermined. The strength of the recurrent connection between two cells in a chart is set as a Gaussian function of the proximity of their place fields. The place cells connect with a “path integration” (PI) system, thought to be in the subiculum, in which neurons respond to combinations of the rat’s location and orientation

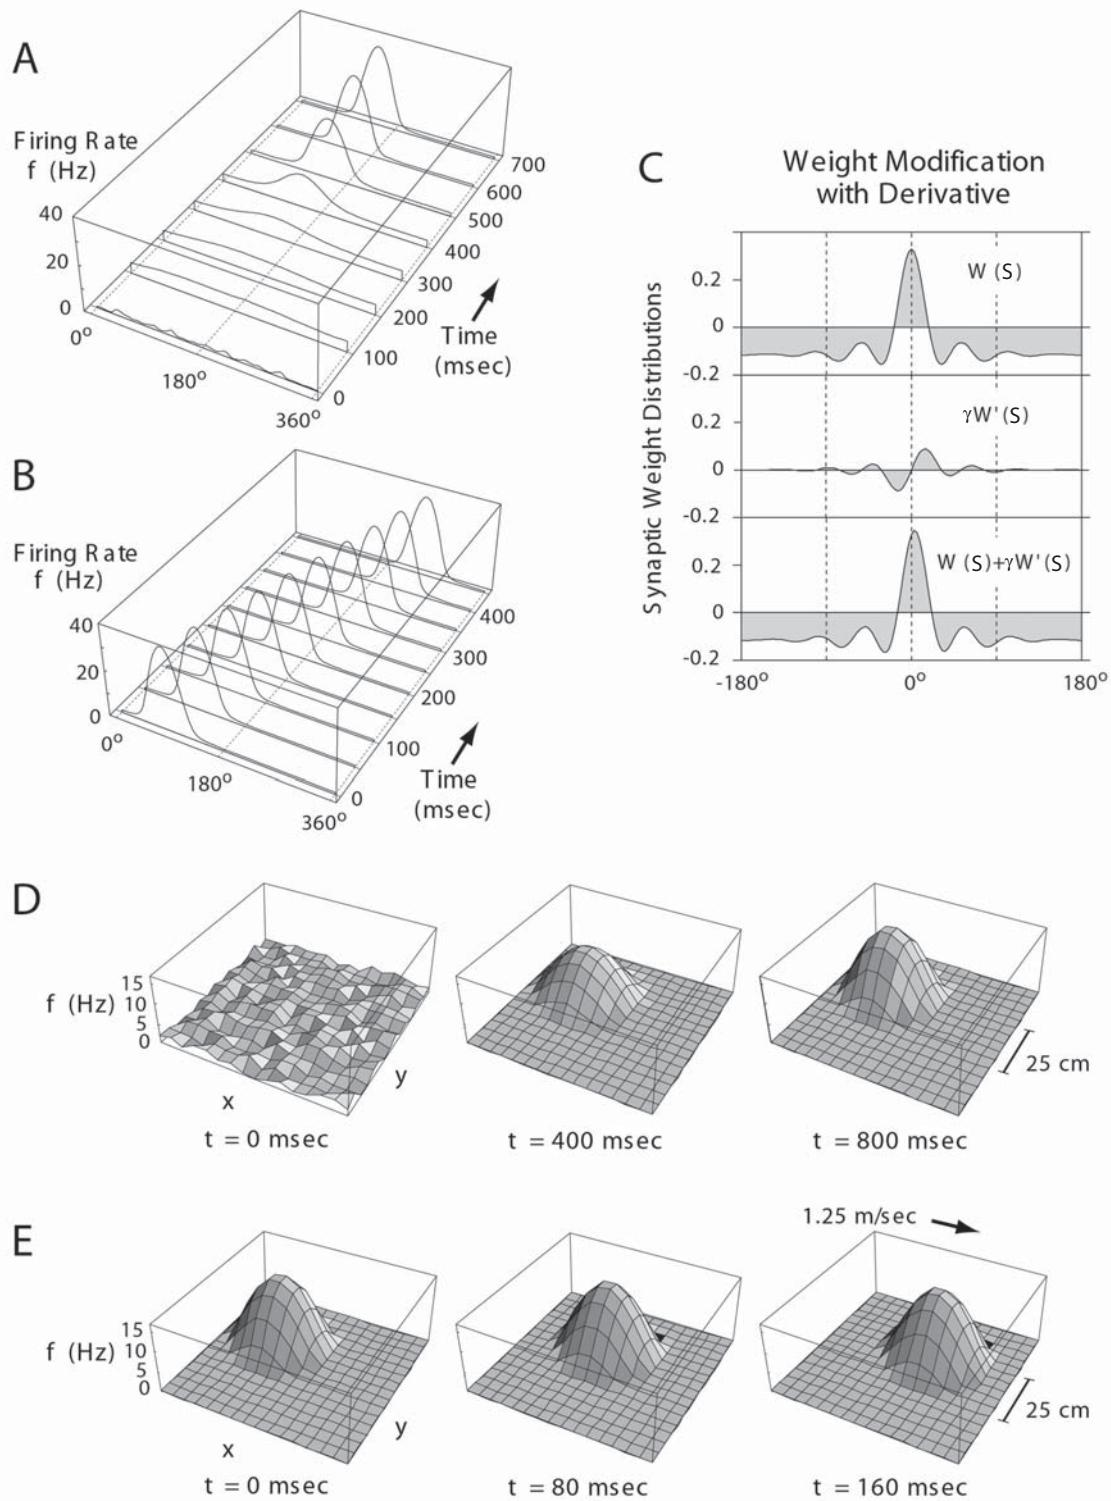

**Figure 14-3.** Point attractors and line attractors in neural systems (see Box 14-2). *A*. Point attractor is a pattern of activation  $a = (a_1, a_2, a_3, \dots)$  into which other nearby patterns evolve under the dynamics of the network (determined by the pattern of connection strengths, update rule, and so on). In some cases a function can be defined that can only decrease under the dynamics (a Lyapunov function, or the energy ( $E$ ) of a physical system), so that attractor states lie at local minima of this function. *B*. Population encoding and decoding. Neural populations can encode the current value of a variables, say in the pattern of activation across neurons, each of which is tuned to respond to a preferred value. These are often imagined to be laid out so that the position of each neuron on the ordinate corresponds to its preferred value. For example, a set of head-direction (HD) cells might each be tuned to a different

“preferred” direction (top). If firing rates are noisy, it may be difficult to estimate the actual value of the variable (middle). Recurrent connections can be organized so all other patterns of activation evolve into smooth bump-shaped patterns of activation (below). This process can provide an optimal way of decoding the value of the variable from the population (the peak of the bump is the dashed line). *C*. The set of smooth bump-shaped patterns of activation form a “line attractor,” a continuous set of patterns of activity onto which other nearby patterns evolve but along which movement is unimpeded. Locations along the line attractor can be thought of as estimates of the variable ( $\hat{S}$ ); all of the patterns of activity that end up at a given estimate (such as  $\hat{S}_1$ ) form a subspace  $a(\hat{S})$  within which the intersection with the line is a point attractor. (Source: Adapted from Latham et al., 2003.)

(Sharp, 1996; Cacucci et al., 2004). Specifically, the place cells connect to PI neurons representing similar locations, and the return projections connect back to place cells representing slightly different locations shifted along the rat’s direction of motion. The gain of this return projection is modulated by information relating to the rat’s speed of self-motion (presumably carried by motor efference signals). This system, although demanding a highly specific set of hard-wired connections, provides a self-consistent continuous attractor representation of location that moves automatically with self-motion. Finally, the hippocampus also receives sensory input so that when the rat is placed in an environment for the first time associations between the sensory scene and the internal representation of location can be formed, which can then be used to reset the system periodically. Overall, the model can be seen as a possible implementation of O’Keefe and Nadel’s (1978, pp. 220–230) view of the role of path

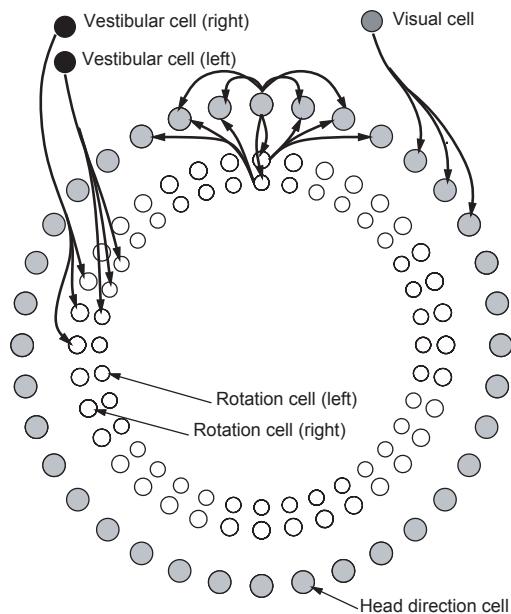

integration in supporting short-term continuity in a cognitive map.

The Samsonovich and McNaughton model is consistent with data showing that the stability of the place cell representation is dependent on NMDA receptors (Kentros et al., 1998) and that place field locations remain consistent with each other but slowly drift in the absence of anchoring sensory cues or if the rat is consistently disoriented before each trial (Knierim et al., 1995). In addition, the involvement of some form of path integration is suggested by the increased influence of the boundary the rat is running from compared to the one it is running toward (Gothard et al., 1996; O’Keefe and Burgess, 1996; Redish et al., 2000). Note that the important role played by path integration in this model does not, conversely, imply that the hippocampus is necessary for guiding behavior in tests of path integration (e.g., Alyan and McNaughton, 1999). The role of the CA3 recurrent collaterals

**Figure 14-4.** Continuous attractor networks of place and head direction cells (HDCs). *A*, Emergence of a stable firing profile from an arbitrary initial state in a network of HDCs arranged as a one-dimensional continuous attractor. The cells are indexed by their preferred firing direction and connected by weights with a symmetrical distribution (i.e., an even function of the difference between cell's tuning directions—see *C*, top row). *B*, Movement of the peak caused by an asymmetrical component in the weight distribution (see *C*, middle row). *C*, Distribution of connection weights in a one-dimensional attractor network (bottom row), showing a symmetrical component (top row) and an additional asymmetrical component (middle row). Note the slight asymmetry in the combined connec-

tion weights. The asymmetrical component is the spatial derivative of the symmetrical component along the direction of drift, and its size ( $\gamma$ ) determines the speed of drift of the represented head direction. *D*, Two-dimensional place cell network similar to the one-dimensional HDC network, showing emergence of a stereotyped stable firing profile from an arbitrary initial state, using symmetrical weight distribution (a Gaussian with constant inhibitory background). *E*, As with the one-dimensional network, the addition of an asymmetrical component to the connection weights causes the represented location to drift (again, the asymmetrical component is the spatial derivative along the direction of drift, and its size determines the speed of drift). (Source: Adapted from Zhang, 1996.)

**Figure 14-5.** Skaggs et al.’s (1995) model of HDCs, showing the lateral connections among HDCs providing a continuous attractor and connections from left or right rotation cells, visual inputs, and vestibular inputs. The input from rotation cells serves the same purpose as the asymmetrical component of lateral connections in Figure 14-4. (Source: Adapted from Skaggs et al., 1995.)

in self-localization; forming the most accurate representation of location within a continuous attractor network given conflicting inputs was also stressed by Redish and Touretzky (1998). In addition, they elaborated the relation of this system

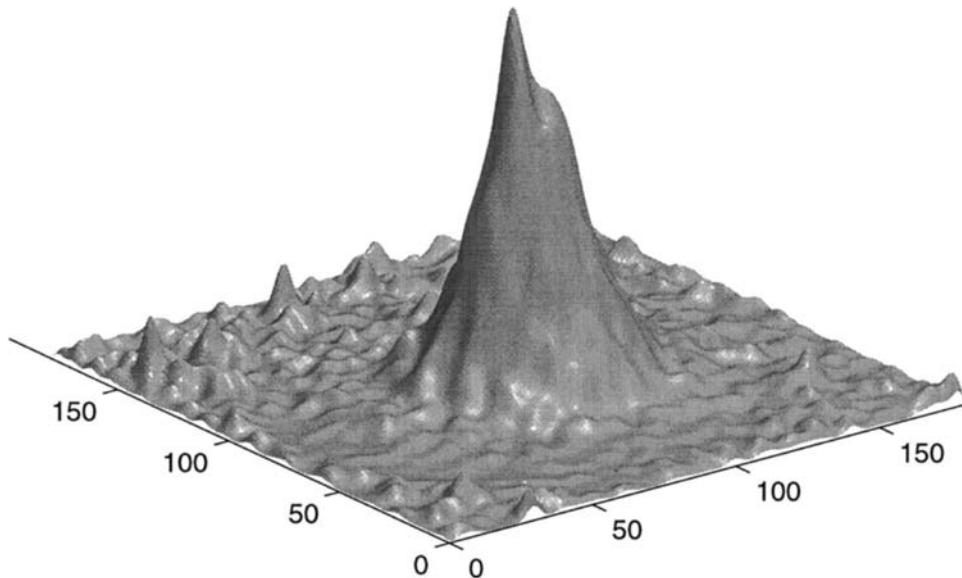

with other systems for path integration and for maintaining orientation (Touretzky and Redish, 1996). However, no specific mechanism has been proposed for the path integration. Because errors accumulate so rapidly in this system, it can be expected to behave very differently from a perfect system. The integration by place cells of visual inputs and inputs from a recurrently connected parietal system, and its relation to remapping, was explored further by Guazzelli et al. (2001).

Samsonovich and McNaughton suggested that remapping reflects the system switching between uncorrelated charts. This is a reasonable model of the situation after fast-remapping, which is consistent with each chart acting as an attractor (Wills et al., 2005), although in this case the charts would not be preconfigured but formed by the process of fast remapping. However, the model is not consistent with the situations in which individual place fields can move relative to each other in response to environmental change (e.g., O’Keefe and Burgess, 1996; Fenton et al., 2000). To fit these data requires feedforward inputs to dominate, replacing the model’s main feature. The model is also not consistent with slow remapping (Lever et al., 2002) or partial remapping (e.g., Skaggs and McNaughton, 1998). The experimental conditions and neural mechanisms resulting in fast versus slow remapping are currently not well understood (Knierim, 2003).

Recurrent networks have also been used to model place field directionality, as modeled in a feedforward manner by Sharp (1991). In these models (Brunel and Trullier, 1998; Kali and Dayan, 2000), place cell firing is initially derived from orientation-specific sensory input at each location (referred to as the “local view” from that location), and the dynamics of the network are strongly dependent on the recurrent connec-

**Figure 14-6.** Place cell activity on a “chart.” The activity of a population of 36 simultaneously recorded place cells shown symbolically distributed in the box (in which the rat foraged for food) each cell being placed at the center of its place field. Units on horizontal axes are centimeters. The animal is located at the center

of the square and is moving to the left and toward the viewer. The shape of the activity packet does not depend on velocity, acceleration, future trajectory of motion, or theta frequency. (Source: Samsonovich and McNaughton, 1997.)

tions in CA3. If exploration is unconstrained and random, Hebbian learning in the recurrent collaterals of these models results in a continuous attractor of the sort hard-wired by Samsonovich and McNaughton and an orientation-independent place cell representation of space. One caveat to this is that the Hebbian learning must be modulated by novelty to prevent inhomogeneous exploration from causing highly nonuniform weight structures and unrealistic firing patterns (Kali and Dayan, 2000). Such novelty information has been suggested as a function of the cholinergic septal inputs to the hippocampus (Hasselmo et al., 1996; but see Hasselmo and Fehlau, 2001 and Lisman and Grace, 2005). As with Sharp (1991), in these models directionally constrained exploration results in orientation-dependent place fields.

Kali and Dayan (2000) also simulated the effects of changing the environment on the pattern of place cell firing. The model first learns a representation in one environment, as described above, and is then exposed to a second environment. If the second environment is sufficiently novel, the pattern of sensory input is assumed to be completely different and novelty-modulated learning is enabled. As a result, the system successfully learns a second, unrelated, place cell representation, corresponding to complete remapping. In simulations using two similar boxes (as in Skaggs and McNaughton, 1998), similar firing in the two boxes is imposed by similar sensory input, and the model is also shown to be capable of storing and recalling partially overlapping representations. Finally, if the second environment differs from the first only geometrically, the same sensory inputs are assumed to be used (but with different values, as the distances to boundaries have changed) and there is no new learning. This results in parametric changes to the pattern of firing. In this case, the effect of the recurrent collaterals is to preserve the relative spatial relation of the place fields and so acts to maintain the positions of fields in terms of the ratio of distances between boundaries (effectively scaling up the representation). By contrast, the sensory inputs are equivalent to the boundary vector cell model (O'Keefe and Burgess, 1996; Hartley et al., 2000) and so act to maintain the position of fields in terms of their absolute distance from boundaries. Thus, this model can account for both types of behavior. To fit the data in O'Keefe and Burgess (1996), the model should be dominated by the sensory input rather than the recurrent connections, as place fields tend to maintain a fixed distance to environmental boundaries in this experiment. By contrast, the apparently similar experiment of Muller and Kubie (1987) results in complete remapping. It is not yet clear whether models such as that of Kali and Dayan (2000), which depend on assigning different amounts of similarity to two environments, can capture the complexities of the data concerning remapping. For example, the differences between fast and slow remapping referred to above imply some learning in the feedforward connections (to model slow remapping, see, e.g., Barry et al., 2005; Fuhs and Touretzky, 2000), as well as in the recurrent connections (to model fast-remapping). Like Sharp's (1991) model, these recurrent models are also inconsistent with hints

that place cell firing in open fields is initially nondirectional but can become directional as a result of experience.

Finally, note that the recent discovery of grid cells in the dorsomedial entorhinal cortex (Hafting et al., 2005) are likely to have profound implications for ideas of hippocampal function. Each cell fires when the rat occupies multiple spatial locations laid out on a startlingly regular hexagonal grid. The orientation and scale of these grids seems to be constant in different environments and between different nearby cells. Overall, grids get larger as the recording site moves ventrolaterally. Because the grids of neighboring cells have the same orientation and scale and appear to have fixed offsets, it is possible that the recurrent connections between local sets of grid cells could be endlessly tuned to perform path integration, irrespective of the location of the animal, providing the continuous attractor envisaged in CA3 by Zhang (1996) and Samsonovich and McNaughton (1997). The stable association of each grid to the environment might occur via connections to place cells that, by virtue of generally having only a single firing location, could be associated with the environmental stimuli at that location. If this is correct, place cell firing could reflect the superposition of multiple grids that all overlap at the place field, and remapping could reflect changes in offset in these multiple inputs (O'Keefe and Burgess, 2005, see also Fuhs and Touretzky (2000) and McNaughton et al., (2006)).

#### 14.3.4 Modeling Phase Coding in Place Cells

The origin of the intriguing phenomenon of the phase coding of place cell firing with respect to the concurrent theta rhythm of the EEG (O'Keefe and Recce, 1993) has been the subject of several computational models. Before considering these models, I briefly review the relevant experimental findings (see Chapter 11 for more details). The theta rhythm is a large-amplitude oscillation of around 6 to 10 Hz of the EEG and is present whenever the rat is moving its head through the environment. As the rat runs through a place field, the corresponding place cell tends to fire spikes with a systematic phase relation to the theta rhythm. On entering the field, spikes are fired at a "late" phase; as the rat passes through the field, spikes are fired at successively earlier phases so that on exiting the field the phase of firing may be up to 360° earlier (corresponding to an "early" phase). This effect is most pronounced when the rat runs repetitively in a directionally constrained manner (e.g., on a linear track). Interestingly, the phase of firing correlates better with the location of the rat in the place field than with other variables such as the time spent in the field or the instantaneous firing rate of the cell (Huxter et al., 2003).

The apparently tight coupling between location and phase implies that the phase of firing might depend on the sensory input driving the place cell in a simple feedforward way. Thus, O'Keefe (1990, 1991) proposed that each place cell might act as a phasor representing location relative to the centroid and eccentricity, or slope, of a subset of the sensory cues in an environment: the firing rate encoding proximity to the cen-

troid and the phase relative to theta encoding the bearing to the centroid relative to the direction defined by the eccentricity, or slope, of the subset of cues. The advantages of the phasor representation for simple vector calculations were stressed in this model, but its easy relation to the subsequent experimental data on phase is at least as significant. Burgess et al. (1993) suggested a direct interpretation of phase of firing; that it could be used to separate place cells with fields ahead of the rat from those with fields behind the rat, which can be useful for navigation (see Section 14.4.2). This was subsequently verified experimentally (Burgess et al., 1994; Skaggs et al., 1996; Samsonovich and McNaughton, 1997). They also demonstrated that a phase shift in each individual cell is consistent with theta modulation of the net activity of the population of cells. In a simple feedforward model of place cell firing, Burgess et al. (1994) simulated the phase of firing as a function of the rat's position relative to the sensory cues that drove the cell. The input to entorhinal comes from pairs of "sensory" cells, each tuned to respond at a given distance from a particular sensory cue such that the maximum input amplitude occurs at the centroid of the two cues. The phase of firing of entorhinal cells was assumed to reflect the angle of the cue-centroid from the rat: firing at a late phase when driven by cues ahead of the rat and at an early phase when driven by cues behind the rat. This model is broadly consistent with the synchrony and oscillations seen in some sensory circuits (e.g., Nicolelis et al., 1995) but remains more qualitative than quantitative. Bose and Recce (2001) propose an alternative model that also accounts for the lack of phase shift seen in place cells when a rat runs in a running wheel (Hirase et al., 1999), involving the dynamics of the interaction of place cells and interneurons and the assumption that the frequency of the theta rhythm depends on running speed on the linear track but not in the running wheel. However, this picture became more complicated with the subsequent claim that phase shifting does occur in the running wheel at high firing rates (Harris et al., 2002).

An appealingly simple alternative feedforward model is possible (Mehta et al., 2000; Harris et al., 2002): The excitatory synaptic input to a place cell might increase as the rat runs through the place field, and the theta rhythm might reflect a sawtooth-shaped inhibitory input (i.e., inhibition decreasing through each cycle). In this model, the firing phase would advance simply because the increasing excitatory input manages to overcome the inhibitory input successively earlier in each cycle. The cause of the increasing excitatory input might reflect an exaggerated form of the asymmetry reported by Mehta et al. (1997) or an increasing then decreasing input but with lack of firing on the decreasing portion due to effects such as habituation (Harris et al., 2002). These models capture the observation that the phase shift becomes more reliable over the first few runs of a trial, as does the asymmetry of place fields (Mehta et al., 2002), and allows phase to be analyzed in terms of firing rate during nontranslational behaviors such as dreaming or wheel running (Harris et al., 2002). However, the correlation between phase and location is

stronger than that between phase and rate; and on the linear track at least, the weaker correlation is a side effect of the stronger one (O'Keefe and Burgess, 2005).

As with models of place cell firing, a second type of model of the phase shift stresses the recurrent connections in contrast to the feedforward connections. Indeed, simulations of the Samsonovich and McNaughton model, in which net activation is made to oscillate at the theta frequency, shows something qualitatively similar to the phase shift owing to path integration occurring within each cycle. That is, initially the set of active place cells settles to just those place cells with fields centered on the rat and then expands to include those with fields centered ahead of the rat. The first quantitative model of the phase shift was proposed by Tsodyks et al. (1996). In this model, the recurrent connections between place cells in CA3 are asymmetrically arranged so that each place cell projects to place cells farther along a learned path (see also Blum and Abbott, 1996, discussed below). External input to a CA3 place cell arrives at a fixed (early) phase of theta, causing place cell activity at this phase, which in turn propagates through the recurrent connections to place cells with fields farther along the path and causes them to fire. Overall activity is inhibited at the end of each theta cycle, preventing further propagation of activity into the next cycle. Thus, when the rat enters a place field, the corresponding cell starts to fire at a late phase owing to propagated activity from cells with fields earlier on the path; and it fires earlier during each cycle as the rat advances owing to activity having to propagate through fewer cells, until finally firing at the early phase is due solely to external inputs. Several similar mechanisms that depend on the association of place cells firing earlier along a learned path to those firing later along it have now been proposed (Jensen and Lisman, 1996; Touretzky and Redish, 1996; Wallenstein and Hasselmo, 1997). The Jensen and Lisman (1996) model makes interesting suggestions for the gamma rhythm, in separating the firing of cells corresponding to the current and successively farther advanced locations, and for the dynamics of NMDA channels, in separating each route retrieval into successive cycles of the theta rhythm. Wallenstein and Hasselmo (1997) emphasized the role of GABA<sub>B</sub> receptors in varying the relative influence of the inputs to CA1 from CA3 compared to those directly from entorhinal cortex (EC) over the theta cycle: allowing sensory (EC) input to dominate early and predictive input from CA3 to dominate late in the cycle.

These models fit nicely with the observations of Mehta et al. (1997, 2000): They produce a phase shift limited to 360° that is more strongly correlated with position than time, and that is greater for well learned paths than for random exploration. Interestingly, Mehta et al. (2000) suggested a similar model based on learned asymmetry in the connections from CA3 to CA1, the main testable difference here being that the phase shift should not be observed in CA3. Other aspects of these models seem less likely. First, because the initial firing of a place cell depends on both the externally driven activity of other cells and its propagation through the network, it seems likely that on cell-by-cell and run-by-run bases the

initial phase of firing should be more variable than the (externally driven) final phase of firing. This is not the case in the data (Skaggs et al., 1996; Huxter et al., 2003). Second, one mechanism for producing the required asymmetrical connections is that suggested by Mehta et al., (2000). However, it has since been found that, although the development of asymmetry in place fields over the first few runs of a trial is prevented by blockade of NMDA receptors, the phase shift phenomenon is unaffected by this manipulation (Ekstrom et al., 2001).

A third type of model stresses the inherent oscillatory nature of some cellular processes, as did Jensen and Lisman (1996) for different reasons. Thus, O'Keefe and Recce (1993) pointed out that the phase and amplitude characteristics of place cell firing could be modeled as the interference pattern between an 11-Hz external input to the cell (perhaps the sensory input) and a 9-Hz external or internal oscillation corresponding to theta (perhaps driven by the septal input). This produces an oscillation of 10 Hz, corresponding to firing that shifts in phase relative to theta and a 1-Hz envelope, one-half cycle of which corresponds to the place field. This model has since been extended (Lengyel et al., 2003), identifying the first input as a voltage-controlled oscillation of the membrane potential (e.g., Hoppensteadt, 1986) in the dendrites and the second as an inhibitory input to the soma of fixed frequency. The frequency of the dendritic oscillation is assumed to increase above that of the somatic oscillation proportionally with the strength of the dendritic input, which is assumed to be zero outside the place field and proportional to the rat's running speed within it (McNaughton et al., 1983; Czurko et al., 1999; Ekstrom et al., 2001; Huxter et al., 2003). Thus, the two oscillations destructively interfere outside of the place field, whereas phase of firing relative to the somatic input within the field can shift more rapidly as the rat runs faster, preserving the relation between phase and location. In addition, the dendritic oscillation needs to be weakly driven in antiphase to the somatic input so in the absence of any dendritic input it returns to being in phase with it to ensure complete destructive interference. Recent corroborative evidence for interference models comes from the observation that the increase in place field size along the dorsoventral axis of the hippocampus parallels a corresponding decrease in the intrinsic firing frequency of place cells, reducing toward the theta frequency in more ventral regions (Maurer et al., 2005). Intriguingly, the full, repeating, interference pattern is expressed in the recently discovered entorhinal grid cells (McNaughton et al., 2006) as predicted by an inference model (O'Keefe and Burgess, 2005).

## 14.4 Hippocampus and Spatial Navigation

In this section we consider the contribution of hippocampal spatial representations to guiding behavior. I focus on large-scale spatial navigation, the spatial behavior most commonly associated with the hippocampus and medial temporal lobes

(see Chapter 13). This is comparable to behavior in smaller scale spaces and over shorter durations, such as visually guided reaching, which are most commonly associated with the posterior parietal lobe (e.g., Burgess et al., 1999). As with models of spatial representation, these models can be approximately divided into those stressing the role of feedforward connections and those stressing the role of recurrent connections.

### 14.4.1 Spatial Navigation: Data

Behavioral data indicate that rats learn about the spatial layout of their environment during exploration in the absence of explicit goals or rewards (e.g., Tolman, 1948). They can also profit from being placed at the goal location without having explored the rest of the environment (Keith and McVety, 1988). These processes are referred to as "latent learning." Rats also appear to be able to perform short cuts and detours. These abilities contributed to the idea that rats form a cognitive map of their environment rather than simply learning to associate individual stimuli with responses (Tolman, 1948; O'Keefe and Nadel, 1978). Of course, the learning of stimulus-response associations also plays an important role in spatial navigation, such as when the goal is directly visible or when a well learned turn or sequence of turns is to be performed. However, there seems to be good evidence that these types of behavior are less dependent on the hippocampus than those associated with cognitive mapping (O'Keefe and Nadel, 1978; Morris et al., 1982; Packard and McGaugh, 1996). These issues are dealt with in more detail in Chapter 13.

The other main spur to the association of the hippocampus with a cognitive map of the rat's environment was the discovery of place cells whose response is not easily described in terms of a simple response to a single stimulus. However, a gap remains between the properties of place cells and the properties required of a system for spatial navigation. Two features of place cell firing are particularly problematic. First, information about a place in an environment (i.e., firing of the corresponding place cells) can only be accessed locally (by actually visiting that place). Second, place fields appear to be no more affected by the location of the goal than by the location of any other cue. That is, place cells tell you only where you are currently and not where to go to get to your goal (Speakman and O'Keefe, 1990). A caveat to the first point may be indicated by the recording of "spatial view cells" in the macaque hippocampus (Rolls et al., 1997), which fire as a function of where the monkey is looking rather than where it is physically located.

### 14.4.2 Spatial Navigation: Feedforward Models

Zipser's (1986) "view field" model was built on the observation that in some circumstances place cell firing is modulated by the orientation of the rat. In this model, a set of orientation-dependent place cells, or "view-field units," become associated with a set of "goal units," which encode the direction to the goal relative to the current heading direction. So long as the appropriate cells become associated, the

population vector of directions represented by the goal units guide the rat to the goal, as goal units driven by place cells representing the current location fire the most strongly. However, it is unclear how the directions to the goal would become associated with the place units if the goal were not visible. In a second model (the “beta coefficient” model), Zipser suggested that the location of the goal relative to subsets of landmarks is calculated and stored (as the coefficient of the linear sum of landmark locations that is equal to the goal location). In this model, learning at the goal location is sufficient, although the neural mechanisms required to implement the desired calculations are not explained. One possible route to enabling place cells to perform this type of computation was provided by the phasor model of O’Keefe (1991) (see above). A simplistic version of this type of model was simulated by Wilkie and Palfrey (1987), in which the distance of the goal from two landmarks is stored so that navigation back to the goal can be effected by moving so as to match these landmark distances.

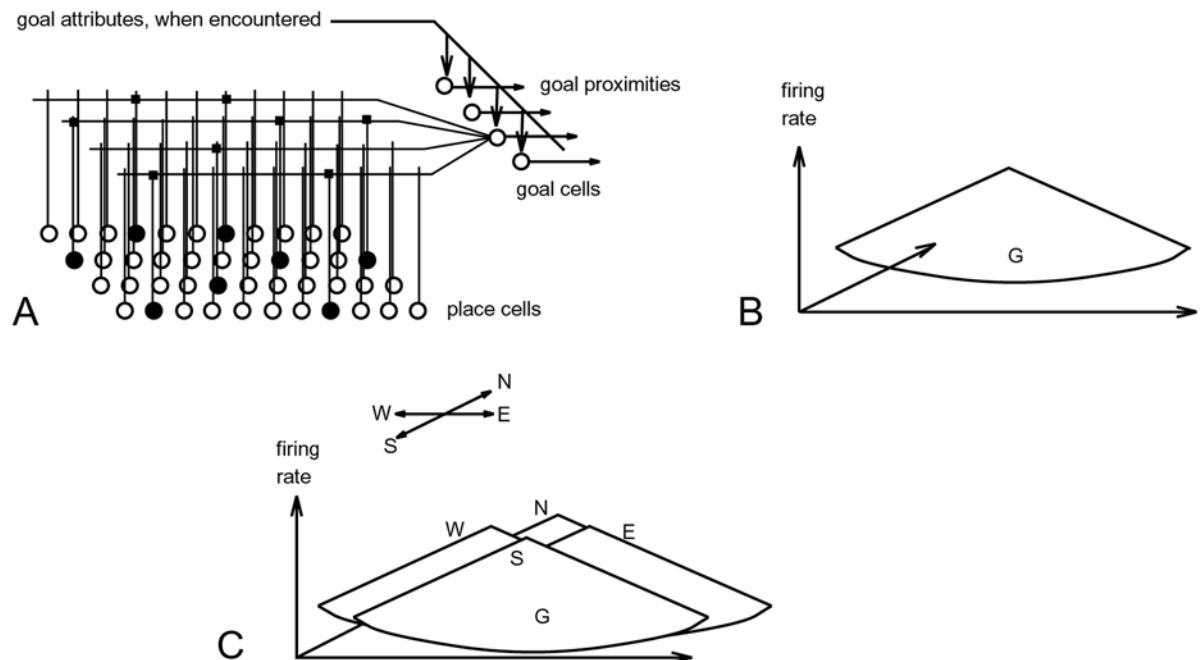

Several models have followed Zipser’s view field model in associating places to movements or local views. See Trullier et al. (1997) for a wider review of biologically based artificial navigation systems. McNaughton and Nadel (1990) suggested that routes might be learned as a chain of associations from a local view to an action and thence to the next local view, and so on. This model was not actually simulated, and simply storing routes is insufficient to enable spatial navigation (see Section 14.6). Even if a given route can be correctly selected in terms of the locations to which it leads, navigational abilities such as generating novel shortcuts and detours are beyond a simple route-based system. The task of accumulating route-independent spatial information faces several problems, including the “credit assignment” problem: deciding which actions along a route are critical for determining whether it eventually leads to the goal.

Brown and Sharp (1995) provided a more sophisticated model for associating locations with actions. In their model the possible actions in a place are represented by a left-turn cell and a right-turn cell (in nucleus accumbens) driven by each place cell. These “turn cells” receive modifiable connections from head-direction cells (HDCs), which support the rat’s spatial learning. When the rat reaches the goal, connections between HDCs and turn cells are modified according to a recency-weighted index of their simultaneous activity. Thus, if turning left in a particular place when facing north leads immediately to the goal, the HDC representing north becomes more strongly associated with the left-turn cell driven by the corresponding place cell. The recency weighting of connection modification is designed to provide an approximate solution to the credit assignment problem (when applied over many trials) by effectively dividing credit according to the number of steps within which an action leads to finding the goal, see reinforcement learning (e.g., Dayan and Abbott, 2002) for a more principled approach. This model successfully simulates learning in the Morris watermaze but would not show latent learning; performance would not be affected by whether the rat can look around from the goal location; and navigation to

the goal would be strongly affected if stereotyped routes were used during learning.

A related way to think about spatial navigation is to imagine defining a surface over the environment such that gradient ascent on it leads to the goal. The simplest model of this sort is for the place cells to be connected to a goal cell via reward-modulated Hebb-modifiable connections such that encountering a goal causes strengthening of connections to it from the concurrently active place cells (Burgess and O’Keefe, 1996). The subsequent activity of the goal cell then increases with the proximity of the goal, as the net activity of those place cells with strengthened connections increases with the proximity to the goal (Fig. 14–7). The task for the rat in finding the goal is then to move in the direction that increases the rate of firing of the goal cell representing the desired goal (Fig. 14–7B). This type of model qualitatively captures the rapid nature of learning a goal location once place cell firing has become established and the ability to learn simply by being at the goal location rather than having to find it many times. However, finding the goal would involve the rat hunting around to determine the best direction in which to move. This behavior, known as vicarious trial and error, can be observed at choice points but is not common. A second problem raised by this model is the range over which spatial information is accessible. If there are no place cells that fire at both the goal location and the current location of the rat, there is no gradient in the firing rate of the goal cell (being locally zero). Hence, this type of model requires the population of place cells to include some cells that have nonzero firing rates at any two points in the environment, however far apart. Consideration of the population of place field shapes and sizes in the environments used so far (i.e., not more than about 2 m in diameter) indicate that this is quite probable (Hartley et al., 2000). However, whether this is true of larger environments is not known.

A more sophisticated model of navigation (Burgess et al., 1994) was proposed to make two improvements on the simple model above. The first was to be able to calculate the direction to the goal from any subsequent location after a single visit to the goal location without having to hunt around. The model made use of the fact that rats placed at the goal location like to rear up and look around and the supposition that place cells firing at a late phase relative to the theta rhythm have fields peaked ahead of the rat (see Section 14.3.4). The model posits a set of goal cells for each goal, such that each cell in a set is associated with a different head direction. The connections from place cells to a “north” goal cell are modified when the rat is at the goal and facing north and similarly for the goal cells associated with other directions. Crucially, connections are modified at “late” phases of the theta cycle so the active place cells (i.e., those from which connections are strengthened) are cells with fields ahead of the rat. Therefore, after spending at least one theta cycle at the goal facing in each direction, a north goal cell has strong connections from place cells with fields peaked to the north of the goal—and similarly for south, east, and west goal cells. As a consequence, a north goal cell’s firing rate forms a surface over the environment that

**Figure 14-7.** Simple model of place cells and navigation. A. A “goal” cell stores a goal’s location by taking a snapshot of place cell activity via Hebbian synaptic modification when the goal cell is excited by the attributes of a particular goal location. Solid circles are active place cells; open circles are inactive place cells; and solid squares mark potentiated synapses between place cell axons and goal cell dendrites. B. Firing rate map of the goal cell (roughly an inverted cone) during subsequent movements of the rat codes for

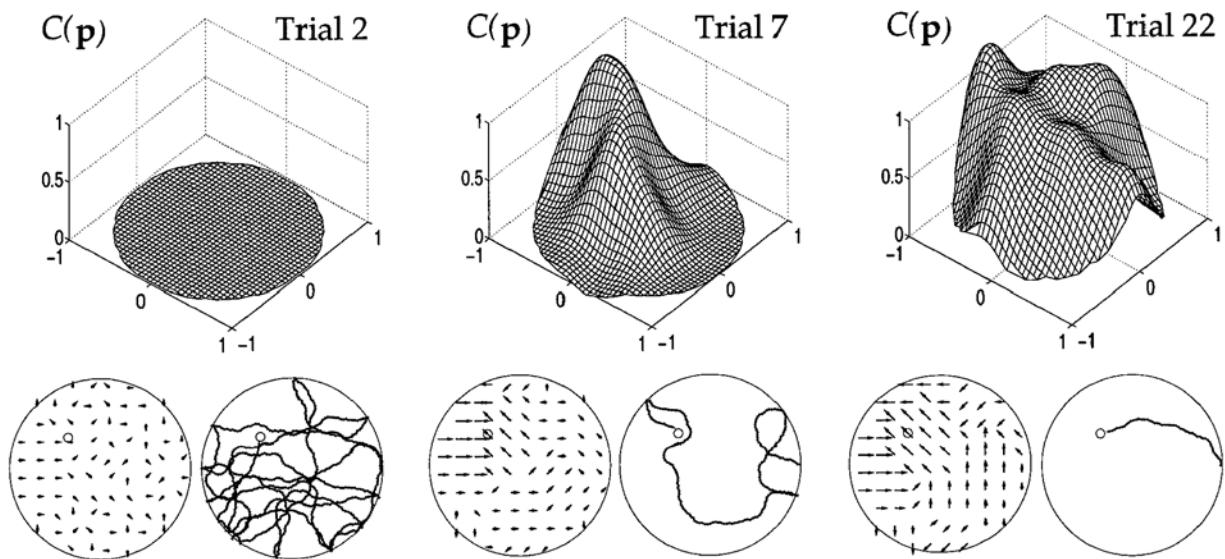

the proximity of the goal (G). C. Firing rate maps of four goal cells whose population vector codes for the goal location (G). Each is associated with the allocentric direction  $u_i$  in which the location of its peak firing rate is displaced from G; thus, the vector sum of the directions  $u_i$  weighted by the instantaneous firing rates  $f_i$  of the goal cells (i.e.,  $\sum_i f_i u_i / \sum_i f_i$ ) codes for the direction of the rat from the goal, and the net firing rate of the goal cells (i.e.,  $\sum_i f_i$ ) codes for the goal’s proximity. (Source: Adapted from Burgess and O’Keefe, 1996.)

is peaked to the north of the goal location—and similarly for south, east, and west goal cells (Fig. 14–7C). This is useful for subsequent navigation, as the rat can now use the relative firing rates of the various goal cells to indicate the direction of the goal. If the rat is to the north of the goal, the north goal cell has a higher firing rate than the south goal cell. More precisely, the population vector (Georgopoulos et al., 1986) of a set of goal cells successfully indicated the direction of the rat from the goal in simulations, and different sets of goal cells can be used simultaneously to indicate different locations of interest. Conversion to egocentric (e.g., left or right) movement directions was envisaged to take place in the parietal cortex or basal ganglia, given knowledge of the current head direction (Burgess et al., 2001a).

The second improvement was to ameliorate the problems of the range over which spatial information is available from place cell firing. The proposed solution was to interpose a set of subiculum cells between the place cells and goal cells. Given weaker inhibitory competition between subiculum cells than between place cells, competitive learning in the connections from place to subiculum cells during exploration causes the subiculum cells to build up larger firing fields, each effectively composed of several place fields. This learning is goal-independent and corresponds to latent learning in preparing the ground for effective one-shot learning of the location of any goals should they be encountered. Large spatial firing fields in subiculum cells are consistent with experimental data

(Sharp and Green, 1994), and larger place fields have since been found in the ventral hippocampus (Jung et al., 1994) that might also serve this purpose.

To model hippocampal navigation Foster et al. (2000; see also Dayan, 1991) used “temporal difference” learning in which the “state” corresponds to the place cell representation of the rat’s current location, and its value reflects the expected number of steps to reach the goal (one unit of reward is received on reaching the goal). Temporal difference learning (Sutton and Barto, 1988) can be implemented by simply connecting place cells to “actor” and “critic” units with connections that are adjusted according to a modified Hebbian rule. Activation of the critic unit is the evaluation of the current state (the expected future reward from that state, discounted by distance into the future—e.g., Dayan and Abbott, 2002), a more principled analogue of the simple goal cell above. The set of action units, only one of which can be active at a given time, represent movements North, South, and so on. At each step the connection weight from a place cell to the critic unit or to the active actor unit is adjusted by an amount proportional to the place cell’s activity times the amount by which the reward exceeds that expected from the change in the activity of the critic unit (Fig. 14–8). This type of learning is consistent with a role for dopaminergic modulation of LTP (e.g., Montague et al., 1996; Schultz et al., 1997). Over many routes to the goal, ideally involving performing all actions at all locations many times, this rule causes (1) the critic to provide an accurate esti-

**Figure 14-8.** Learning in the actor-critic system in a watermaze. The plots for each trial show the critic's value function  $C(p)$  (above), the preferred actions at various locations (below left; the length of each arrow is related to the probability that the particular action shown is taken), and a sample path (below right). Trial 2: After a timed-out first trial, the critic's value function remains zero everywhere, the actions point randomly in different directions, and a long

and tortuous path is taken to the platform. Trial 7: The critic's value function having peaked in the northeast quadrant of the pool, the preferred actions are correct for locations close to the platform but not for locations further away. Trial 22: The critic's value function has spread across the whole pool and the preferred actions are close to correct in most locations, so the actor takes a direct route to the platform. (Source: Foster et al., 2000.)

mation of value and (2) the appropriate actions to be associated with each state (Fig. 14-8). For a given configuration of goal and environment, this can provide the optimal strategy, which is not the case with the approximate recency weighting (see Brown and Sharp, 1995, above; Blum and Abbott, 1996, below) or, if obstacles are present, with goal cells simply indicating the physical proximity of the goal (Burgess et al., 1994). However, learning is both experience-dependent and goal-dependent (e.g., to know to head north from a given place results from this combination having previously led to the goal) and so perhaps does not capture the characteristics of the hippocampal contribution to spatial learning.

To simulate goal independent learning over many trials in which the location of the goal changes, Foster et al. (2000) proposed that a second system learns to form a coordinate representation of the rat's position by using the rat's locally accurate ability to estimate self-motion. The place cells are connected to two units that learn to estimate the  $x$  and  $y$  coordinates of the rat, again using temporal difference learning to adjust connection weights. In this system, the change in a connection weight to the  $x$  unit is proportional to the place cell activation times the amount by which the change in  $x$ , as estimated by self-motion, exceeds that estimated by the change in the activity of the  $x$  unit. The explicit representation of  $x$  and  $y$  coordinates enables accurate navigation after one exposure to the goal and so corresponds well with latent learning. However, it is not clear if such a representation actually exists in the brain, or if it would necessarily be more useful than a place field-like representation that covered the appropriate length scales (e.g., Burgess et al., 1994).

#### 14.4.3 Spatial Navigation: Feedback Models

As well as being linked with spatial representation and associative memory (see Box 14-2), the CA3 recurrent collaterals have also been proposed to play a role in spatial navigation. The first model to formalize such a role was suggested by Muller et al. (1991, 1996) and focused on the Hebb-associative effects of LTP on the recurrent collaterals. If pre- and postsynaptic firing within a short time interval leads to a small increase in synaptic strength, the firing of place cells as the rat moves around an environment leads to the strength of a connection between two place cells depending on the proximity of their place fields. This occurs simply because the greater the overlap between place fields the more often they fire near-coincidentally during random exploration. Muller et al. (1996) showed that after extensive exploration the synaptic strengths represent a "cognitive graph," each approximately representing the minimum path length between the centers of the place fields of the cells it connects. Their model proposes that the rat navigates by moving through the place fields of the cells most strongly connected to the cells with fields at the current and destination positions. This mechanism, reminiscent of a resistive grid (Connelly et al., 1990), works well but relies on a graph search. It is not easy to imagine how such a process could be implemented in a biologically plausible fashion, given the apparent lack of influence of the goal location on the firing of place cells (Speakman and O'Keefe, 1990). One suggestion (Gorchetchnikov and Hasselmo, 2002) is that activation corresponding to the goal location occurs in entorhinal cortex while activation corresponding to the current location

occurs in CA3. Activation in each region spreads along the available paths (although more slowly in CA3 than entorhinal cortex) until a commonly activated location is detected in CA1. This location represents the next immediate destination for the rat, although how this information is interpreted in terms of whether to turn left or right is not described.

In a related model, Blum and Abbott (1996) make use of the temporal asymmetry of LTP to strengthen recurrent connections from CA3 place cells that fire early on the rat's path to those that fire later along it. This causes the activation of place cells to spread backward along the path (see also Mehta et al., 1997, 2000 and models of spatial representation, above). If the firing of place cells is interpreted by systems downstream of CA3 as representing the location of the rat, this shift in firing (backward along the path) would be interpreted as a shift in the location of the rat forward along the path. Blum and Abbott suggested that navigation along a previously performed route could be undertaken by moving from the current location (e.g., read from CA1) to the shifted location represented in CA3, although how this could be implemented was not described. To enable navigation to a goal location, the rules for synaptic change were modified to be proportional to the amount of pre- and postsynaptic activation weighted by how recently it occurred prior encountering the goal (i.e., modification similar to that suggested by Brown and Sharp, 1995, above).

It is interesting to note that the symmetrical pattern of connection strengths learned in Muller et al.'s model resembles that used in continuous attractor models of place cell firing and so also serves to produce a consistent pattern of activity to represent each location (see above). By contrast, the additional asymmetry in connection strengths learned in Blum and Abbott's model serve to shift the represented location along the learned route. Indeed, the latter property has been shown to allow the represented location to move smoothly along the route over time, suggested as a model for mental replay during sleep (Redish and Touretzky, 1998). The goal-independent encoding of spatial proximity (as in the symmetrical connections of Muller et al.'s cognitive graph) or of previously traveled routes (as in the asymmetrical connection of the later models) correspond to latent learning. However, the way these models incorporate a new goal location necessarily requires many trips to the goal and thus probably falls short of a rat's abilities. Another drawback associated with these models is that none makes clear the details of how the rat's brain might deduce the direction it should move in or if it would be able to generate a short-cut or detour. They also assume place fields of fixed relative location but might still make some interesting predictions regarding the locus of search in environments that had changed in shape or size. To build up a true distance metric in complex environments would take a long time, in common with the reinforcement learning approaches (see Foster et al., 2000, above).

These models can be viewed in the context of a more general set of higher-level algorithms for navigation based on directed graphs. Lieblich and Arbib (1982) described a "world

graph" in which locations are represented as nodes connected by (asymmetrical) edges that represent the movement necessary to get from one node to the next. In terms of the navigation of autonomous agents, Scholkopf and Mallot (1995) described a "view graph" in which the local view or sensory perception at given locations form the nodes and the actions required to get from one view to the next form the edges. See also McNaughton and Nadel (1990) for a description of how a view graph might be implemented in the hippocampus. Mallot and Gillner (2000) argued that such view graphs are a good model for human navigation despite their simplicity. One key requirement for building a world graph is to be able to decide whether to assign a new node to a location. This can be done on the basis of its familiarity (see Touretzky and Redish, 1996; Kali and Dayan, 2000, for models relating to this) or possibly on the basis of the sequence of actions that lead back to a location. Lieblich and Arbib further suggested that the nodes of a world graph might also represent a location's motivational valence and thus become a general model for goal-directed behavior, even though its creation might correspond to latent learning.

## 14.5 Hippocampus and Associative or Episodic Memory

In contrast to the vast amount of animal work linking hippocampal damage to deficits in spatial memory, the major impairment noted in humans following bilateral damage to the hippocampus is amnesia: a much more general impairment in memory. The extent of this impairment into various subdivisions of memory and into information acquired prior to the damage is a contentious issue (see Chapter 12). Here I briefly review the data on human hippocampal function in memory, introduce the generic model for it derived from Marr's seminal paper in 1971, and discuss various details and developments of this model over the years.

### 14.5.1 Hippocampus and Memory: Data

Substantial bilateral damage to the hippocampus and medial temporal lobes almost invariably leads to amnesia, characterized as a drop in the memory component of the intelligence quotient (MIQ) of at least 20 points relative to full-scale IQ. Because only a relatively small number of cases of damage restricted to the hippocampus have been studied, it is difficult to draw general conclusions regarding its role in memory, in contrast to the roles of the surrounding cortical areas. However, some general points can be made (see Spiers et al., 2001 and Chapter 12 for details). They include a ubiquitous deficit in memory for personally experienced events that occur after the lesion (i.e., an "anterograde" deficit in "episodic" memory) and spared procedural and working memory. The extent of retrograde amnesia (loss of memory for information acquired prior to the lesion) appears to vary

across patients and possibly across types of information (Nadel and Moscovitch, 1997). Memory loss can extend over the entire lifetime or can be restricted to shorter periods prior to the damage; but it does seem to be relatively limited in the case of lesions to the fornix. More controversial findings include relative sparing of semantic memory (memory for facts) and of familiarity-based recognition in some cases of focal hippocampal damage. Relative sparing of recognition memory is consistent with findings in monkeys showing that this type of memory is perhaps more strongly dependent on nearby cortical areas (e.g., Gaffan, 1994; Zola-Morgan et al., 1994; Aggleton and Brown, 1999; Baxter and Murray, 2001). Finally, it should be noted that the human hippocampus, particularly in the right hemisphere, is also involved in spatial navigation (Burgess et al., 2002).

#### 14.5.2 Marr's Hippocampo-neocortical Model of Long-term Memory

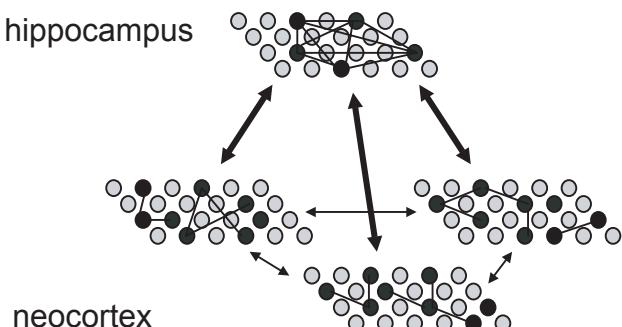

Most modeling work on the role of the hippocampus in memory can be considered part of a long tradition reaching back to Marr (1971). In this section I sketch the main components of Marr's model, which provide a common framework for all of the subsequent models, and indicate how these components correspond to various aspects of the data on human memory (see also Willshaw and Buckingham, 1990; Burgess et al., 2001a). I refer to this as the generic hippocampo-neocortical model (Fig. 14–9).

In Marr's (1971) model, events in the outside world are represented by patterns of activity in neocortical areas. The role of the hippocampus is to store these representations over the short term so relevant events can be categorized and stored for the long term in neocortex (see Marr's 1970 model of the cerebral neocortex). This is achieved by mapping the

neocortical representation of an event into a “simple representation” in hippocampus, with modifiable connections to and from the hippocampus storing the mappings between the full representation and the simple representation. The CA3 recurrent collaterals are modified to store the simple representation as an associative memory—so if a simple representation is incompletely activated, the “collateral effect” results in the full representation being recovered. Thus, partial activation of the neocortical representation of an event can lead to complete reactivation of its simple representation in the hippocampus, which in turn can reactivate the entire neocortical representation. In Marr's view, the capacity of the hippocampal system should be enough to store a day's events so the process of categorization and long-term storage in neocortex can take place during the following night's sleep. Note that this now seems at odds with the much larger extent of retrograde amnesia following hippocampal lesions, and the possibility that some types of information (e.g., episodic, in contrast to semantic) remain forever dependent on the hippocampus (Nadel and Moscovitch, 1997). Marr further suggested that the simple representations need reflect only those parts of the event through which they are addressed, and that they should be sparsely encoded to reduce possible interference between representations. The sparseness of a representation refers to the fraction of neurons that are active: If this fraction is low, the chance of the same neuron being active in the representation of different events is small, and interference between representations is minimized.

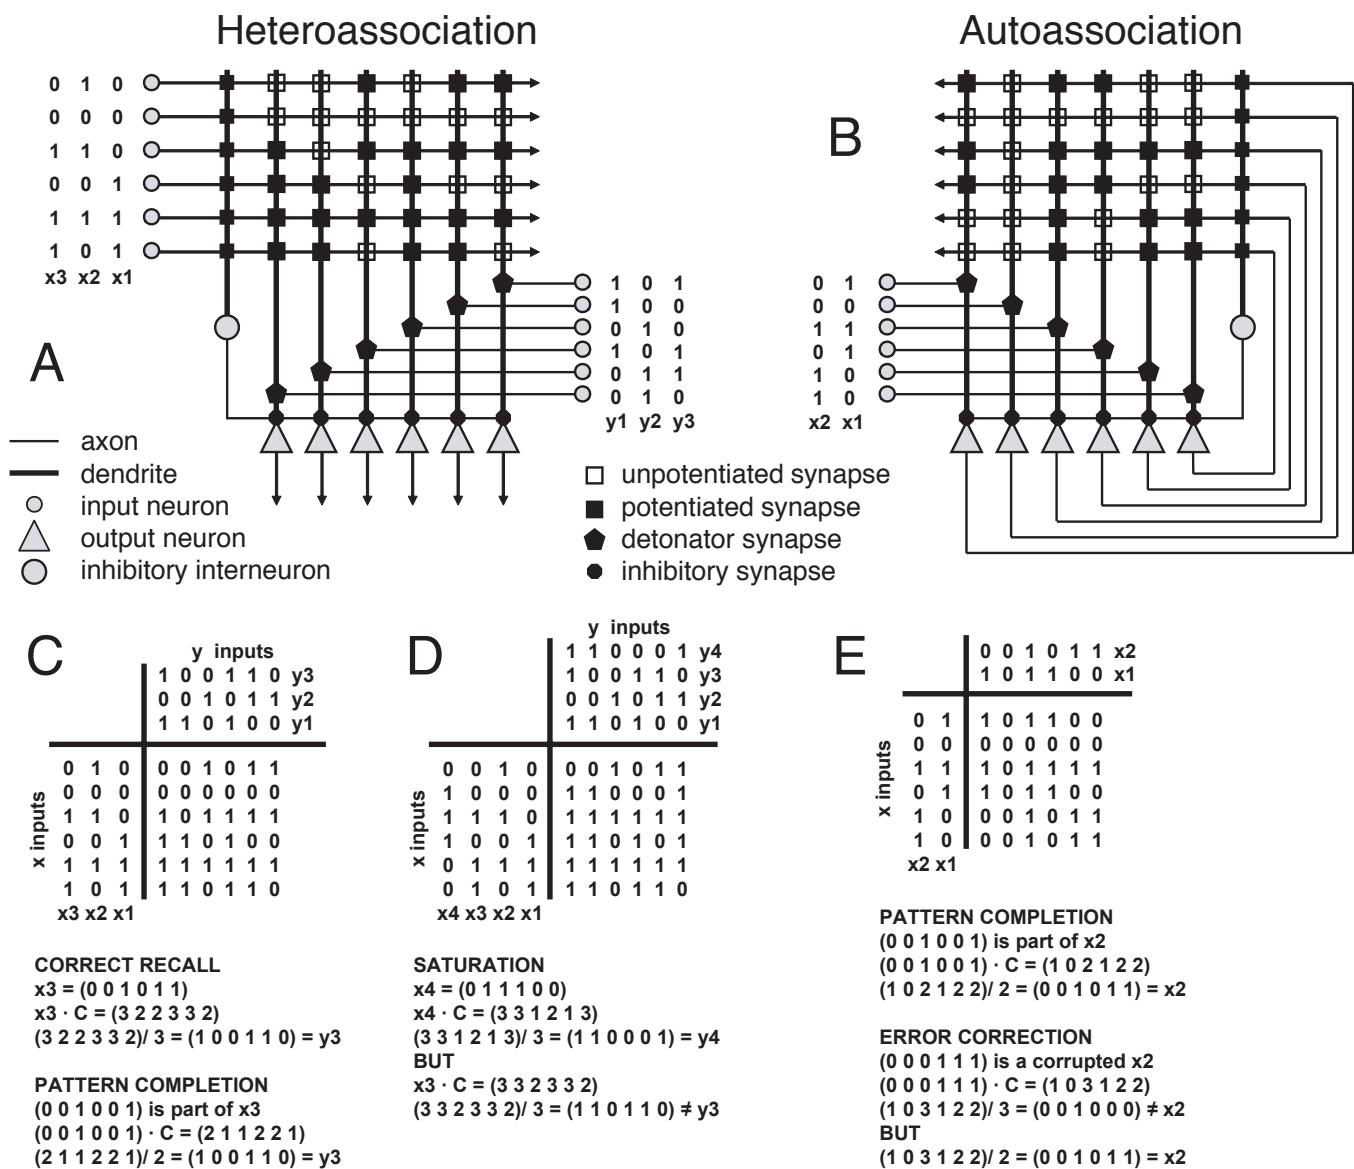

It should be noted that the proposed capacity of the hippocampus has varied widely in subsequent models, as memories remain hippocampus-dependent for more than 1 day and possibly never become fully independent of it (see below). The issue of “capacity” itself is also confounded by the need to specify how to divide continuous experience into discrete binary patterns. Another confusing issue is the correspondence between Marr's rather abstract generic model of memory and the processes of retrieval in human memory. For example, it is not clear whether the model refers to recognition or recollection, where the incomplete retrieval cue comes from, or whether the model applies more to memory for some kinds of information than others. With regard to retrieval cues, the prefrontal cortex probably plays an important role in the strategic organization of retrieval, taking this issue beyond the scope of this chapter (e.g., Roberts et al., 1998). By the end of Section 14.5 some of the other issues are resolved, and others are discussed further in Section 14.6.

**Figure 14–9.** Generic hippocampo-neocortical model of long-term memory. Strong connections and active cells are shown in black. Relatively dense recurrent connections and sparse representations in the hippocampus enable efficient pattern completion. Connections between neocortex and hippocampus allow the hippocampal representation of an event to be associated with its sensory details, including reactivation of the representations in various neocortical areas dealing with different sensory modalities. Abstracted semantic representations may also be learned over time in the neocortex. The recurrent connections in each neocortical area allow unimodal recognition. (Source: Burgess et al., 2001a.)

#### 14.5.3 Associative Memory and the Hippocampus

Much of the development and analysis of the generic model has followed from basic research on the associative properties of feedforward networks (e.g., Willshaw et al., 1969) and recurrent networks (Kohonen, 1972; Gardner-Medwin, 1976; Hopfield, 1982) based on Hebbian learning (Fig. 14–10). Much of the initial development of the model concentrated on matching the major anatomical properties of the hippocam-

**Figure 14-10.** Biological implementation of associative memory in the hippocampus. **A.** Heteroassociative network associates pattern of activity  $y_1$  with input  $x_1$ , and  $y_2$  with  $x_2$ , and so on to form an associative memory. (The matrix of connection weights shown in A is the result of successive presentations of input pattern  $x_1$  and output pattern  $y_1$ ,  $x_2$  and  $y_2$ ,  $x_3$  and  $y_3$  to an initially blank matrix.) This enables input  $x_1$  to reproduce activation  $y_1$ . Even an incomplete or corrupted version of  $x_1$  can reproduce  $y_1$  (see C). Storing too much information leads to “saturation” of the system and retrieval failures (see D). **B.** Autoassociative network associates pattern  $x_1$  with itself,  $x_2$  with itself, and so on to form an autoassociative memory. This enables an incomplete or corrupted pattern to be cleaned up (see E). The essential functional components of these networks are a set of powerful “detonator” synapses that can impose the pattern of activity to be stored, a set of extensively connected inputs with modifiable synapses, and a set of inhibitory interneurons whose role is to set a divisive threshold for the activity of the cells. **C–E.** Details of associative memory using the correlation matrix formalism (Willshaw et al., 1969; Kohonen, 1972). Pairs of

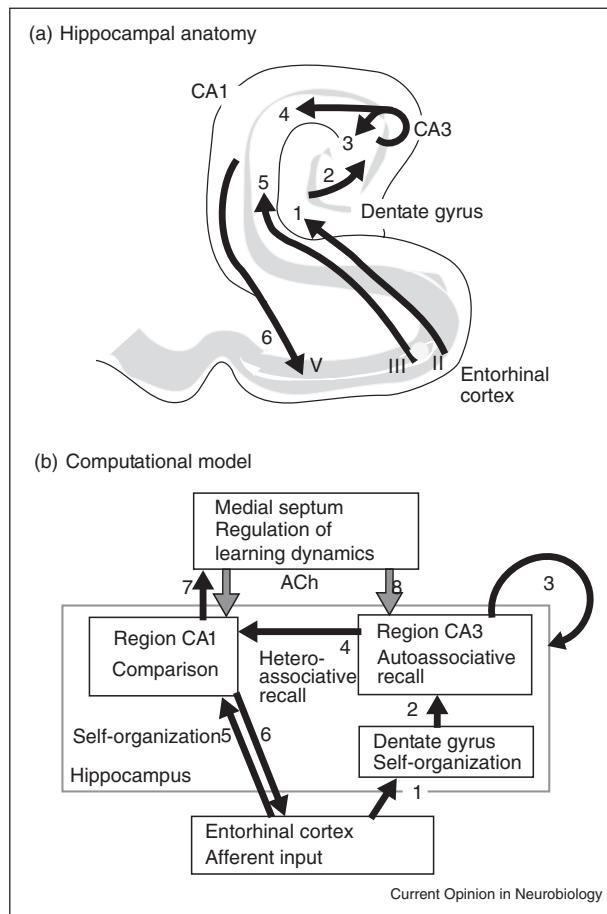

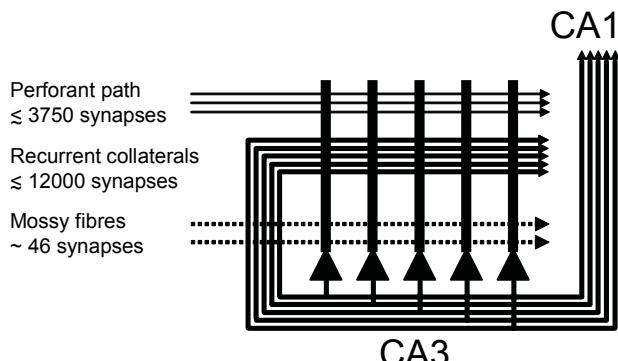

binary vectors (e.g.,  $x_1$ ,  $y_1$ ) are presented to the system for storage. A Hebbian learning rule is used: A synaptic connection is strengthened (set to 1 from 0) given pre- and postsynaptic activity (i.e., both inputs set to 1). Because the net input to a cell is the sum of inputs multiplied by the strength of the connection mediating it, the net input to a cell corresponds to the number of active inputs arriving via strengthened connections. To fire, the net input to a cell must equal the number of currently active inputs. Thus, retrieval of a vector given its corresponding paired associate is achieved by matrix-vector multiplication (e.g., pattern  $y_3$  in A is extracted by multiplying the matrix rows by corresponding elements of vector  $x_3$  and summing the columns) followed by integer division by the number of active bits in the input vector. Provided not too many patterns have been stored, any unique subset of an  $x$  vector can recall the correct  $y$  vector. The autoassociative cases (B and E) work as the heteroassociative cases (A, C, D) with output  $y_1 =$  input  $x_1$ ,  $y_2 = x_2$ , and so on. (Source: Adapted from McNaughton and Nadel, 1990.)

pus (see Chapter 3), with constraints on the representations and learning mechanisms indicated by functional analysis of associative memory (see Figs. 14–10 to 14–12). The first major attempt of this sort (McNaughton and Morris, 1987) highlighted the potential contribution of the dentate gyrus (DG).

First, the much larger number of projection cells in the DG (around one million granule cells in the rat) than in either the entorhinal cortex (EC) (around 200,000 layer II cells project into the hippocampus) or region CA3 (around 300,000 pyramidal cells) indicate that it could be used for “pattern separation” (Amaral et al., 1990). This means that distinct (i.e., nonoverlapping) patterns of activation are created in the DG despite similarity in patterns of EC activation representing similar events. This process is also referred to as orthogonalization. Thus pattern completion in CA3, so important for retrieving the representation of a familiar event, does not lead to a similar novel event also causing retrieval of the representation of the familiar event. Of course, one cannot have perfect pattern completion of the representation of an event from partial cues *and* perfect pattern separation of it from the representations of similar events in the same system. One mechanism must fail once the partial cue is less similar to the old event than the new event.

Second, the specific nature of the various synaptic inputs to CA3 pyramidal cells suggests different functions for them. The input from DG comes from a small number (around 46) of very large synapses around the soma. A much large number of connections are received farther up the dendrites from within CA3 (up to 12,000), and up to 3750 connections are received from the EC onto the distal apical dendrites. It was suggested (McNaughton and Morris, 1987) that the powerful input from DG (via “detonator synapses”) serve to impose a new pattern of activity to be learned. A strong input is required to impose a new pattern of activity in CA3 in the face of the interference due to feedback via the recurrent connections, which tend to cause the system to return to a previously stored pattern of activity. Once the representation of a new event has been imposed, the Hebbian modification of both the recurrent connections and the connections from EC can

**Figure 14–11.** Anatomy of the inputs to CA3 pyramidal cells, showing the approximate number of synapses onto each cell in the rat. (Adapted from Treves and Rolls, 1992.)

**Figure 14–12.** Hippocampal anatomy (a) and a computational model of hippocampal episodic memory function (b). Numbers label synaptic connections mediating various functions in the model. 1: Synapses of the perforant path fibers projecting from entorhinal cortex layer II to the dentate gyrus undergo sequential self-organization to form sparse, less overlapping representations of entorhinal activity patterns. 2: Mossy fibers projecting from dentate gyrus to region CA3 transfer dentate gyrus activity to CA3. 3: Excitatory recurrent connections in region CA3 mediate autoassociative encoding and retrieval of the features of episodic memories. 4: Schaffer collaterals from region CA3 to CA1 encode and retrieve associations between CA3 activity and activity patterns induced by entorhinal input to region CA1. 5: Perforant path input to region CA1 undergoes self-organization, forming new representations of entorhinal cortex input for comparison with recall from CA3. 6: Projections from region CA1 to deep layers of the entorhinal cortex store associations between CA1 activity and entorhinal cortex activity, allowing representations in CA1 to activate the associated patterns in entorhinal cortex. 7: Output from region CA1 to the medial septum regulates cholinergic modulation. 8: Cholinergic modulation from the medial septum sets appropriate dynamics for encoding in hippocampus. (Source: Hasselmo and McClelland, 1999.)

occur. The large number of recurrent synapses per cell allow large autoassociative memory capacity, and the large number of synapses in the input from EC allow large heteroassociative memory capacity in associating the EC representation to the CA3 representation (Treves and Rolls, 1992) (Fig. 14–11).

Third, the requirements of Hebbian learning in the CA3 recurrent connections and the connections from EC to CA3, but not in the connections from the DG, are consistent with the physiology of these various connections. The synapses in the former two pathways are thought to be capable of NMDA receptor-dependent LTP, whereas the mossy fiber connections from DG show only non-Hebbian modification (see Chapter 10). Equally, the divisive normalization required by associative nets (Willshaw et al., 1969) (see Box 14–2) is consistent with the action of interneurons providing inhibition by opening ion channels near the soma-to shunt input current in the dendrites (Fig. 14–10). Further analysis of autoassociative memory indicates that “progressive recall” improves performance (Gardner-Medwin, 1976). With this model, inhibition is slowly reduced during retrieval so the first few cells that become active are the most likely to be correct, and feedback from their activation decreases the chances of subsequent erroneous activation. Such periodic fluctuation of inhibition (or, equivalently, the cells’ firing threshold) may provide a functional interpretation for the theta rhythm.

In Marr’s model an incomplete or incorrect neocortical representation feeds into the hippocampus, where the correct hippocampal representation is retrieved and feeds back to complete or correct the neocortical representation. This simple picture has been elaborated to include separate input and output representations in the entorhinal cortex (in the superficial layers and deep layers, respectively). The processes of storage and retrieval obviously do not start and end at the entorhinal cortex. The processes of feedforward cueing of a representation, its pattern completion and feedback can be modeled as occurring sequentially in the cortical areas between sensory cortex and entorhinal cortex (Rolls, 1996). The principal difference between the processes in the hippocampus and EC and those in lower cortical areas are the additional pattern separation provided by the DG and the greater autoassociative power of the much longer-range recurrent collaterals in CA3 compared to cortex. The long-range recurrent collaterals in CA3 also provide the best opportunity to associate information from different sensory modalities. Many of the above ideas are reviewed or developed further in the literature (e.g., Amit, 1989; McClelland et al., 1995; Rolls and Treves, 1997; Hasselmo and McClelland, 1999; Redish, 1999).

#### **14.5.4 Hippocampal Representation, Context, and Novelty**

The above considerations of sparseness and pattern separation regarding the hippocampal representation of an event raise the issue of how these representations relate to the various elements of its content and context. First note that the conflicting processes of pattern separation and pattern completion serve to define the similarity space of retrieval (i.e., which dimensions a retrieval cue can vary along but still retrieve the event and which dimensions serve to discriminate events). In the limit of complete orthogonalization in the den-

tate gyrus, the hippocampal representations are independent of the details of the events and can be thought of as simply an index for them (Teyler and DiScenna, 1986). However, as the hippocampal representation must initially be activated by the neocortical representation, the overall memory system is still “content addressable” and its behavior (e.g., pattern separation or pattern completion) depends on how different aspects of an event and its context contribute to the activation of its hippocampal representation. This relates to Marr’s observation that the hippocampal representation should include those aspects of an event used for its retrieval.

In a simple associative memory, all elements of the representation of the event are equally associated with all other elements. However, as implied by Marr, it seems plausible that some aspects of an event are better able to cue associative retrieval than others, and other aspects of an event can be associatively retrieved more easily than others. Thus, the “simple representations” envisaged for the hippocampus would reflect some aspects more than others. A related suggestion is that the hippocampal representation reflects efficient compression of the neocortical representations—extracting the distinguishing features of each event (Gluck and Myers, 1996). For example, the name of someone you met only once is often a good cue to recalling the meeting but can be difficult to retrieve, whereas the location of the meeting is often both a good cue and relatively easy to retrieve. Similar to someone’s name, the sequential position of an item in a list is easier to use as a cue than it is to retrieve (Jones, 1976). Thus, even the simplest associative model of memory should include asymmetrical associations between the elements of an event.

One of the distinguishing features of episodic memory is the ability to retrieve the ongoing context within which the event occurs (Gardiner and Java, 1993; Tulving, 1993; Knowlton and Squire, 1995), and one suggestion for the role of the human hippocampus is that it provides the spatiotemporal context for episodic memory (O’Keefe and Nadel, 1978). Theoretical analyses of associative memory have also made the distinction between the content of the event and its context (e.g., Raaijmakers and Shiffrin, 1981) or between the record of the event and the “header” or index term used to reference it (e.g., Morton et al., 1985). One possibility is that the hippocampus serves to associate the content of the event with its context (e.g., Wallensteen and Hasselmo, 1997) (see Section 14.6). A related possibility is that the role of the hippocampus is to generate a representation of temporal context itself (e.g., slowly varying patterns of activity generated by its own recurrent dynamics) (Levy, 1996). This type of model coincides with a considerable psychological literature of models of memory in which retrieval of stored items is held to depend, at least in part, on their association with a representation of context that changes slowly with time or experience. In some of these models the context representation changes independently of the to-be-remembered items (Mensink and Raaijmakers, 1988; Burgess and Hitch, 1992; Davelaar et al., 2005), whereas in others the context representation is derived from the items themselves (Howard and Kahana, 2001).

Retrieval corresponds to finding the item most strongly associated with a re-presented context.

I briefly describe the operation of one of these models, the temporal context model, as I return to it in the section on models attempting to draw links between the medial temporal roles in spatial and episodic memory. As with other models of episodic memory described above, item representations are associated with context representations such that a given item is retrieved according to the similarity between the context at retrieval and that associated with the item. However, in this model the context representation is derived from the presented or retrieved items themselves, becoming a recency-weighted sum of the context arising from each item. After presentation of the list, the context vector is most similar to the most recent items, producing the well known recency effect. In addition, when an item is presented, it affects the context vector with which subsequent items are associated. Thus, recall of a given item changes the context vector so that retrieval of immediately subsequent items in the list is more likely (by making the context vector more similar to how it was when those items were presented). This leads to an asymmetry such that forward associations in the list are stronger than backward associations, as is often found with free recall.

Consideration of the different requirements of encoding and retrieval also raises some interesting questions. Notwithstanding McNaughton and Morris's suggestion that "detonator synapses" from the dentate gyrus can impose a new pattern of activation on CA3 despite the retrieval-related feedback from recurrent connections, there must be some mechanism to determine whether the system should be in encoding or retrieval mode (McNaughton and Morris, 1987). One proposal is that the supply of acetylcholine (ACh) from the medial septum switches the hippocampus between encoding and retrieval modes (Hasselmo et al., 1995; Murre, 1996; Wallenstein and Hasselmo, 1997). In this model, increased ACh increases the rate of synaptic modification of the recurrent connections in CA3 and suppresses the synaptic transmission of intrinsic activity (within CA3 and from CA3 to CA1), enabling new patterns of activity to be stored. The level of delivery of ACh is determined by the novelty of the neocortical input, as represented by direct activation of CA1 from EC, compared to the most similar previously stored event, as represented by the input to CA1 from CA3 after it settles to a stored state. Specifically, if both CA3 and entorhinal cortex inputs to CA1 are matching (as with a familiar stimulus), strong activation of CA1 activates interneurons in the medial septum, which decrease the activity of the cholinergic cells projecting to the hippocampus (Fig. 14–12).

Two types of evidence support this model. First, by emphasizing the connections between the hippocampus and the medial septum, the model begins to address data showing the importance of the fornix, the large fiber bundle connecting the hippocampus with the medial septum and other subcortical structures. In the model, sectioning the fornix prevents the learning of new memories due to lack of ACh, which corresponds well to reviews of the effects of damage to the fornix in

neuropsychological patients (e.g., Spiers et al., 2001) (see Chapter 12). Second, blocking the ACh receptors prior to encoding (by injecting scopolamine) seems to impair recall more strongly than recognition (Hasselmo and Wyble, 1997). This is also the case in the model, assuming that CA3 serves to associate events and their contexts because recall is more reliant on these associations than recognition. However, disruption of the hippocampus might also impair recall more than recognition in many other models (e.g., due to disrupting associations with context) (see Section 14.6). In addition, more recent work has begun to include the role of dopamine in novelty and encoding (Lisman and Grace, 2005).

#### **14.5.5 Consolidation and Cross-modal Binding of Events in Memory**

Ever since the initial reports of dense anterograde amnesia but weaker or temporally graded retrograde amnesia after bilateral medial temporal lobectomy (Scoville and Milner, 1957) (see Chapter 12 and the caveats in Section 14.5.2), researchers have considered how the hippocampus contributes to the long-term consolidation of memories. One mechanism for consolidation, consistent with the preservation of information acquired prior to hippocampal damage, is that the hippocampus enables information to be stored elsewhere in the brain after which it is no longer needed for retrieval. Marr's (1971) model follows this view, suggesting that the day's events are stored in the hippocampus and that this information is used to allow long-term categorization and storage in the neocortex. Note that processes of temporal consolidation might also occur in the hippocampus (i.e., without transfer of information from one region to another).

The experimental data regarding the gradient of retrograde amnesia (i.e., the sparing of memories acquired sufficiently long enough before the damage) is inconsistent and remains controversial in animals (see Chapter 13) and humans (see Chapter 12) (Spiers et al., 2001). One problem in the human data is that the amnesia often extends back to childhood, implying that the hippocampus stores several decades worth of information. Several computational arguments have also been put forward for the transfer of information out of the hippocampus for consolidation in the neocortex. Marr (1971) suggested that a short-term buffer is needed to store information online (i.e., the hippocampus), whereas only information deemed relevant to the animal's future needs to be incorporated into the animal's long-term store of knowledge and must be first appropriately categorized with respect to it. The hippocampal store of unprocessed experience necessarily has a limited capacity, and the process of abstracting relevant information from this experience to expand a long-term database requires extensive offline processing, perhaps during sleep (see also McClelland et al., 1995).

A second argument concerns the anatomical convergence of information from different sensory modalities at the hippocampus. Thus, in the absence of long-range connections between different sensory cortical areas, associations between the elements of an event, such as its sight, sound, and smell,

cannot be formed in the lower-level cortices. Damasio (1989) suggested that “convergence zones” must exist where these associations could be formed. Several models have extended this idea to include rapid learning of a hippocampal, or medial temporal lobe, representation reciprocally connected to all the unimodal cortical representations of the event which allows them to be associated with each other (Alvarez and Squire, 1994; Murre, 1996; Moll and Miikkulainen, 1997). These models also suggest that, after multiple rehearsals of a memory driven by the hippocampus, long-range associations can be learned directly between the unimodal representations, finally making the stored information independent of the hippocampus.

The arguments regarding data abstraction and anatomical convergence are represented in a model by Kali and Dayan (2004). In this model the hippocampus serves to aid the learning of a hierarchical semantic system by being able to reinstate the top-level (i.e., entorhinal/ perirhinal/ parahippocampal) representation of events during sleep. The semantic system contains reciprocal connections between higher cortical areas and those immediately below them in the hierarchy but no direct connections between areas at the same level. Aided by the hippocampus, the neocortical system learns to form an associative representation of patterns of activation in lower cortical areas. This is achieved by the higher level representations learning a “generative model” of representations lower in the hierarchy (e.g., Hinton and Sejnowski, 1999). Thus higher-level representations can be cued by input from a subset of lower cortical areas and can then cause pattern completion in all lower areas via the reciprocal connections. During further simulations, Kali and Dayan (2004) noted that regular reactivation of episodic hippocampal representations is required to maintain them in register with the slowly changing semantic representations.

A third argument for consolidation refers to the effects of interference. In some learning systems—such as using a fixed feedforward structure and the error back-propagation learning rule (Rumelhart et al., 1986) to form associations consistent with a set of examples—new information can interfere with previously stored information, sometimes “catastrophically” such that all information is lost. This problem can also occur with associative memories (Fig. 14–10). McClelland et al. (1995) proposed a solution to this in which long-term neocortical learning involves random interleaved re-presentation of all previous knowledge along with newly acquired knowledge to produce a single integrated neocortical representation of semantic knowledge. Note, however, that this mechanism requires the temporary store to have capacity for the entire data set. Other solutions include associative memories with continuous but bounded connection weights (Hopfield, 1982) and “constructive” algorithms in which the addition of new information is accompanied by the addition of new processing units (Gallant, 1986; Mezard and Nadal, 1989; Fahlman and Lebiere, 1990; Frean, 1990). The latter algorithms may relate to the recent observation of neurogenesis in the adult dentate gyrus that is related to learning (Shors et al., 2001).

A reinterpretation of the experimental data regarding the gradient of retrograde amnesia associated with medial temporal lobe damage led Nadel and Moscovitch (1997) to a different conclusion regarding consolidation. Noticing that in many instances retrograde amnesia extends back over a much longer time than that envisaged by Marr, they proposed that the hippocampus remains necessary for the retrieval of detailed episodic or spatial information (but for evidence that early spatial memories become hippocampus-independent see Teng and Squire, 1999; Rosenbaum et al., 2000). They proposed a new model to account for both the common occurrence of a temporal gradient in memory for other types of information and the possibility of partial damage to the hippocampus in some cases. In this model, whenever a memory is rehearsed or reactivated, a new hippocampal representation is formed, again connected to all of the neocortical representations. The result is that although a complete lesion of the medial temporal lobe impairs retrieval of all memories, the older the memory, the more robust it is to partial damage by virtue of being represented in multiple locations. Some evidence for the reactivation of specific memories comes from the recently revived study of reconsolidation (Nader et al., 2000). In these experiments re-presentation of the context of an event (usually application of an electric shock) appears to render the memory for the event labile in the sense that protein synthesis is again required for long-term storage of the memory, as is the case when the event is first experienced.

#### 14.5.6 Hippocampal Contributions to Various Types of Memory and Retrieval

A distinction has been made between retrieval of episodic information, retrieval of semantic information, and familiarity-based recognition (see Chapter 12). Episodic retrieval is characterized by the ability to retrieve detailed information about the event and its context. Semantic retrieval is characterized by factual knowledge without retrieval of the individual events and contexts in which it was acquired. Familiarity-based recognition depends purely on an unattributable feeling of familiarity associated with a stimulus in the absence of detailed information about the event and context in which it was encountered. Of these three processes, the hippocampus is claimed to be primarily involved in episodic retrieval (e.g., Aggleton and Brown, 1999) (see Chapter 12).

The hippocampo-neocortical model suggests that semantic knowledge is abstracted from combinations of hippocampal memories of unique events, but eventually becomes independent of the hippocampus. This is consistent with memory for the unique content and context of a specific event (episodic memory) depending on the hippocampus but semantic memory depending on other areas of the temporal lobe (e.g., Graham and Hodges, 1997). It is also consistent with the suggestion of Nadel and Moscovitch (1997) that semantic memories show a temporal gradient of retrograde amnesia, whereas detailed episodic memories do not. The model is less obviously consistent with the observation that semantic informa-

tion can be acquired despite early bilateral hippocampal pathology (Vargha-Khadem et al., 1997). However, the possibility of partial sparing of the hippocampus (Squire and Zola, 1998) or the use of external rehearsal of information (Baddeley et al., 2001) might provide explanations for these developmental cases within the framework of the model.

The distinction between episodic retrieval and familiarity-based recognition also has interesting parallels in the hippocampo-neocortical model. It has been argued that the hippocampus is required to provide associations between representations in disparate cortical areas, whereas associations within each area can be formed locally. Thus, effects mediated by the familiarity of single stimuli might be supported by the association of elements within each of the neocortical areas, independent of the hippocampus. By contrast, correct recognition of a pair of cross-modal associates among equally familiar distractors would require the hippocampus. Evidence indicates that simple recognition memory does not depend on the hippocampus but on nearby neocortical areas (Zhu et al., 1996; Baxendale et al., 1997; Vargha-Khadem et al., 1997; Murray and Mishkin, 1998; Aggleton and Brown, 1999; Wan et al., 1999; Holdstock et al., 2000; Baddeley et al., 2001; but see also Manns and Squire, 1999; Zola et al., 2000). In contrast, there is some evidence that recognition of cross-modal associations is impaired by bilateral damage restricted to the hippocampus (Vargha-Khadem et al., 1997; Holdstock et al., 2000). More extensive unilateral damage may also impair the binding of elements within the same modality (Kroll et al., 1996). The logical extension of this idea is that episodic memory requires full recollection of an event and its context in all of its multimodal detail and so requires an intact hippocampus.

Much of the analysis of the differential role of the hippocampus in episodic retrieval (or “recollection”), and familiarity-based recognition has focused on the idea that these two processes contribute independently to the performance of recognition memory tests (e.g., Yonelinas, 2002). In forced choice and yes–no recognition paradigms, the recollective component is assumed to be “all or nothing” and “high-threshold.” That is, the stimulus is recalled in great detail or not at all, and a novel foil is never falsely recalled. By contrast, the familiarity-based process is more like a signal detection problem: The subject guesses whether the item is familiar, informed by a noisy measure of familiarity (see Chapter 13). The hippocampus has been associated with the recollective component (Aggleton and Brown, 1999; Yonelinas et al., 2002) and so should provide a high-threshold, all-or-nothing mechanism in recognition memory tests. One method for detecting this component involves the receiver-operator characteristic (ROC) curve: the plot of the proportion of previously seen items that are correctly identified (“hits”) versus the proportion of new items incorrectly identified (“false alarms”) as a function of the subject’s confidence in their response. Recollection is marked by high-confidence hits in the absence of high-confidence false alarms, producing a positive intercept in the ROC curve. See Chapter 13 and Rugg and Yonelinas (2003) for a review.

The hippocampal contribution to recognition memory (via “recollection”) can be modeled by using the stimulus-driven medial temporal neocortical representation as the cue to retrieval of a stored pattern of activation in CA3 and comparing the retrieved activation to the stimulus-driven activation in the entorhinal cortex (Norman and O’Reilly, 2003). By explicitly retrieving an entire stored pattern, the process is all-or-nothing, and even foils that resemble presented patterns and are not falsely recognized because the retrieval product still differs from the stimulus-driven activation. The use of sparse hippocampal representations, orthogonalized via the dentate gyrus, serves to prevent interference between different stored events. By contrast, familiarity-based recognition is modeled in terms of “sharpening” of the neocortical representation. With this model, although a new item is represented by weak activation of a large number of neocortical neurons, repeated presentation of the item results in strong activation of a smaller number of neocortical neurons via a competitive learning mechanism. Activation of the neocortical neurons that fire in response to a given stimulus can then be used as a measure of familiarity-based recognition. One advantage of this scheme is that repeated presentations of some items in a list does not impair recognition of the other items in the list, as seen experimentally (Ratcliff, 1990), which is not true of some other psychological models of recognition memory (Norman, 2003). A characteristic of this model is that hippocampal damage specifically impairs recognition memory when related lures (novel items that resemble previously seen items) are included in the test. The familiarity-based recognition mechanism would produce false alarms to these stimuli, whereas the hippocampal recollection mechanism would not. Some evidence consistent with this hypothesis has been found (Holdstock et al., 2002).

## 14.6 Reconciling the Hippocampal Roles in Memory and Space

In this section I discuss some of the models that have attempted to draw together the common strands present in the plethora of hippocampal models reviewed above. One feature common to most of the spatial and nonspatial models is use of the autoassociative properties of the recurrent network in CA3. Even feedforward models of spatial representation (see Section 14.3.2) usually note that the various sets of cells used to represent different environments might be stored in this way (e.g., McNaughton and Nadel, 1990; Burgess et al., 1994; Kali and Dayan, 2000).

Many other models concern the common functional requirement of storing and retrieving a *sequence* of patterns of activation. For example, Redish and Touretzky (1998) used replay of a spatial route as a demonstration of episodic recall. In Levy’s (1996) model, the slowly varying patterns of activity (resulting from the presence of asymmetrical connections in CA3) (see Section 14.3.3) might be used as a context repre-

sentation, associations to which could store sequences of memories. In a rat moving through its environment, it is argued that they might also resemble place fields, although it is not clear that this would be the case for a trajectory that crosses itself. Jensen and Lisman's (1996, 2005) model of long-term memory and working memory, involving association of one item to the next and preservation of serial order during each theta cycle, is also applied to model the storage of routes as sequences of place fields.

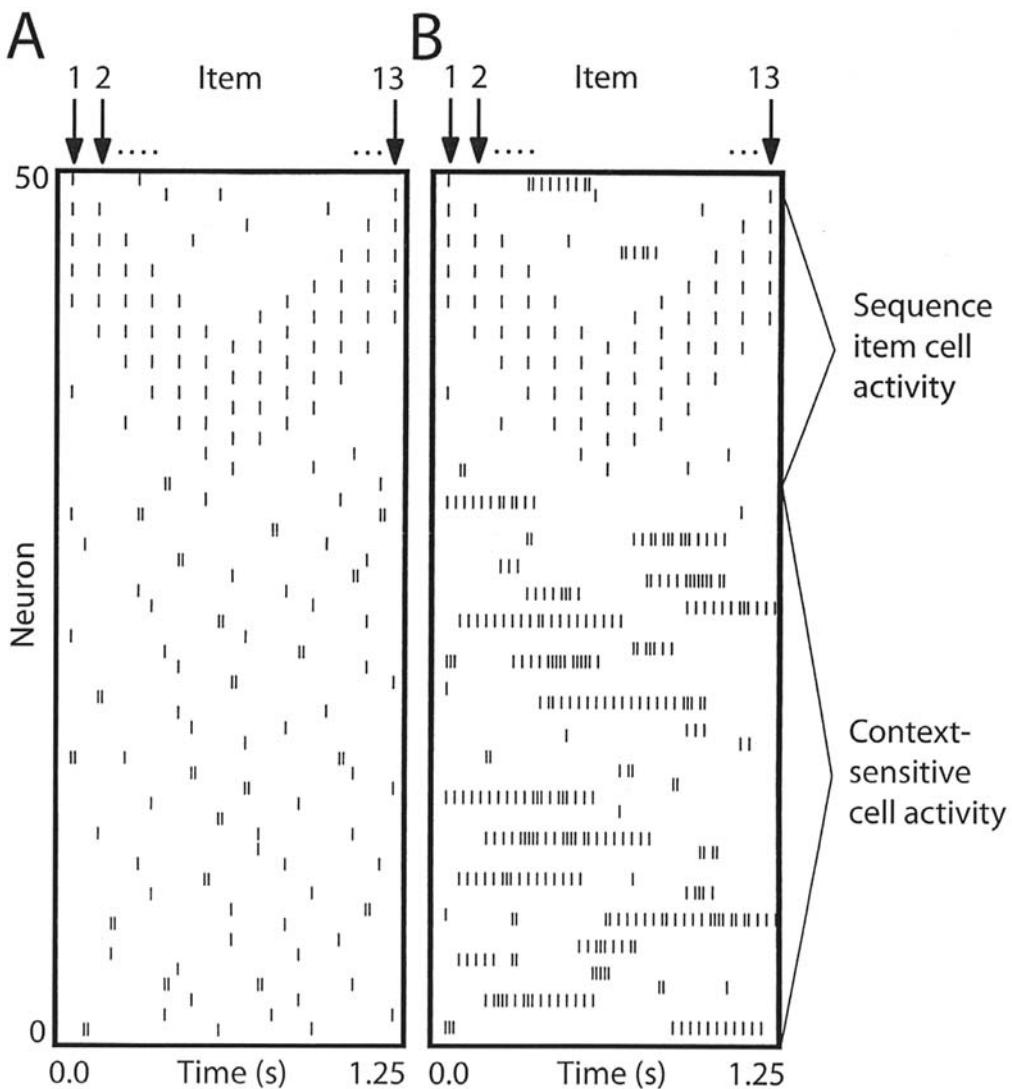

However, spatial navigation is not just a subset of episodic memory; simply storing routes and sequences of places would not enable accurate navigation, detours, or shortcuts. These require a metric or at least a representation of proximity (see Section 14.4.2). Put another way, specific constraints apply to spatial information that are not necessarily required of a more general memory system. What then is the relation between the constraints involved in spatial and episodic memory such that a unique structure, the hippocampus, might support both? O'Keefe and Nadel (1978) argued that the spatial function seen in the rat hippocampus is augmented by a linear sense of time in humans, which allows the human hippocampus to supply the spatiotemporal context of events required by episodic memory. This idea has been taken up by two types of model: one investigating the provision of temporal context and the other the provision of spatial context.

Following the models of Levy (1996) and Jensen and Lisman (1996) described above, Wallensteiner et al. (1998) investigated the idea that the hippocampus could provide a signal representing temporal context as a solution to the need to form associations between temporarily discontiguous events. Associating events that occur much farther apart in time than the time scale required for pre- and postsynaptic activity to induce LTP (i.e., around 100 ms) (see Chapter 10) obviously requires some kind of bridging mechanism. One indication that the hippocampus is involved in this process comes from "trace conditioning," in which the animal must learn to respond at a fixed delay after the disappearance of a cue, because the timing of the response is disrupted by hippocampal lesions. This contrasts with "delay conditioning" in which the cue does not disappear, for which there is no hippocampal lesion effect (see Chapter 13). In Wallensteiner et al. (1998), as with Levy (1996), unsupervised learning in the hippocampus in the presence of temporally correlated inputs creates patterns of activity that vary more slowly in time than the original stimuli (Fig. 14–13). Associations between the various states of this temporal context signal can allow the original stimuli to be reproduced in order. Indeed, this type of mechanism provides a good model for short-term serial recall (Burgess and Hitch, 2005). This model can be extended to spatial navigation in terms of associations between spatially discontiguous events, but note that, as with storing temporal sequences to aid navigation, temporal contiguity alone is insufficient to generate metric information.

Howard et al. (2005) attempted to draw parallels between the roles of the hippocampal region in both spatial and episodic memory by extending the "temporal context model"

(TCM) of free recall (Howard and Kahana, 2001), described above, to model the noisy place-specific firing of some cells in entorhinal cortex (Quirk et al., 1992; Frank et al., 2000; Fyhn et al., 2004). To model free recall, the TCM forms a context representation derived from a recency-weighted sum of the contributions to context from the nature of the list items themselves. Howard et al. proposed that, in terms of spatial memory, these context contributions might be encoded by neurons with firing rates reflecting running speed in particular head directions. If each context neuron performed a recency-weighted sum of one of these inputs, they would be effectively supporting an approximate route memory, or "path integration." In simulations, these cells show noisy place-specific firing, rather like some cells in the entorhinal cortex, as they fire most following a series of movements along their preferred direction (e.g., a cell with a west head direction input fires most along the west edge of the environment). They also show "retrospective coding": that is, modulation of firing by the recent history of movements, as found by Frank et al. (2000). In addition, cells whose firing rate reflects the time integral of their input have been found in entorhinal cortex (Egorov et al., 2002), and systematic errors in path integration have been found that are consistent with recency weighting (Etienne et al., 1996). However, the model predicts that entorhinal cell firing is directionally selective and always peaks at the edge of the environment, which may not be the case (Fyhn et al., 2004). This idea of entorhinal processing may also have to be reviewed in the light of the discovery of grid cells (Hafting et al., 2005) (see Section 14.3.3).

The idea of using spatial context to index memory was combined with Marr's hippocampo-neocortical model to produce a simple navigation system (Recce and Harris, 1996). In this model, perceptual representations of the environment are stored in parietal cortex and retrieved via an index representation in the hippocampus corresponding to the location of the animal. This allows retrieval of the correct perceptual map for a given location. Navigation additionally requires that the location of an encountered goal be added to the perceptual maps (the mechanism for this is not specified). A more detailed model of long-term memory and retrieval of a spatial environment (Becker and Burgess, 2001) also serves as a model of memory for the spatial context of an event (Burgess et al., 2001a) (Fig. 14–14). This model explicitly makes use of the constraints associated with spatial information, and our detailed knowledge of how it is represented in the brain. The representations of spatial layout in long-term memory are assumed to be allocentric (e.g., independent of the orientation of the person) in contrast to the egocentric short-term representations involved in perception, action, and working memory (Goodale and Milner, 1992; Burgess et al., 1999; Milner et al., 1999). By extension from spatial models of the hippocampus (Hartley et al., 2000), the geometry of the environment is encoded in (parahippocampal) boundary vector cells bidirectionally connected to (hippocampal) place cells. The place cells are connected up to form a continuous attractor. This

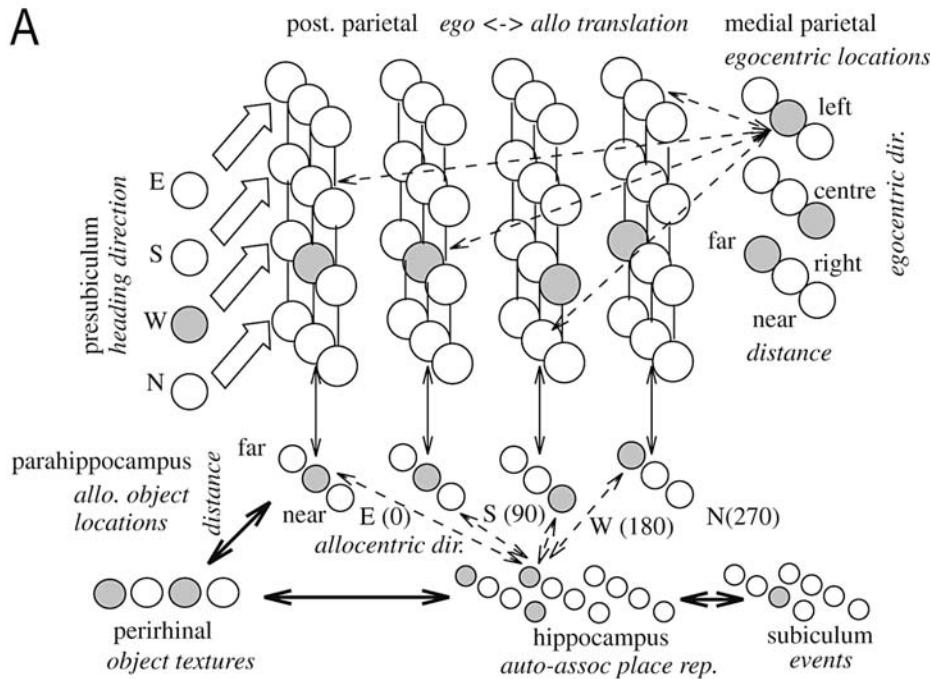

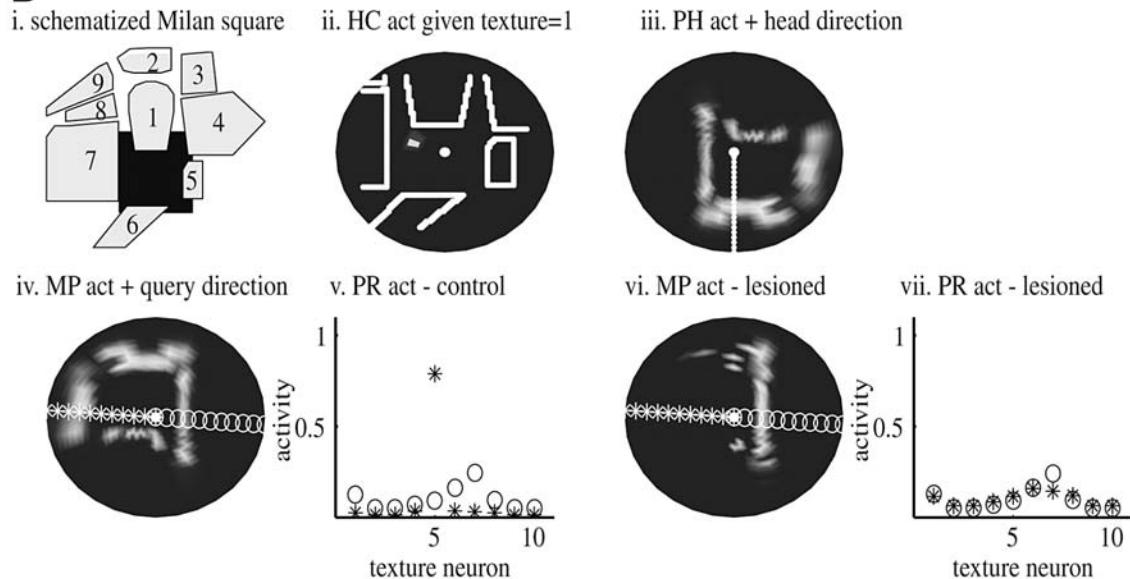

**Figure 14-13.** Context field development. Each rectangle shows a subset of 50 simulated pyramidal cells firing across time, each action potential represented by a vertical line. A unique group of five cells firing at the same time encodes a single item in a 13-item sequence (see the top portion of each rectangle). This can be thought of as afferent activation of CA3 pyramidal cells due to a specific pattern of sensory events. *A*. Note the background firing during the first learning trial that does not encode sequence items directly. This stems from activity at recurrent excitatory synapses. Repeated exposure to the same sequence can lead to enhanced

synaptic potentiation between cells firing in the background and cells that encode sequence items owing to a simple Hebbian learning rule. *B*. After the fourth learning trial, this repeated potentiation leads to a condition where background cells begin to respond to the appearance of contiguous segments of the entire sequence. The portion of the full sequence to which the cell responds is called the “context field” of the cell. Because the context fields overlap, the entire sequence can be reconstructed by interdigitating them in the proper order. (Source: Wallenstein et al., 1998.)

acts as a spatial memory system in that partial activation of boundary vector cells (representing the occurrence of particular large objects at particular distances and bearings) causes activation of the corresponding place cells, which then activate the boundary vector cells representing the remaining landmarks in the environment. The location of a specific event is represented by a goal cell, as in the simple model of navigation (Burgess and O’Keefe, 1996) (see Section 14.4.2). Bidirectional connections between place cells and these “event” cells allows for both navigation to the location (via the

feedforward connections) and retrieval of its spatial context (via the feedback connections).

Retrieval of allocentric spatial information into a format appropriate for visual imagery requires that it be translated into an egocentric reference frame. Accordingly, in the model, the parahippocampal boundary vector cell representation (arranged in terms of distances and bearings) is translated successively into trunk-centered then head-centered representations by networks designed for this purpose to model posterior parietal cortex (e.g., Pouget and Sejnowski, 1997).

**A****B**

**Figure 14–14.** A. Functional architecture of the model for encoding and retrieving the spatial context of an event. Neurons shown in gray illustrate a possible pattern of activation corresponding to an imagined location with extended landmarks nearby to the west, far away to the north, and at intermediate distances east and south; the imagined westerly heading direction means that these landmarks are imagined as far to the right, near straight ahead, and at an intermediate distance to the left (and behind, but this is not in view). (Source: Burgess et al., 2001a.) B. Simulation of retrieving spatial information in the Milan square experiment of Bisiach and Luzzatti (1978). i: Training consists of simulated exploration of the square (shaded area, north is up). The system is cued to imagine being near the cathedral (i.e., the perirhinal cell for the texture of building 1 and parahippocampal cell for a building at a short distance north are activated), and the hippocampal-parahippocampal-perirhinal system settles. ii: The hippocampus settles to a location in the

northwest corner of the square (hippocampal cell activity shown as the brightness of the pixel corresponding to the location of each cell's place field). iii: The parahippocampus correctly retrieves the locations of the other buildings (parahippocampal cell activity shown as the brightness of the pixel for the location encoded by each cell, relative to the subject at the center). The line indicates that the imagined head direction is south. iv: Medial parietal (MP) cell activity. The parahippocampal map has been correctly rotated given head direction south (straight ahead is up); stars indicate a direction of inspection to the left, circles to the right. v: Perirhinal (PR) cell activations correctly showing building 5 to the left and building 7 to the right. vi: Effect of a right parietal lesion on the medial parietal representation (note lack of activation on the left) and perirhinal activations (vii). Note the decrease in activation of building 5 when inspection is to the left. (Source: Adapted from Becker and Burgess, 2001.)

Likewise, forming an allocentric representation from egocentric perception requires translation in the reverse direction. Visual imagery occurs in medial parietal areas using the final head-centered representation with the intermediate representations buffered in retrosplenial cortex. This model is consistent with the observation of hemispatial neglect in imagery following parietal damage (e.g., Bisiach and Luzzatti, 1978) and functional imaging of the retrieval of spatial context (Burgess et al., 2001b). It also provides an explanation for the involvement of Papez's circuit (see Chapter 3) in supporting both episodic memory (see Chapter 12) and the representation of head direction (see Chapter 11). Finally it implies a strong link between episodic recollection (and its neural bases) and mental imagery.

## 14.7 Conclusions

As in other areas of neuroscience, the ability to specify a proposed mechanism of hippocampal function in terms of a computational model has been invaluable in many ways. First, it reduces ambiguity and "hypothesis drift." Second, it enables quantitative simulation of the resulting behavior. At the very least this can serve as a demonstration of the viability of a given proposal. Beyond this, it enables quantitative predictions to be made at the levels of cells, systems, and behavior regarding the effects of experimental manipulations. Some of the models reviewed here have been used to make such predictions and have also contributed to the design of experiments to test them. Many questions for future research are prompted by these models, not least the possibility of comparing or combining the influences of spatial and temporal contexts as retrieval cues. Because any worthwhile theory must make potentially falsifiable predictions, computational modeling has a crucial role to play in the development of the field. Investigating the link between the properties of cells interacting in a complex system such as the brain to the resulting behavior of the animal would become almost impossible without the aid of computational models.

## Stress and the Hippocampus

### 15.1 Overview

Anxiety, fear and stress are, on the face of it, very different entities from memory, and it may therefore come as a surprise that the hippocampus has also been implicated in these processes. This chapter focuses primarily on the role of the hippocampal formation and other “higher” structures, such as the amygdala and prefrontal cortex, in the negative feedback regulation of the hypothalamic-pituitary-adrenal (HPA) axis—the major system involved in orchestrating the body’s reactions to both acute and chronic stress. There are two main aspects to consider. The first concerns how hippocampal memory processing and synaptic plasticity is modulated by stress hormones, with particular reference to an inverted U-shaped function relating stress to optimal performance. The second is how the hippocampus interconnects with structures that, in turn, innervate the paraventricular nucleus of the hypothalamus to “complete the loop” of HPA axis regulation. The larger part of the chapter is concerned with the first of these topics, about which much more is known, but we also touch on the second.

Before outlining these subjects, it is important to note that an early proponent of the idea that fear and anxiety were mediated by the hippocampus was Gray (1982) with his “septo-hippocampal” theory. It was based on the notion of hippocampal processing of signals of reward and punishment and the specific role the hippocampal theta rhythm, at frequencies of around 7 Hz, might play in mediating the inhibition of prepotent behavioral responses that lead to punishment or frustrating nonreward. One experimental phenomenon—increased resistance to extinction after partial reinforcement for running in a simple runway—was a cornerstone of the original theory. Over the years modifications became necessary, and it was been updated and elaborated by Gray in 2000. Not alone in maintaining that the brain has a behavioral inhibition system (BIS) of which the hippocampal

formation is a part, others also have suggested that inhibitory processing should not be ignored (as it tends to be in the memory theories discussed in Chapter 13) because hippocampal lesions also cause deficits in various forms of nonspatial-context extinction, negative-occasion settings, and discrimination reversal (Chan et al., 2001; Davidson and Jarrard, 2004). Acceptance of the earliest version of the septo-hippocampal theory of anxiety suffered from exclusion of the amygdala from the BIS despite growing evidence of the role of the amygdala in learned fear and the modulation of memory in emotional situations. This exclusion has been remedied in the updated theory that now extends the envelope of the putative BIS to a number of brain structures that are held to mediate the neural processing involved in coordinating behavior in conflict situations, such as those involving fear and anxiety. McNaughton and Corr (2004) have taken this further by incorporating the Blanchards’ idea of a categorical distinction between fear and anxiety and by extending their intriguing concept of “defensive distance” (Blanchard et al., 1997). Fear, according to this view, is a set of behaviors elicited by a predator that includes fight, flight, and freezing. What behavior is chosen depends, in part, on the perceived “distance” of the prey from the predator. Anxiety, in contrast, is a process of risk assessment associated with the potential presence of a predator that is expressed as the inhibition of whatever behavior in which the prey animal is then engaged. Anxiety—but not fear—is thought to be sensitive to anxiolytic drugs and only learned anxiety mediated by the amygdala/septo-hippocampal system. Fear is in the province of the amygdala. The main empirical basis for implicating the hippocampus in anxiety is the perceived similarity between the pattern of effects of a wide range of anxiolytic drugs on hippocampus-dependent tasks and that of the frank lesions that define such tasks (Gray, 2000). Certain studies pointing to differential functions of the dorsal (septal) and ventral (temporal) regions of the hippocampal formation provide partial support for this idea, as lesions of the ventral hippocampus do impair tasks involving

both unconditioned fear (Kjelstrup et al., 2002) and some anxiety-related behaviors (Bannerman et al., 2004). However, the theory's treatment of amnesia as "hypermnesia" rather than true memory loss does not command much support.

An ostensibly related idea, but of distinct provenance, is that the hippocampus has a key role in the regulation of the HPA axis. The discovery by McEwen in 1968 that the hippocampus contains a high density of corticosteroid receptors opened up a field of research that had hitherto focused largely on the HPA axis alone (McEwen et al., 1968). This field has enabled classic concepts, such as the "general adaptation syndrome" of Selye (1936) and the inverted U-shaped function relating stress to alterations in many aspects of performance, to be tackled at a more mechanistic level. Modern molecular and cell-biological research coupled to behavioral studies is also helping us toward an understanding of why low levels of stress are good for cognitive flexibility and memory formation but higher levels are not. Indeed, sustained high levels of stress cause deleterious structural changes to specific regions of the hippocampal formation. On this view, two strands of thinking about the hippocampus are linked: its role in stress and in memory. Thinking about this issue is also a preliminary to the topic of the final chapter of this book, which deals with the hippocampus and neurological disease (see Chapter 16).

Following his pioneering work, further studies by McEwen and his colleagues revealed that the highest concentrations of mineralocorticoid receptors in the brain are found in the hippocampus (McEwen et al., 1980). As increased release of corticosterone from the adrenals occurs during stressful situations, these observations linked the hippocampus directly with bodily responses to stress, a concept that is extremely difficult to define precisely because it can refer to both distress and exhilaration (Goldstein and McEwen, 2002). McEwen's seminal observations on corticosterone led to the birth of the stress–hippocampus link (Lupien and Lepage, 2001). There has since been a great deal of research evaluating the participation of the hippocampus in the many facets of Selye's general adaptation syndrome. Five key lines of evidence implicate the hippocampus in stress (see Box 15–1).

On perception of a "stressor," be it physical or cognitive, the central nervous system (CNS) mediates the synergistic activation of the neuroendocrine, immune, and autonomic nervous systems. In so doing, it optimizes physiological parameters that help subserve short-term coping needs (e.g., gluconeogenesis, enhanced oxygen delivery, increased heart rate, effective vigilance). The most commonly studied physiological systems—the sympathetic-adrenal medullary system (SAM) and the HPA axis—coordinate a two-phase cascade of events. First, emotional arousal triggers rapid sympathetic adrenergic activity, inducing the release of catecholamines from the adrenal medulla into the bloodstream. This SAM activation mediates the rapid phases of the "fight or flight" response to a threat, with adrenaline modulating the memory for events triggering this arousal via an action within the amygdala (McGaugh, 1973; Davis et al., 1993). The second wave—HPA

### **Box 15–1**

#### **Evidence Linking the Hippocampus and Stress**

1. The presence of mineralocorticoid and glucocorticoid receptors in the animal and human hippocampus.
2. An inverted U-shaped function between level of acute stress and memory.
3. Stress modulation of intrinsic hippocampus excitability and activity-dependent synaptic plasticity associated with learning and memory.
4. Chronic exposure to high levels of stress or stress hormones is associated with structural changes in area CA3 of the hippocampus and, during pregnancy, fetal reprogramming of the HPA axis that lasts into adulthood.
5. Stress or stress hormones can impair neurogenesis in the dentate gyrus.

axis activity itself—has multiple effects, including the cascade of corticotrophin-releasing hormone (CRH) release from the paraventricular nucleus (PVN) of the hypothalamus, leading to ACTH secretion in the anterior pituitary and consequently glucocorticoid (GC) release from the adrenal cortex into the circulatory system. The cortisol (humans) or corticosterone (rodents) so released then feeds back onto both hypothalamic and higher brain structures, including the hippocampus. The HPA axis also functions in constitutive "housekeeping" mode by regulating the secretion of GCs in response to the diurnal cycle of rest and activity, primarily through "reflexive" feedback routes rather than via higher brain structures mediating planning and memory. Under basal conditions, GCs exhibit a 24-hour circadian rhythm during which maximum steroid concentrations (cortisol in humans, corticosterone in rats and mice) are associated with awakening and minimum levels with nocturnal sleeping periods. A rhythm is also observed in nocturnal species but with a different pattern of entrainment.

The term "allostasis" was introduced by Sterling and Eyer (1988) to characterize how blood pressure and heart rate responses vary with experience and throughout the day and how the "set-point" for these can be changed. McEwen (2002) argued for a broader definition in which allostasis refers to a process, including activation of the SAM and HPA axes, whose essential function is to actively maintain homeostasis. Allostasis is thus a process of "stability through change" (somewhat analogous to the shock absorbers and suspension of a car), and it applies not only to protective internal physiological responses but also to overt, ostensibly paradoxical alterations in cognition or behavior that favor future survival (McEwen, 2002). It may, for example, include enhanced memory for significant aspects of a stressful experience coupled with poorer consolidation of other unrelated information. This shift in the pattern of information processing is to be distinguished from merely asserting that, for example, memory has gotten better or worse. Stress has a further downside if it is sustained. The separate concept of "allostatic load" (McEwen, 2000) refers to the pathological cost of prolonged or overactive allostatic

stress that can, over time, induce tissue damage and maladaptive functioning.

This chapter considers findings relevant to the stress–hippocampus link beginning with a model of HPA axis regulation; it then turns to allostatic modulation of hippocampal processing and, next, to the problems that arise with allostatic load. This is followed by discussion of the interaction between the hippocampus and other brain structures in regulating stress and, finally, the mechanistic issue of how the hippocampus orchestrates certain cognitive sequelae of arousing aversive experiences.

## 15.2 Glucocorticoid Receptors and Hippocampal Function

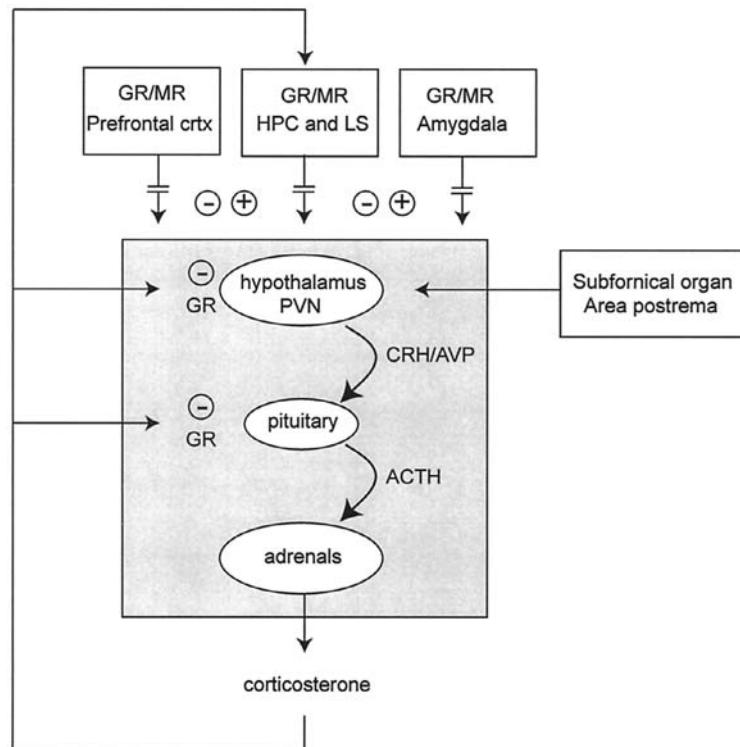

### 15.2.1 Glucocorticoid Receptors Are Present in the Animal and Human Hippocampus

The discovery that glucocorticoid receptors are highly expressed in the rodent hippocampus led to the conjecture that they might regulate aspects of the HPA axis. A number of early studies led to the supposition that the hippocampus has an inhibitory action (i.e., negative feedback) on circulating levels of glucocorticoids (Feldman and Conforti, 1980; Fischette et al., 1980; Wilson et al., 1980; Sapolsky et al., 1984, 1990; Lupien and Lepage, 2001). The primary observation was a sustained corticosteroid response to various stressors in animals given hippocampus or fornix lesions. However, this result

is not always obtained. Whereas neurotoxic lesions of area CA3 of the hippocampus do cause stress-induced hypersecretion of corticosterone in rats (Roozendaal et al., 2001), large selective neurotoxic lesions of the entire hippocampus have, paradoxically, been observed to cause no changes in corticosterone levels at rest or under stress (Tuvnæs et al., 2003). Moreover, work during the 1970s revealed inconsistencies in the patterns of regional retention of naturally occurring corticosterone and synthetic corticosteroids, raising the possibility of there being more than one adrenal steroid recognition system (de Kloet et al., 1975; McEwen et al., 1976). These questions are now resolved in favor of models such as that shown in Figure 15–1 in which the HPA axis itself (shown in gray) is regulated reflexively by input from, for example, the subfornical organ and more “cognitively” by a composite of higher brainstructures.

Following the development of selective “pure” glucocorticoid compounds (Veldhuis et al., 1982) confirmed that corticosterone binds to two separate glucocorticoid receptor types in the rat hippocampus. These receptors are transcription factors and now commonly referred to as the high-affinity mineralocorticoid (MR), or type I, receptor and the lower-affinity glucocorticoid (GR), or type II, receptor. They display differential binding properties, distribution, and intracellular mechanisms (Joels, 2001). MRs are highly expressed in the hippocampus and amygdala, and they have an approximately 10-fold higher affinity for corticosterone than GRs. In contrast, GRs are widely expressed in most brain tissues and are detected, among other regions, in limbic structures, the cerebral cortex, and brain stem monoaminergic nuclei (Reul and de Kloet, 1985; de Kloet et al., 1999; Helm et al., 2002; de

**Figure 15–1.** Neural afferents, corticosteroids, and hypothalamo-pituitary-adrenal (HPA) control. The HPA axis (gray shading) consists of the paraventricular nuclei (PVN) of the hypothalamus that is activated (+) and inhibited (-) via descending pathways from the prefrontal cortex, the hippocampus and lateral septum, and the amygdala. It is also regulated reflexively by corticosteroid signals entrained to the diurnal circadian rhythm and by neural input from the subfornical organ and area postrema. The PVN releases cortico-releasing hormone (CRH) and vasopressin (AVP) via the portal blood vessels to activate the pituitary, which, in turn, releases adrenocorticotrophic hormone (ACTH) into the bloodstream, which activates the adrenal gland. The corticosterone then released into the bloodstream finds its way to the “higher” brain structures involved in its feedback regulation. Binding of corticosteroid to mineralocorticoid (type I) receptors (MRs) and glucocorticoid (type II) receptors (GRs) triggers genomic and nongenomic mechanisms with one eventual result being negative feedback (-) from the hippocampus onto the PVN. (Source: After Welberg and Seckl, 2001 and Herman et al., 2003.)

Kloet, 2004). It is now recognized that corticosteroid actions in the brain are, at least in part, mediated by both MRs and GRs, with the ratio of receptor activation at these two sites being critical to the modulatory effects observed on cellular activity, neural excitability, and network function (de Kloet et al., 1999; Joels, 1999). We shall see that other parameters, such as the context in which a stressor is perceived, also influence the dynamics of the HPA axis response.

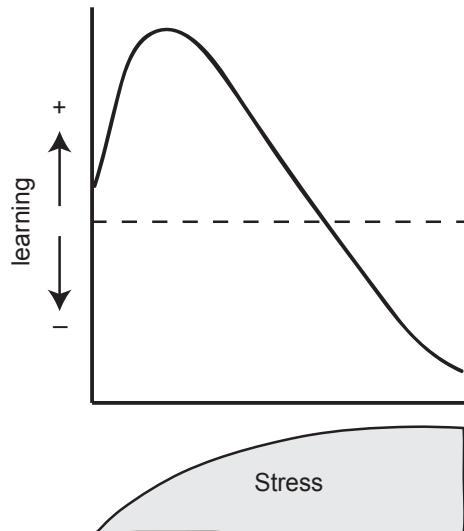

The various routes by which these higher brain structures might affect the PVN are gradually being unraveled (Herman et al., 2003). A key idea is the contrast between a “reflexive” and an “anticipatory” route by which the PVN is activated or inhibited. With the former, sensory information reflecting actual homeostatic challenges (e.g., nociception) promotes the activity of the PVN and thus the appropriate release of stress hormones. With the latter, signals associated with planning and decision-making (prefrontal lobe), memory of stressful or potentially stressful experiences (hippocampus), and learned fear (amygdala) can all activate pathways leading to hypothalamic nuclei in the neighborhood of the PVN. In this way, stress hormone release anticipates the circumstances in which it may be needed. For example, lesions of the ventral subiculum reduce the corticosterone response to novelty (Herman et al., 1998). Conversely, binding of corticosterone to MRs and GRs in the hippocampus can also inhibit PVN activity upon termination of the stressor or the risk associated with it and so limit the duration of a stress response. As we have seen, it was the extended duration of the stress response in hippocampus-lesioned animals that indicated that this structure participated in regulation of the HPA axis. That this response is not always seen suggests that multiple brain systems are capable of exerting independent tonic inhibition of the HPA axis.

Risold and Swanson (1996) suggested that there may be two routes by which the hippocampus mediates such memory-associated effects. One is via the orderly CA3 output to the lateral septum (LS) and thence, via the precommissural fornix, as a tripartite projection to the hypothalamus. The other route is via the postcommissural fornix, which arises in the subiculum and ends in the mammillary body and anterior thalamus. Interestingly, there do not appear to be any direct, monosynaptic inputs from the hippocampal formation to the PVN. The sophisticated summary by Herman et al. (2003) of the relevant neuroanatomy suggests that central stress regulation “relies heavily on hierarchical rather than dichotomous pathways” (p. 169) with the overall output of the stress response (+ or -) being dependent on the overall set of both reflexive and anticipatory inputs. Forebrain influences on the PVN are polysynaptic, with the hippocampus having interactions with the bed nucleus of the stria terminalis (BST) and the hypothalamus, whereas the prefrontal lobe projects to the BST and nucleus of the solitary tract. Notwithstanding numerous important anatomical studies, it is still unclear how activity in the hippocampus can both trigger corticosterone release and limit its duration.

### 15.2.2 There Is an Inverted U-Shape Function Between Level of Stress and Memory

It is commonplace for parents and schoolteachers to assert that a small amount of stress is good for you while also recognizing that too much can be harmful. This folk wisdom is now on a firmer scientific footing (Fig. 15–2), with a large scientific literature attesting to an inverted U-shaped function between severity of acute stress and cognitive function in animals—the so-called Yerkes-Dodson law. This now classic idea emerged from studies showing the initially synergistic but later deleterious effects of increasing stress on learning in mice (Yerkes and Dodson, 1908). Experimentally, this is often investigated with surrogate indices, such as “stress” being administration of a particular dose of adrenal steroids and “cognitive function” being performance in a watermaze or other learning/memory task. For example, mild stress and low concentrations of administered steroids can facilitate spatial memory (Sandi et al., 1997; Akirav et al., 2004), passive avoidance learning in chicks (Sandi and Rose, 1994, 1997; Liu et al., 1999), contextual fear conditioning (Cordero et al., 2003), and classic eye-blink conditioning (Shors, 2001). Conversely, moderate to high levels of stress or exogenous steroid have been reported to impair spatial memory (Diamond et al., 1996; de Quervain et al., 1998; Stillman et al., 1998; Conrad et al., 1999; Diamond and Park, 2000), recognition memory (Baker and Kim, 2002), and contextual fear conditioning (Pugh et al., 1997; Rudy et al., 1999). These data fall neatly across the putative inverted U-shaped function linking levels of stress to learning ability, the first part of the function being the improvements that mild stress can bring about, and the later parts of the curve being the impairments (Fig. 15–2). Although the criticism can be

**Figure 15–2.** Yerkes-Dodson law. Cognitive function, including learning, has a biphasic relation to levels of stress. As stress increases, learning first improves and then declines to levels below baseline.

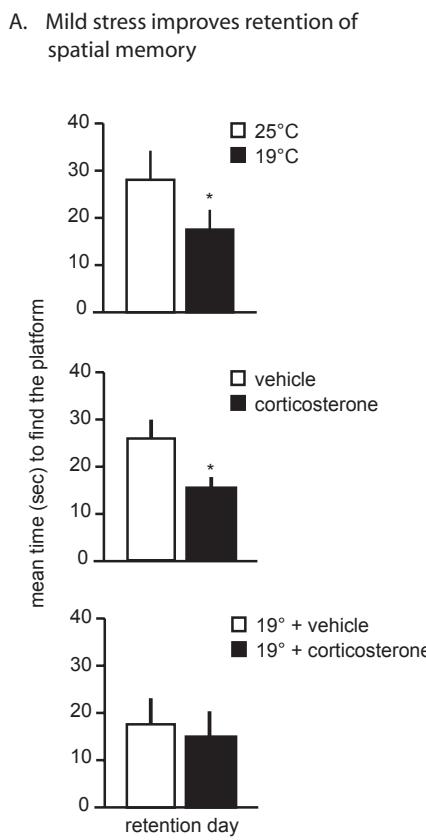

made that the full inverted-U function has been witnessed in few if any behavioral studies, this interpretation of the data is still reasonably secure.

Two illustrative examples of behavioral studies of the inverted U-shaped function are the work of Sandi et al. (1997), in which mild stress improved the performance of rats in a conventional watermaze, and that of Diamond et al. (1999) in which exposure to a predator impaired performance in a working-memory version of a radial-arm watermaze. In Sandi et al.'s (1997) study, rats trained over 3 days with the water temperature at 19°C showed a faster rate of acquisition and better retention 1 week later than those trained at 25°C (Fig. 15–3A). When trained at 25°C and given injections of either vehicle or corticosterone immediately after each training session, retention in the corticosterone-treated group was comparable to that of the 19°C trained animals from the first experiment. In the third study of the series, the corticosterone-induced improvement did not occur when it was given to animals being trained in 19°C water. These data reflect the left-hand side of the inverted U-shaped function. In Diamond et al.'s study (Fig. 15–3B), the rats were trained for

four trials per day in a hippocampus-dependent radial-arm watermaze (with the water at 24°C), which contained either four or six arms, and then given a retention trial 30 minutes later as their fifth exposure to the maze. Training continued across days with a new start and goal location (hidden platforms) on each day. This is a working-memory task in which the animals must acquire new information daily and flexibly retrieve information acquired that day, rather than a previous day, during the retention trial. As shown in Figure 15–3B, exposure of the animals to a cat predator during the memory delay interval between training and retention, which demonstrably increased stress in the rats exposed to the cat, resulted in an elevation of the number of errors in the six-arm maze and in one of two training protocols for the four-arm maze. These data reflect the right-hand side of the inverted U-shaped function, with the stress-induced impairment being more prominent on a more difficult learning task.

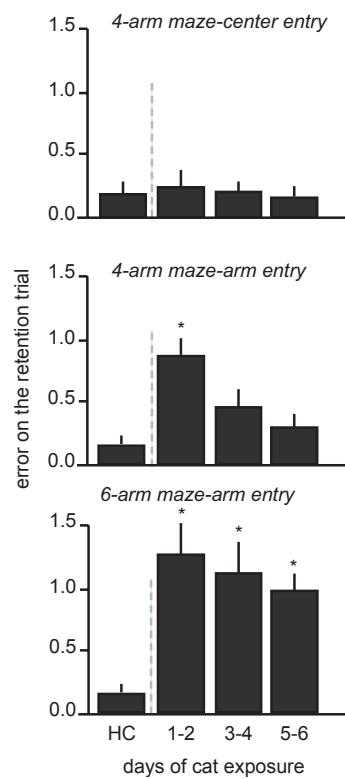

In keeping with this body of work, the performance of adrenalectomized (ADX) rats is impaired in a variety of behavioral tasks but is restored by administration of steroids in a dose-dependent manner (Vaher et al., 1994; Conrad et al.,

**Figure 15–3.** The inverted U-shaped impact of stress on spatial learning. A. Mean escape latencies during a retention test 1 week after training in a water maze at two temperatures. Training at the colder temperature produced better performance (lower escape latency). This response was mimicked after administration of corti-

costerone at the higher but not the lower water temperature during training. (Source: After Sandi et al., 1997.) B. Exposure to a cat predator after daily training trials caused disruption of performance (increased errors) in a difficult radial-arm watermaze but not an easier one. HC, home cage. (Source: After Diamond et al., 1999.)

B. More severe stress impairs retention of spatial memory

1997; McCormick et al., 1997). In a striking report, it has been claimed that steroids can even reverse the deficit in memory in a watermaze task that is induced by neurotoxic CA3 lesions, though it is unclear how they can compensate for the interrupted intrahippocampal communication that would necessarily occur with such lesions (Roozendaal et al., 2001). Indeed, with respect to the freezing response that reflects conditioned fear and is often used in studies of contextual fear conditioning, the reestablishment of control levels of performance by steroid administration in ADX rats is reported to occur only when the hippocampus is intact (Takahashi, 1995).

There are several outstanding puzzles with respect to these ideas and data. First, the definition of “severity” of stress differs across research groups and behavioral paradigms. For example, lowering water temperature during watermaze training by 6°C has been described as moderate to high stress (Akirav et al., 2004), whereas repeated foot shocks given over 5 days has been reported as mild (Xiong et al., 2003). The basis of these assignations is unclear. There is also circularity of the attempts to identify “severity” because comparisons of exposure to foot shock, placement in a watermaze, or confrontation with a potential predator are not easily made in procedural terms but can be quantified by resorting to the surrogate measure of circulating corticosteroid levels. This is probably reasonable but clearly assumes the very relation that the experiments are in part intended to help establish. Although many studies have shown a correlation between presumed severity of stress and circulating corticosterone levels, elevations in serum concentrations also accompany nonaversive “arousing” experiences such as the presentation of a sexually receptive female to a male rat. Spatial working memory was unimpaired by the exposure to a sexually receptive female rat, a stimulus that was novel and arousing but not aversive. There was, nonetheless, an equivalent increase in serum corticosterone levels in the male rats exposed to a cat or to the female rat, but only the cat-exposed rats exhibited a significant correlation between corticosterone levels and impaired memory (Woodson et al., 2003).

Second, defining stress for animals used in experimental work can also be problematic. In humans, specific arousing or aversive situations may be perceived and then declared stressful by some but not others, an opportunity for distinguishing differing potential stressors that we do not have with animals. Even in humans, stress really is an interaction between disposition or personality on the one hand and a range of different physical or cognitive “potential” stressors on the other. As animals cannot make overt declarations of what is stressful to them, there is no alternative but to resort to assumptions or surrogate markers. The likely cognitive outcome of stress after a training experience, such as facilitated or impaired memory consolidation, seems to depend on the aversive qualities of the stress experience and stressor-specific pathways activated (i.e., sensory or psychological) and even the sex of the animal (de Kloet, 2003; Shors, 2004).

A third concern about some research on stress using animals is that it sometimes seems needlessly cruel, such as pro-

cedures in which rodents are exposed to long periods of enforced immobility and unavoidable electric shock. That these procedures work is not in doubt, but it is unclear that such extreme conditions are really necessary to investigate the biological mechanisms of stress. Opinions change over time, and the techniques used by Seyle (1936), for example, would not be regarded as ethical today. Mindful of the “neuroethological strategy” discussed in relation to the cognitive map theory (see Chapter 13), the assumption that the delivery of electric shock is a biologically “valid” stressor is less clear than researchers on stress may appreciate. Appearances may, however, be deceptive as exposure to the first day of swimming in the more “ecologically” natural situation of a watermaze can yield changes in corticosterone levels comparable to those seen after delivery of electric shock. This habituates rapidly such that a watermaze probe test as early as day 3 of training is associated with minimal corticosterone release (Tuvnæs et al., 2003). The use of predator stress, introduced by Diamond (Diamond et al., 1999; Mesches et al., 1999), appears to be a useful step forward and one that avoids using a stimulus that, like shock, can cause overt tissue damage.

Research on the inverted U-shaped function in humans has, for the most part, substantiated the dose-dependent effect of GCs on cognitive function. Supraphysiological stress (or administration of cortisol) impairs declarative memory (Kirschbaum et al., 1996; Newcomer et al., 1999; de Quervain et al., 2000). In contrast, acute low doses of cortisol administered 1 hour before memory encoding has been shown to facilitate word recall performance (Becker and Olton, 1980). It also improves the long-term recall of emotionally arousing pictures compared to neutral stimuli (Buchanan and Lavallo, 2001). Not all such effects are likely to be due to the actions of GCs alone, however, with a well known study by (Cahill et al., 1994) showing that the enhanced memory of an emotionally laden prose passage compared to that of a more neutral story can be blocked by the  $\beta$ -adrenergic receptor antagonist propranolol. When focusing on hippocampal regulation of the HPA axis, it is vital not to ignore the key role that the SAM plays in immediate reactions to anxiety- and stress-provoking stimuli. Discrepancies in published findings also exist and have been explained as being a consequence of differential time of steroid administration during the natural circadian rhythm (Lupien and Lepage, 2001). These disquieting items aside, a body of work using a plethora of methodologies and behavioral paradigms in both humans and animals has provided solid evidence that varying corticosteroid levels may account for many aspects of the inverted U-shaped function with respect to the hippocampus and, indeed, other brain structures.

### **15.2.3 Stress Modulates Intrinsic Hippocampal Excitability and Activity-dependent Synaptic Plasticity Associated with Learning and Memory**

When thinking about the mechanisms by which stress has its impact on hippocampal function, the time course is critical. Some effects are fast. Immediate effects of a stressor, such as

those mediated by the sympathetic system, may occur via the action of adrenaline on the amygdala, which then affects the hippocampus through their mutual anatomical connections. Corticosteroid receptor activation can also induce immediate responses through reaggregation and molecular remodeling of receptor molecules in the cytoplasm (de Kloet, 2003). The modulatory effects on glutamate and  $\gamma$ -aminobutyric acid (GABA)-mediated transmission, apparent after as short a period as 20 minutes, are two examples of responses now thought to be mediated by fast nongenomic mechanisms. For example, Karst et al. (2005) have shown very rapid increases in the frequency of miniature excitatory postsynaptic currents (EPSCs) in CA1 pyramidal cells *in vitro* that are blocked by an MR antagonist and absent in MR knockout mice. They suggested that such effects are likely due to MRs that have shuttled from the nucleus/cytoplasm to cell membranes.

However, the delayed effects of corticosteroids are now widely agreed to involve gene transcription. Intracellular studies *in vitro* by Joels and her colleagues have examined the consequences of delayed GC transcriptional regulation (Joels, 2001). Although no striking effects on hippocampal electrical activity are observed following MR occupation, there are a number of clear effects: reduced turnover of dentate granule cells, reduced after-hyperpolarization (AHP), weaker responses to serotonin (5-HT), and smaller  $\text{Ca}^{2+}$  currents. Moreover, induced alterations in membrane potential have revealed effects of GR activation on  $\text{Ca}^{2+}$  currents through voltage-dependent  $\text{Ca}^{2+}$  channels. The increased influx of  $\text{Ca}^{2+}$  may, for example, activate  $\text{Ca}^{2+}$ -dependent  $\text{K}^+$  currents that help limit excitability. As this then limits the fast transfer of excitatory information, it causes subtle alterations in hippocampal network activity that may be the basis of the impaired memory seen in the presence of a strong stressor.

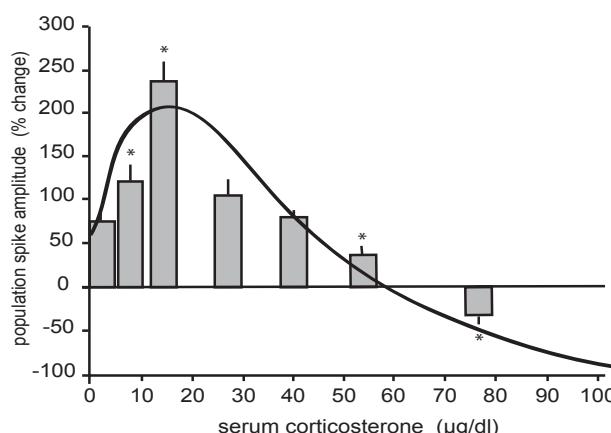

As discussed in Chapter 10, long-term potentiation (LTP) and long-term depression (LTD) are physiological models of activity-dependent synaptic plasticity and memory formation. Extensive observations obtained using *in vitro* and *in vivo* electrophysiological techniques and a variety of physical and psychosocial stressors have revealed that high levels of stress impair both LTP and primed burst potentiation (PBP), a lower threshold form of LTP, whereas they enhance LTD induction in the dentate gyrus and CA1 regions of the hippocampal formation (Foy et al., 1987; Diamond et al., 1992; Kim et al., 1996; Garcia et al., 1997; Xu et al., 1997; Mesches et al., 1999; Diamond and Park, 2000). Furthermore, low corticosteroid serum levels and acute, low doses of glucocorticoid receptor agonists are positively correlated with facilitated induction of both PBP and LTP (Bennett et al., 1991; Pavlides et al., 1994). PBP appears to be particularly sensitive (Diamond et al., 1992). These findings indicate that adrenal steroids and acute stress reversibly and biphasically modulate synaptic plasticity in the hippocampal formation (Fig. 15–4A), leading to the suggestion that stress and associated steroids might also induce “metaplasticity” (i.e., alter the physiological range of endogenous plasticity without necessarily inducing either LTP or LTD directly) (Abraham, 1996, 2004;

de Kloet et al., 1999; Kim and Diamond, 2002). The parallel effects of varying levels of stress on synaptic plasticity and on certain forms of memory is tantalizing and can be taken as indirect support for the “synaptic plasticity and memory” hypothesis outlined in Chapter 10.

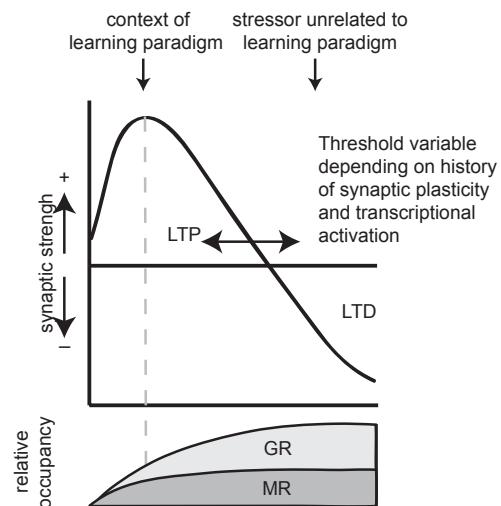

How stress engenders such dose-dependent biphasic effects on hippocampal plasticity and memory performance has been explained in terms of differential concomitant corticosteroid receptor mediated action—a theory known as the “binary hormone response” (Evans and Arriza, 1989) or the “MR/GR balance” (Oitzl et al., 1995) hypothesis. Owing to the high affinity of MRs to bind GCs, MRs are thought to be predominantly, though not entirely, occupied at basal circulatory levels of corticosteroids (observed during the circadian trough and nonstress periods). As corticosterone levels increase, GRs become progressively occupied until both MRs and GRs are extensively activated. The action of GRs has a higher capacity to be modulated through this progressive increase in occupancy. In contrast, MR actions can be regulated through a change in receptor number more than by ligand occupation per se. For example, acute swim stress, which leads to upregulation of MR expression in the hippocampus (Gesing et al., 2001), can result in prolongation of LTP in the dentate gyrus when given after the induction of early LTP (Korz and Frey, 2003). Similarly, rats treated with the antidepressant amitriptyline resulted in increased MR mRNA expression in the hippocampus, and this increase correlated positively with their improved spatial memory performance in a watermaze (Yau et al., 1995). These effects are shown in Figure 15–5. MR activation and partial GR occupancy is associated, through cell-biological mechanisms that are still unclear, with stable or even enhanced glutamatergic receptor transmission. This promotes the maintenance of hippocampal information flow and a tonic influence on the HPA system (de Kloet et al., 1999; Joels, 2001). In contrast, strong stress and consequent GR saturation attenuate excitatory input, a state thought to underlie the negative effects on plasticity mechanisms. These opposing effects are also schematically represented in the model linking synaptic plasticity to the classic inverted U-shaped function shown in Figure 15–4B.

In parallel with these differential effects on neural plasticity, MR and GR activation are thought to modulate distinct components of information processing. Pharmacological intervention using selective receptor antagonists administered at specific stages of information processing indicate that MR activation can influence processes involved in the attention to and interpretation of environmental stimuli and the consequent selection of appropriate behavioral responses in animals (Oitzl and de Kloet, 1992; Sandi and Rose, 1994), a process akin to “selective attention” in humans. For example, Oitzl and de Kloet (1992) showed that blocking MR receptors can alter the search strategies of rats in a watermaze. In contrast, activation of GRs is thought to regulate the acquisition and consolidation processes of memory (Oitzl and de Kloet, 1992; Conrad et al., 1999). For example, in an elegant study using a Y maze, Conrad et al. (1999) investigated the effects of

## A. Primed burst potentiation with increasing corticosterone

## B. MR/GR regulation of synaptic plasticity

**Figure 15-4.** The inverted U-shaped relation between stress, synaptic plasticity, and cognitive function. A. The magnitude of primed burst potentiation (PBP) as a function of corticosterone levels. (Source: After Diamond et al., 1992). B. Stress is plotted on the x-axis as the endogenous corticosteroid level induced by a stressor or as the surrogate of an artificial exogenous corticosteroid dose.

As it increases, it differentially occupies MRs and GRs. The y-axis depicts the potential for altering synaptic plasticity (+ or -) and/or cognitive performance. The diagram depicts a model of how the pattern of activation of the hippocampal corticosteroid receptors could affect both plasticity and memory. (Source: After de Kloet et al., 1999.)

MR/GR agonists and antagonists on both ADX and unoperated rats. They found that spatial memory was impaired during both complete blockade of GRs (left-hand side of inverted U) and high occupation (right-hand side) but was normal for all other treatments. In a similar protocol, Oitzl and de Kloet (1992) had earlier shown that GR, but not MR, blockade interfered with the consolidation of spatial information. Taken together, this suggests that GRs may, paradoxically, be responsible for both the upward and downward slopes of the

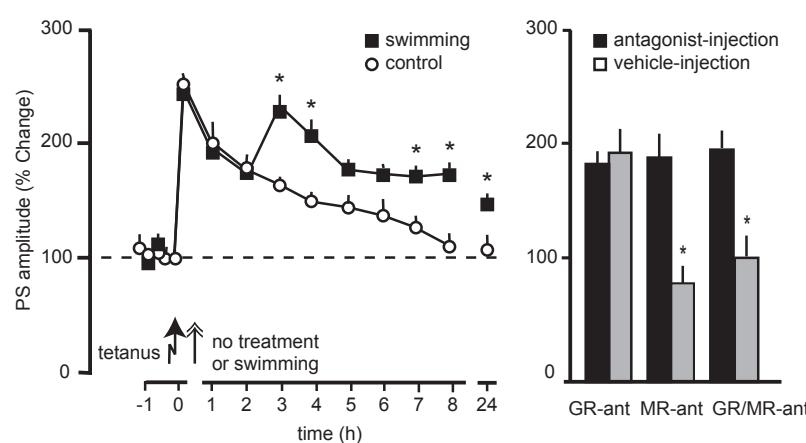

U-shaped function, whereas the positive action of MRs and GRs acting in concert on attentional and consolidation processes may account for the peak in the inverted curve.

The molecular mechanisms underlying the delayed modulatory effects of corticosterone on hippocampal cell properties are known to be transcription-dependent (de Kloet et al., 1998; Joels, 2001). Current understanding of the mode by which transcription is regulated is predominantly based on investigations of GR processes in CA1 pyramidal and dentate

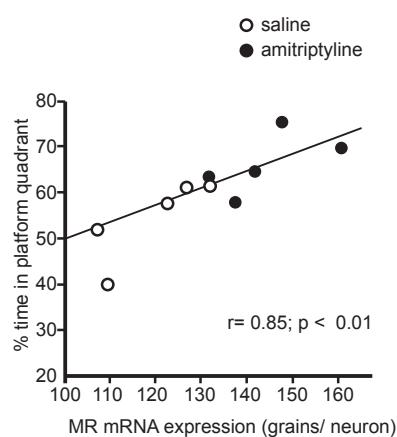

**Figure 15-5.** Parallels between the persistence of long-term potentiation (LTP) and spatial memory induced by exposure to stress. A. Induction of LTP by a weak tetanus results in decaying E-LTP unless followed by a 2-minute period of swimming in cold water. This exposure increases serum corticosterone. The persistence of

LTP over 24 hours is sensitive to an MR antagonist but not a GR antagonist. (Source: After Korz and Frey, 2003.) B. Rats treated with the antidepressant amitriptyline showed an increase in MR mRNA. The extent of the increase correlated positively with spatial memory. (Source: After Yau et al., 1995.)

## B. Mineralocorticoid mRNA and spatial learning

granule cells of the hippocampal formation. However, there is some indication that these molecular processes may differ between receptor types. The long-established view was that GR complexes translocate to the nucleus, where they bind as homodimers to glucocorticoid response elements (GRE) in DNA of target genes, such as *N*-methyl-D-aspartate (NMDA) receptors (Weiland et al., 1997) and *sgk* (rat serum- and glucocorticoid-inducible kinase), one of the genes proposed to be involved in memory consolidation of spatial learning in rats (Tsai et al., 2002). In addition, however, GR complexes have also been reported to regulate gene expression through transactivation or protein–protein interaction with transcription factors such as AP1, NFKB, and CREB (Auphan et al., 1995). This finding indicates that steroid receptor-mediated and transcription-dependent events in the hippocampus potentially operate through the same signaling pathways. Given this, if cross-talk between signaling cascades were to occur, the timing and nature of the inputs would be critical for determining whether gene transcription was enhanced or repressed. It is important to emphasize, however, that MR/GR gene-mediated processes that alter neuronal activity do so conditionally, such as only when the membrane potential is shifted from its resting level (de Kloet, 2003). Thus, there is considerable potential for dynamic interaction between the strictly neural and strictly neuroendocrine modes of cellular communication.

Glucocorticoid receptor action is only part of the story: Stress-induced alterations in electrophysiological function are likely to involve multiple mechanisms and pathways over various time courses. Several endogenous neurotransmitter/modulators (e.g., catecholamines, GABA, serotonin, opioids, and tissue mediators such as glucose and neuropeptides to name but a few) can modulate intrinsic properties and cellular activity in the hippocampus and elsewhere in the forebrain (McEwen and Sapolsky, 1995; McEwen, 2000; Joels, 2001). Whether these mechanisms act independently in parallel or are “downstream” of adrenal steroid action is yet to be elucidated. Nevertheless, progress in this field has provided valuable insight into the neurobiological processes underlying acute allostatic responses as well as the chronic maladaptive stress consequences that may contribute to conditions such as depression and neurodegenerative diseases such as Alzheimer’s that have been associated with aberrant HPA axis activity and hippocampus-dependent cognitive deficit (Holsboer and Barden, 1996; Welberg and Seckl, 2001; Muller et al., 2004).

### 15.3 Stress and Hippocampal Structure

#### 15.3.1 Chronic Exposure to High Levels of Stress or Stress Hormones Is Associated with Structural Changes in the Hippocampus

Evidence that adrenal steroids have a role in neuronal aging in the hippocampus was first provided by Landfield et al. (1978) and Sapolsky et al. (1984). This led Sapolsky to formulate the “glucocorticosteroid cascade hypothesis” (Sapolsky et al.,

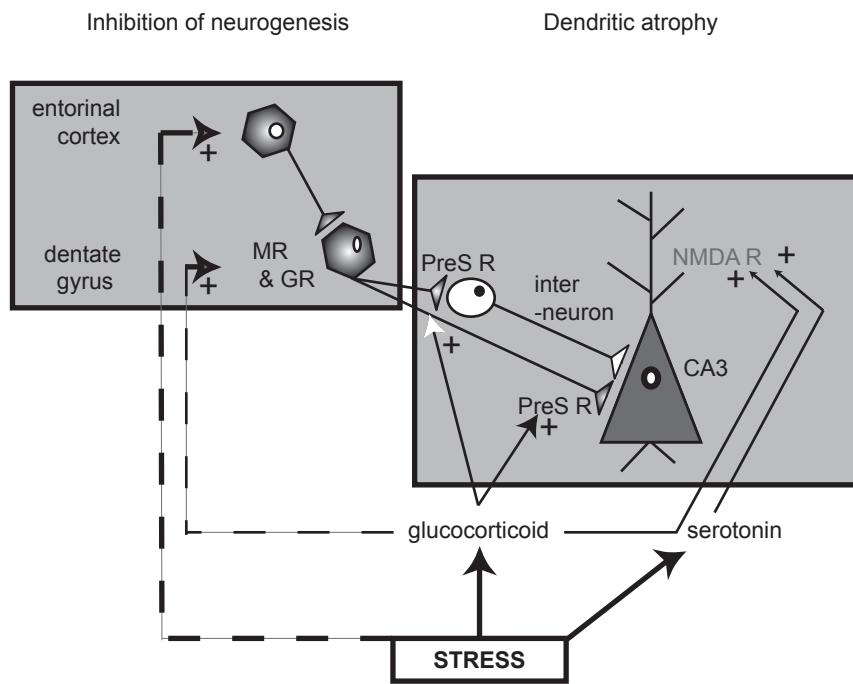

1986), a theory relating the effects of chronic stress to hippocampal damage and dysfunction. As McEwen described it: “The hypothesis states that glucocorticoids participate in a feed-forward cascade of effects on the brain and body, in which progressive GC-induced damage to the hippocampus promotes progressive elevations of adrenal steroids and dysregulation of the HPA axis” (McEwen, 1999). Subsequent research has generally provided support for this hypothesis, the key observation being that prolonged stress and chronically elevated HPA activity results in microscopic and even gross structural changes in the hippocampus in a variety of species.

There are several lines of evidence for different types of structural change in the hippocampal formation (Fig 15–6). First, moderate durations of stress and high GC exposure in rats (and tree shrews) cause reversible atrophy of apical dendrites of CA3 pyramidal cells and dentate gyrus neurons (Woolley et al., 1990; Magarinos and McEwen, 1995; Magarinos et al., 1996) and alteration in synaptic terminal structure (Magarinos et al., 1997). Not surprisingly, such dendritic remodeling is accompanied by reversible impairment of the initial learning of a spatial reference memory task (Luine et al., 1994). Second, chronic longer-term physical and psychosocial stress was reported to result in overt loss of hippocampal CA1 and CA3 neurons in rats and primates (Sapolsky et al., 1985; Kerr et al., 1991; Mizoguchi et al., 1992). However, these findings have not been replicated using improved stereological methodology (West and Gundersen, 1990; West, 1993), and whether cell death occurs in response to stress is now an issue of debate. Third, MRI studies of individuals suffering from Cushing’s disease—a syndrome associated with chronic endogenously induced elevated levels in cortisol—show atrophy of the hippocampus. Specifically, significant correlations have been found between the severity of the hypercortisolemia, the extent of atrophy, and the magnitude of cognitive impairment in a verbal learning and recall test (Starkman et al., 1992).

Stress-induced changes in hippocampal morphology can be attributed to reduced dendritic branching (in CA3) or possibly to apoptosis (in the dentate gyrus). However, a third factor has recently been considered as an additional contender: suppression of adult neurogenesis in the dentate gyrus.

#### 15.3.2 Stress or Stress Hormones Can Impair Neurogenesis in the Hippocampus

Neurogenesis, the generation of new neurons in the adult brain (see Chapter 9), is now known to occur in (at least) two regions of the CNS: the lateral ventricle and the subgranular zone in the dentate gyrus (DG) of the hippocampus. It has been reported in a range of species, including rodents, monkeys and humans, as discussed in detail in Chapter 9. Extensive studies using both acute and chronic stress/steroid protocols have also revealed that corticosteroids can inhibit postnatal and adult granule cell proliferation (Cameron and Gould, 1994; Gould et al., 1997). As granule cell precursors do not express MR and GR, this implies an indirect glucocorti-

coid mechanism, which Kim and Diamond (2002) suggested may occur through NMDA receptor activation.

McEwen argued that short-term structural plasticity (dendritic pruning in CA3) and inhibition of neurogenesis (Fig. 15–6) are examples of adaptive “protective” mechanisms (allostasis) that could reduce the impact of glutamate and glucocorticoids causing more permanent damage. However, stress is also known to exacerbate the effects of neurological insults such as hypoxia, ischemia, and seizures, increasing the susceptibility of hippocampal cell death putatively through both GC-induced inhibition of glucose transport and enhanced  $\text{Ca}^{2+}$  influx. Why such a maladaptive response occurs after neurological injury is puzzling. An intriguing idea proposed by Sapolsky, supported by evidence that the HPA glucocorticosteroid cascade is an evolutionary conserved phenomenon, is that “the body simply has not evolved the capacity or tendency to not secrete glucocorticoids during a crisis” (Sapolsky, 2004). In effect, evolution has only gotten so far.

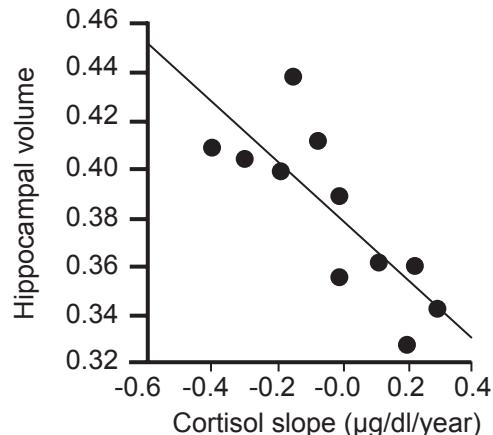

With this view, during protracted periods of intermittent stress the hippocampus may become impeded in its role in “shutting off” HPA axis stress activity. This results in increased secretion of GCs and, in a positive feedback cycle with negative consequences, ends up damaging the hippocampus itself, thereby further reducing the ability of the hippocampus to regulate the HPA axis. The observations by Lupien et al. (1998) of reduced hippocampal volume and poorer memory in humans in association with chronically high levels of cortisol is an apparently striking example of such an effect (Fig. 15–7). Whether hippocampal atrophy and inhibition of neurogenesis are the causes or consequences of elevated GCs is therefore a “chicken or egg” question. What is apparent is that this brain structure is both centrally involved in the neural reaction to aspects of prolonged stress and itself a target of chronic stress.

**Figure 15–6.** Chronic stress causes structural changes in the hippocampal formation. A model of the mechanisms by which stress alters neurogenesis and cell death (left), and the integrity of the dendrites of area CA3 of the hippocampal formation. (Source: After McEwen, 1999.)

### 15.3.3 Fetal Programming of GC Regulation

Adverse events during early life can influence prenatal development and may cause structural and functional changes in the brain that persist for the life-span, a phenomenon known as “early-life programming” (Seckl and Meaney, 2004). Fetal exposure to GCs has been proposed as a likely programming factor. Although GCs are clearly necessary for normal development, excess exposure has deleterious effects: inhibiting fetal growth and altering the trajectory of tissue maturation. For example, exposure of pregnant rats to exogenous or endogenous GCs not only reduces the birth weight of their progeny, it produces permanent hypertension, hyperglycemia, and hyperinsulinemia in the offspring, continuing through to adult life.

**Figure 15–7.** Stress and hippocampal size in humans. A longitudinal study of the correlation between sustained cortisol levels and hippocampal volume in humans. Higher cortisol levels are associated with a smaller volume, providing evidence for the atrophy predicted in the model. (Source: Lupien et al., 1998.)

Given that MRs and GRs are highly expressed in the developing brain (Fuxe et al., 1985; Kitraki et al., 1997), it is not surprising that the brain is particularly sensitive to early environmental manipulations. The fetus is normally protected from the relatively high levels of maternal physiological GCs by an enzyme called 11 $\beta$ -HSD2, which catalyzes the conversion of active GCs to inert forms; this enzyme is highly expressed in the placenta. There is also abundant 11 $\beta$ -HSD2 in the CNS at mid-gestation that presumably “protects” vulnerable developing cells from the premature action of GCs (Brown et al., 1996). Expression of this enzyme is then dramatically switched off at the end of mid-gestation in the rat and mouse brain, and similarly in the human fetal brain between gestational weeks 19 and 26 (Stewart et al., 1994), thereby allowing exposure of the developing brain regions to circulating GCs during the later stages of pregnancy.

In animal studies, stress and late prenatal GC exposure permanently increase HPA axis activity and impair cognitive function in adults. This is likely, in part, because of reduced MR and GR expression in the adult hippocampus. Interestingly, postnatal events such as “neonatal handling” or adoption can reverse the effects of prenatal stress (Maccari et al., 1995; Vallee et al., 1999). Thus, there appear to be several distinct time windows during which GC exposure has minimal (early) or maximal (late) effects in rodents. The human HPA axis also appears to be programmed by the early life environment. Maternal stress during pregnancy in humans reduces birth weight, just as it does in rats. Mutations of the 11 $\beta$ -HSD2 gene that alter its effectiveness to protect the developing fetus also cause low birth weight, and low birth weight in humans has been shown to correlate with increased basal and stimulated cortisol levels during adult life. Interestingly, the glucocorticoid agonist dexamethasone (DEX) is often given in obstetric practice, such as when preterm labor threatens during the last trimester. However, DEX readily crosses the placenta, but its effects on cognition and behavior in humans have not yet been investigated in detail. This point is important to investigate as human neonates exposed to DEX may be at risk of later disturbances of the HPA axis.

Insight into the molecular mechanisms by which early life environmental factors may program offspring physiology have come from studies dissecting the processes that underpin postnatal environmental programming of the HPA axis in the “neonatal handling” paradigm (Meaney et al., 2000). A short period of daily handling of rat pups during the first 2 weeks of life (around 15 min/day) results in enhanced maternal care-related behaviors and permanently increased hippocampus GR levels. This potentiates the HPA axis sensitivity to GC-negative feedback and lowers plasma GC levels throughout life—a programmatic resetting of the axis. The “daily handling” model is of physiological relevance because natural variation in such maternal behavior correlates similarly with offspring HPA physiology and hippocampal GR expression (Liu et al., 1997). The altered maternal care-related behaviors elevate thyroid hormones, which then induces 5-HT to increase GR gene expression in the hippocampus via 5-HT7

receptors, increase cAMP generation, and the induction of specific transcription factors, most notably NGFI-A and AP-2. These then bind to the GR gene promoter, inducing a specific GR transcript in the hippocampus (McCormick et al., 2000).

However, a key question that remains is how perinatal environmental events (e.g., stress) can *permanently* alter gene expression. Some evidence is emerging for methylation/demethylation of specific promoters of the GR gene. This may change histone structure (acetylation/deacetylation), permanently opening or hiding specific transcription features for the life-span. Preliminary data suggest that the putative NGFI-A site on the GR promoter (around exon 1, one of the six alternate first exons/promoters of the GR gene that is utilized in the hippocampus) is subject to differential and permanent methylation and/or demethylation in association with variations in maternal care (Weaver et al., 2004).

To summarize this section, chronic exposure to GCs can cause structural changes in the hippocampus, can alter neurogenesis, and during pregnancy can program cardiovascular, metabolic, and neuroendocrine disturbances that persist into adult life. The molecular mechanisms may reflect permanent changes in the expression of specific transcription factors including GR itself.

## **15.4 Other Higher Brain Structures Implicated in Stress and Their Interaction with the Hippocampus**

In a book focusing on the hippocampus, it is important to recognize once again that it cannot be considered alone and, specifically, to appreciate the synergistic role that other brain structures play in hippocampus-mediated aspects of stress. For example, electrophysiological and lesion studies provide strong evidence that activation of the amygdala plays a critical role in the rapid mediation of the effects of emotionally arousing events on memory consolidation (McGaugh, 2000; McGaugh and Roozendaal, 2002). Adrenaline, like glucocorticoid, is known to modulate long-term memory consolidation for fear-related or emotionally arousing events. Gold and Van Buskirk (1975) were the first to demonstrate that systematic injections of adrenaline (epinephrine) administered after inhibitory avoidance training produced dose-dependent enhancement of long-term retention. Subsequent research has indicated dose- and time-dependent effects of epinephrine in the consolidation of a variety of aversion- and appetite-motivated tasks (Cahill and McGaugh, 1998). Many effects of amygdala activation are entirely separate from hippocampal function, but not all.

An accumulating body of evidence suggests that the amygdala, particularly the basolateral nucleus, is involved in modulating memory storage processes in the hippocampus. For instance, the integrity of the basolateral nucleus is essential for the memory-modulatory effects induced by intrahippocampal infusion of GR agonists and antagonists (Roozendaal,

2002). Amygdala lesions also prevent the stress-induced suppression of hippocampal LTP (Kim et al., 2001, 2005), and amygdala stimulation potentiates the long-term persistence of hippocampal LTP (Frey et al., 2001). Moreover, intra-basolateral amygdala (BLA) infusions of a GR antagonist impair retention of spatial memory in the watermaze (Roozendaal and McGaugh, 1997). Such findings have been interpreted as support for the concept of “emotional tagging,” which refers to the idea that, “emotional arousing events mark an experience as important” (Richter-Levin and Akirav, 2003). More specifically they suggest that full expression of the effects of stress on the persistence of hippocampus-dependent memory requires the co-activation of the amygdala, acting via reciprocal hippocampus-amamygdala circuitry (Majak and Pitkänen, 2003). Furthermore, in a study using event-related functional magnetic resonance imaging (MRI) to measure neural activity in young healthy female adults during the retrieval of emotional and neutral pictures after a 1-year retention period, it was found that emotion selectively enhanced activity that indexed retrieval success in both the amygdala and the hippocampus (Dolcos et al., 2005). As Dolcos put it: “One way of explaining their co-activation during emotional recollection is that emotion enhances recollection-related activity in the hippocampus, whereas recollection enhances emotion-related activity in the amygdala.” The two brain structures are acting in synergy. Emotional tagging and the related idea of synaptic tagging (see Chapter 10) both provide ways of thinking about how activity in an afferent brain structure can modulate the persistence of synaptic potentiation in the hippocampus. A detailed discussion of the impact of adrenal stress hormones on the amygdala and its contribution to the modulation of memory is beyond the scope of this book but is discussed by McGaugh and Roozendaal (2002).

Another brain area implicated in regulation of the HPA axis is the prefrontal cortex (Diorio et al., 1993). In humans, an individual’s perception of an experience, intricately tied to past experience of similar events, strongly influences whether a specific arousing event has a positive or negative effect on performance. For example, the impact of a specific physical stressor on animals may depend on whether they can perform any adaptable response to escape it or must merely endure it. Such psychologically driven factors are thought to involve planning and decision-making in higher brain structures (e.g., frontal cortex) that then positively triggers “top down” stressor specific pathways resulting in decreased HPA axis activity (de Kloet, 2003). In this and other ways, the frontal cortex has now been elevated to the status of being part of the regulatory HPA feedback circuitry (Lupien and Lepage, 2001), an additional anatomical component, as shown in Figure 15–1.

The role of the frontal cortex during short-term and chronic stress has also received attention. Interest has arisen, in part, by the discovery that the GR distribution in humans and nonhuman primates differs from rodent expression patterns (Sarrieau et al., 1986; Patel et al., 2000; Sanchez et al., 2000). For instance, in monkeys GRs are reported to be preferentially distributed in cortical areas particularly the pre-

frontal cortex but are detected only weakly in the hippocampal formation (Sanchez et al., 2000). Lupien and Lepage (2001) have also drawn attention to studies indicating that frontal lobe processing, (e.g., executive and working memory tasks) can be more sensitive than hippocampus-dependent processing to acute and short-term increases in corticosteroids. In short, although research of stress-induced frontal lobe dysfunction is in its relative infancy, it is now recognized that other higher brain structures than the hippocampus play a role in engendering changes in cognitive function associated with stress states. Stress is thus partially “emancipated” from the grip of pituitary control.

There is a wider context in which to understand the changing role of higher brain structures, such as the hippocampus and prefrontal cortex, over the course of evolution. As discussed by Keverne et al. (1996), much behavior in small-brained mammals is part of physiological homeostasis and strongly determined by endocrine state. Thus, maternal behavior never occurs outside the context of pregnancy and parturition; sexual behavior is inevitably reproductive and generally restricted to periods of fertility; and foraging and feeding frequently occur in response to signals from the gut and fat reserves. In contrast, in large-brained mammals such as primates and humans, most sexual activity is nonreproductive; feeding occurs to avoid, rather than react to, hunger; and females do not necessarily have to undertake pregnancy and parturition to be maternal. Decision-making has switched from hormonal to cognitive determinants (Keverne, 2004). The mediation of stress by the HPA axis can be considered another example of how the evolution of the mammalian brain has provided increased executive control of behavior and a degree of emancipation from hormonal determinants (Herman et al., 2003). In the case of human stress, cortisol is still released from the adrenals, but the entire HPA axis is regulated, both positively and negatively, by cognitive processing in areas of the brain involved in planning, decision-making, and memory.

## **15.5 How the Hippocampus Orchestrates Behavioral Responses to Arousing Aversive Experiences**

To conclude, several lines of evidence support the idea of an allostasis–hippocampus link. They point to likely mechanisms by which stress steroids generate changes in hippocampal excitability and synaptic plasticity and how the hippocampus (with other higher brain structures) is involved in stress feedback circuitry. The final topic for discussion is the nature, or character, of hippocampal processing during stress and the impact that cognitive changes induced by it may have on behavior during such experiences.

First, acute stress induces an adaptive response that not only involves internal physiological mechanisms serving short-term coping needs but also changes in behavior that

favor future survival. Which action is taken—fight, flight, freeze—is determined in part by information acquired during the stress episode or recalled from previous episodes. Focused attention to and encoding of salient features of an individual stress experience is therefore critical to the “adaptiveness” of the response. That emotionally arousing experiences tend to be well and long remembered could be one selection pressure that may have helped the various body and brain mechanisms mediating stress to evolve (Cahill and McGaugh, 1996; Schafe et al., 2001; McGaugh and Roozendaal, 2002).

Why does stress have both positive and negative effects on hippocampus-dependent memory? Severity of stress is one factor influencing the outcome—the system may have evolved to cope constructively with mild stress, but the mechanisms involved play the dangerous price of interacting with important entities such as  $\text{Ca}^{2+}$  channels. Another possibility is that retrograde amnesia induced by unrelated (i.e., “out of context”) stress, whereas ostensibly a “negative” outcome is actually a positive adaptive response that helps to ensure greater priority to the storage of information relevant to enhancing survival. Spatial memory in rats is impaired when learning is followed by a variety of unrelated stressors, including inhibitory avoidance training, contextual fear conditioning, and forced exposure to an unfamiliar environment or predator (Diamond et al., 2004). Diamond suggested that unrelated stressors cause alterations in synaptic weight (owing to LTP-like plasticity in the hippocampus caused by stress), which results in neural representations of the stressful experience itself having the effect of “overwriting” any original and unrelated learning going on at the time.

Emotionally charged experiences “within the context” of a learning task have been the focus of much research by Sandi. With others, she has recognized that strong context-related aversive stimuli can also give rise to poor memory of very demanding learning tasks. However, her data also indicate that moderate cold-water stress elicited during training can result in better acquisition even though the corticosteroid levels then induced are actually equivalent to those seen in stressful situations that are deleterious to memory (Sandi et al., 1997; Akirav et al., 2001, 2004). A possible explanation relates to the in-context nature of the stressor and an apparent rightward shift in the inverted U-shaped function; that is, high corticosterone levels are now within the optimum performance zone.

Facilitation of memory induced by mild within-context stress has also been explained in terms of the enhanced attention and reactivity to stimuli and improved consolidation of information (de Kloet et al., 1999; Akirav et al., 2004; Joels et al., 2006). These factors may also contribute to a striking human memory phenomenon—flashbulb memory—in which the vivid and persistent memories for the context of an emotionally arousing public event are also associated with surprisingly good memory for otherwise innocuous details of the circumstances in which they were witnessed. Different generations have different exemplars of this phenomenon, such as remembering when and where one heard the news of

the death of President John Kennedy (November 1963) or the unfolding events of the 9/11 tragedy (September 2001). Importantly, it is not only the stressor itself that is marked as important material to be remembered but also certain trivial details of the day on which it happened. Simultaneous hippocampal and amygdala memory processing is likely to be involved in the encoding, storage, and consolidation of any potentially relevant information that may then aid adaptive action another time (McGaugh et al., 1993; Nadel and Jacobs, 1996; Frey and Morris, 1998).

Another connection between HPA “housekeeping” activity and the hippocampus is in relation to the processing of novel contextual information. Humans with unilateral or bilateral hippocampal damage do not show the normal peak cortisol response to awakening even though the remainder of the diurnal cycle is unaffected (Buchanan et al., 2004; Wolf et al., 2004). The psychological significance of the cortisol awakening response is unclear. However, one explanation is that it is part of the process of detecting change such as the transition from the sleeping state to the waking state. It would be interesting to know if this response is larger when a person awakens in an unusual or unexpected place (e.g., a different place from that in which they went to sleep).

Finally, the experience of unique, acute, life-threatening traumatic events (e.g., being unexpectedly involved in military action) can give rise to a persistent clinical condition called posttraumatic stress disorder (PTSD). Evidence from extensive studies investigating the neurobiology and cognitive characteristics of PTSD implicate GR receptor mechanisms in the hippocampus. Three lines of evidence support this assertion. First, blood samples from PTSD subjects indicate lymphocyte GC receptors are more numerous and have increased sensitivity (Yehuda et al., 1995). Second, enhanced cortisol suppression in response to administration of exogenous corticosteroids (i.e., “sensitization” of the HPA axis) is consistent with the clinical presentation of hyperreactivity (Yehuda, 2001). Third, brain imaging studies point to hippocampal atrophy and lack of the activation sometimes seen in the hippocampus during declarative memory tasks (Bremner et al., 1995; Gurvits et al., 1996; Bremner, 2001; Villarreal et al., 2002), and deficits in attention and short-term verbal memory are commonly reported (Elzinga and Bremner, 2002; Sala et al., 2004).

From a psychological perspective, individuals suffering from PTSD display repetitive reliving of the stress experience and evident amplification of memory for the traumatic stimulus with, in contrast to flashbulb memory, poor memory for the surrounding contextual material (Layton and Krikorian, 2002). This failure to consolidate material proximate to the trauma could be due to strong activation of the amygdala and a negative impact of GCs on hippocampal function. This would then be expected to give rise to the memory of the trauma lacking any spatial and temporal frame of reference (Nadel and Jacobs, 1996). Instead of the events being firmly bound in the past, the memory takes on a quality of the here and now, leading individuals to believe they are literally reexperiencing the event.

The themes of this chapter have been that stress mediates certain of its effects via the hippocampus, which provides feedback regulation of the HPA axis. Acute stress has a biphasic effect on synaptic plasticity and cognition. Chronic stress is, however, maladaptive and destructive—one of a number of ways in which the hippocampal formation can become damaged through life. Other pathological changes that affect the hippocampal formation include the onset of specific neurological diseases, such as epilepsy and neurodegenerative conditions such as Alzheimer's disease. It is to these topics that we turn in Chapter 16.

## ACKNOWLEDGMENTS

R.G.M.M. acknowledges the advice and help of Helen Knight, Marie Pezze, Carmen Sandi, and Joyce Yau on preparation of the chapter and the critical comments of Marian Joels and Joyce Yau on the text.

## Hippocampus and Human Disease

### 16.1 Overview

The hippocampus is involved in many disparate disease processes, but only in rare instances is the hippocampus the sole site of pathological damage. It is subject to the same pathologies that can affect other cortical areas, such as tumors, vascular malformations, and cortical dysgenesis; but in addition the hippocampus is also notable for its particular vulnerability to damage as a consequence of ischemia/hypoxia, trauma, and hypoglycemia. There are also instances in which involvement of the hippocampal formation is critical to the manifestation of the disease; foremost among them are Alzheimer's disease and temporal lobe epilepsy, representing approximately 60% of all partial epilepsies. Alzheimer's disease and epilepsy are among the most prevalent of all neurological diseases, with 20 million and 50 million people affected, respectively. Damage to the hippocampus is also the central component of a variety of rare conditions, such as limbic encephalitis and dementia with isolated hippocampal sclerosis. In addition, involvement of the hippocampus is being increasingly recognized in schizophrenia, another common neuropsychiatric disorder.

Acute encephalitis due to herpes simplex virus shows a predilection for limbic structures, and infection can result in selective damage to the hippocampus, amygdala, and associated structures, resulting in acute limbic encephalitis. Subacute limbic encephalitis has also been described in which the pathology more specifically affects the limbic system (Corsellis et al., 1968). The clinical presentation is characterized by behavioral and psychiatric problems (usually aggression and depression), disorientation, short-term memory deficits, hallucinations, seizures, and sleep disturbances (Corsellis et al., 1968; Gultekin et al., 2000). The pathological finding is aggregation of lymphocytes around blood vessels (perivascular lymphocytic cuffing), neuronal cell loss, and gliosis particularly affecting the hippocampus, dentate gyrus, amygdala, cingulate, and parahippocampal structures. There

is also often coincidental involvement of the brain stem and cerebellum. Limbic encephalitis can occur in response to certain cancers such as small-cell lung carcinomas, lymphomas, thymomas, and testicular tumors, as an immune-mediated syndrome (one of a number of so-called paraneoplastic syndromes). A similar syndrome has, however, been described in association with Wernicke's encephalopathy, systemic lupus erythematosus, and herpes simplex encephalitis. In these cases, there is a strong association with anti-neuronal antibodies directed against intracellular antigens, but the pathological role of these antibodies remains uncertain. Treatment of the underlying malignancy can alleviate the symptoms.

Hippocampal sclerosis has been observed in a proportion of elderly patients presenting with cognitive impairment. In one study (Dickson et al., 1994), hippocampal sclerosis was observed in 26% of demented patients over the age of 80 years and in 16% of all patients aged over 80. In all cases there was neuronal loss and gliosis affecting CA1, the subiculum, and dentate granule cells, with additional neuronal loss in the entohinal cortex in a proportion of cases. However, concomitant pathology, such as ischemic vascular damage or Alzheimer pathology, was noted in most of the cases in this study; "pure" hippocampal sclerosis is much rarer, affecting only 0.4% of patients with dementia (Ala et al., 2000). These rare instances of pure hippocampal sclerosis are not associated with any increase in risk factors for cerebrovascular disease, and in none of the cases was there a history of a hypoxic episode preceding the onset of cognitive impairment. The relation between hippocampal sclerosis, as a rare cause of dementia in the elderly, and mesial temporal sclerosis, as a substrate for epilepsy affecting a younger age group, remains undetermined, but it is possible that the two diseases arise as a consequence of differing etiologies, with pure hippocampal sclerosis occurring as a consequence of a primary degenerative process rather than secondary to a systemic insult such as hypoxia or fever.

Schizophrenia is thought to involve primarily the prefrontal cortex (Grossberg, 2000), but there is accumulating evidence

for involvement of mesial temporal lobe structures in its pathophysiology. Indeed, there is evidence accumulating that schizophrenia may be a result of fronto-hippocampal integration. Some patients with temporal lobe epilepsy exhibit a psychosis indistinguishable from schizophrenia. Structural neuroimaging studies have shown a subtle but definite reduction in hippocampal volume (Nelson et al., 1998), which in some cases is present early in the disease; and functional imaging studies using magnetic resonance spectroscopy have documented a reduction in levels of the metabolite *N*-acetyl-D-aspartate, a marker of neuronal viability, in patients with schizophrenia (Maier et al., 1995). Neuropathological studies indicate that the loss of hippocampal volume correlates with a reduction in the size of hippocampal neurons rather than neuronal loss (Arnold et al., 1995). A reduction in neuronal density in certain hippocampal regions, with the CA2 interneurons particularly affected, is also observed in schizophrenia, as well as in manic depression (Benes et al., 1998). Loss of synaptic proteins in the hippocampus (Eastwood and Harrison, 1995) and abnormal MAP2 expression in subicular neuron dendrites also indicate abnormalities of connectivity in patients with schizophrenia (Cotter et al., 2000). The lack of demonstrable gliosis in those with schizophrenia has been argued to support a neurodevelopmental rather than degenerative disease process; the demonstration in schizophrenia of cytoarchitectural abnormalities of pre-alpha cells in the entorhinal cortex and of abnormal orientation of hippocampal pyramidal neurons (Conrad et al., 1991) also support a maldevelopmental disorder.

The human hippocampus is the beneficiary of a generous arterial supply originating from a number of major arteries, including the anterior choroidal artery and branches of the posterior cerebral artery (Erdem et al., 1993). Despite this, the vascular supply to the hippocampus may be interrupted as a result of embolic disease, as well as by prolonged anoxic insults. Ischemic damage to the hippocampus can occur in isolation or as part of a more widespread cerebrovascular disease process. In addition, animal experiments have shown that hippocampal damage, particularly affecting the CA1 subfield, can occur as a result of chronic nonembolic vascular insufficiency (de la Torre et al., 1992). Despite the known vulnerability of CA1 to ischemic damage (an observation dating back to the observations made by Sommer in 1898) and evidence from animal studies that the hippocampus is particularly sensitive to ischemic insult (Schmidt-Kastner and Freund, 1991), there exist in the clinical literature very few cases in which selective damage to the hippocampus has been observed. Hypoglycemia results in a pattern of damage different from that of ischemia, as it causes necrosis of predominantly the dentate granule cells (Auer and Siesjo, 1988); the clinical significance of such damage is not clear. Lastly, mesial temporal structures are particularly vulnerable to traumatic brain injury; this is partly because of their location in the middle cranial fossa, leaving them susceptible to contusion and vascular injury, but it may also be due to direct excitotoxic effects (Tate and Bigler, 2000).

The characterization of hippocampal involvement in human disease has been of great value to neuroscientists and clinicians. For instance, the unilateral nature of hippocampal sclerosis in temporal lobe epilepsy has provided the opportunity to analyze the individual functions of the left and right hippocampi. Also, the identification of hippocampal sclerosis by high-resolution magnetic resonance imaging (MRI) in epilepsy patients has stimulated the use of curative epilepsy neurosurgery. The hippocampal atrophy that occurs as a result of the pathological changes of Alzheimer's disease can be detected and quantified using *in vivo* neuroimaging techniques. As a biomarker of disease, the presence of hippocampal atrophy provides important corroborative information at the time of the clinical diagnosis, and the demonstration of progressive hippocampal volume loss is valuable for tracking disease progression. Finally, case studies documenting the nature of cognitive impairments in those rare patients with selective hippocampal pathology have provided important insights into the functions of the human hippocampus (see Chapter 13).

This chapter focuses on two disorders in which the role of the hippocampus has been extensively investigated: Alzheimer's disease and temporal lobe epilepsy. Although in Alzheimer's disease the disease process results eventually in widespread destruction of the cerebral cortex, the damage in the earliest stages of disease is restricted to the entorhinal cortex and the hippocampus, and the memory impairment that results from this disruption of the hippocampal formation represents one of the common characteristics of Alzheimer's disease. In temporal lobe epilepsy, the pathological damage is often restricted to the hippocampus in the form of hippocampal sclerosis. However, unlike Alzheimer's disease, in which the hippocampal damage is secondary to the underlying pathological process, the hippocampus in temporal lobe epilepsy is not only sensitive to damage by seizure activity but can also act as the substrate for epileptic seizure generation.

## 16.2 Mesial Temporal Lobe Epilepsy and Hippocampal Sclerosis

### 16.2.1 Introduction

Epilepsy is the propensity to have seizures and is one of the most common serious neurological conditions, affecting 0.4% to 1.0% of the world's population (Sander and Shorvon, 1996). There are approximately 20 to 70/100,000 new cases per year, and the lifetime chance of seizures is 3% to 5% (Sander and Shorvon, 1996). Seizure types can be divided into partial seizures, arising from one part of the brain, and generalized seizures, arising simultaneously throughout the cortex; respectively, these constitute approximately 40% and 50% of seizures in newly diagnosed epilepsy (10% of seizures are unclassifiable) (Sander and Shorvon, 1996). Epilepsy itself can be divided into a number of syndromes determined by seizure

type, electroencephalographic (EEG) abnormalities and concomitant neurological deficits. Although all epilepsies are the result of an underlying brain abnormality (e.g., tumor or scar tissue in partial epilepsies, and a metabolic or genetic basis in generalized epilepsies), a convincing cause is identified in only approximately 30% of patients with epilepsy (Sander and Shorvon, 1996). The clinical manifestation of a seizure depends not only on where the seizure starts but also on the speed and pattern of seizure spread. Differing epilepsy syndromes have different pathophysiologies and mechanisms; in this chapter we are concerned solely with temporal lobe epilepsy.

Temporal lobe epilepsy represents approximately 60% of all partial epilepsies. The commonest neuropathological lesion identified in temporal lobectomy series in patients with mesial temporal lobe epilepsy (TLE) is hippocampal sclerosis, or Ammon's horn sclerosis, which is seen in approximately half of the cases (Bruton, 1988). Other major pathologies can be grouped under "lesion-associated TLE" and include vascular malformations, malformations of cortical development, and glioneuronal tumors (Wolf et al., 1993). Of those patients with drug-resistant epilepsy, hippocampal sclerosis is the commonest aetiology.

In 1825, Bouchet and Cazauvielh presented their findings on 18 autopsied patients in a thesis that attempted to establish the relation between epilepsy, "l'épilepsie," and insanity, "l'aliénation mentale" (Bouchet and Cazauvielh, 1825). They noted that in five cases where there were changes in the cornu ammonis four were characterized by induration and one had softening. Sommer (1880) further described in detail the neuropathological finding of hippocampal sclerosis in the brains of patients with chronic epilepsy. He noted gliosis and pyramidal cell loss in predominantly the CA1 region of the hippocampus, and he proposed that these lesions were the cause of the epilepsy. That same year, Pfleger described hemorrhagic lesions in the mesial temporal lobe of a patient dying in status epilepticus and concluded that neuronal necrosis was the result of impaired blood flow or metabolic disturbances that occurred during the seizure (Pfleger, 1880). Since that time the debate as to whether hippocampal sclerosis is the cause or result of epilepsy has continued.

Three lines of evidence indicate that seizures originate in the sclerosed hippocampus. First, hippocampal sclerosis is closely associated with a particular seizure semiology, the psychomotor seizure—a seizure type first recognized by John Hughlings Jackson. Second, EEG evidence points to seizure onset in the sclerosed hippocampus. Lastly, surgical resection of the sclerosed hippocampus results in seizure remission.

### 16.2.2 Clinical Features

The typical history of a patient with hippocampal sclerosis is contained in Figure 16–1, see color insert. There is often an antecedent history of an insult (usually febrile seizures) followed by a gap before seizures begin many years later. These seizures often prove resistant to treatment. There is an

increased co-morbidity including psychiatric problems (depression, psychosis), increased mortality and neuropsychological deficits that relate to the side of the hippocampal sclerosis: verbal memory deficits with dominant (usually left) temporal lobe involvement and nonverbal memory deficits with nondominant lobe involvement.

### Seizure Semiology

Mesial temporal lobe seizures usually take the form of complex partial seizures, in which consciousness is disturbed, and less commonly simple partial seizures, in which consciousness is preserved (Walker and Shorvon, 1997). The seizure usually has a gradual evolution over 1 to 2 minutes (substantially longer than extratemporal seizures) and lasts longer (2–10 minutes) than complex partial seizures originating in extratemporal sites. The commonest warning (often termed aura, literally "breeze") is that of a rising sensation from the stomach. Other gastrointestinal auras can occur, especially nausea, stomach rumbling, and belching. Auras can also consist of olfactory-gustatory hallucinations, autonomic symptoms, affective symptoms, disturbances of memory, or visual hallucinations and illusions (especially with seizures involving the temporal neocortex). Autonomic symptoms include changes in heart rate and blood pressure, pallor or flushing of the face, pupillary dilatation, and piloerection. Affective symptoms typically take the form of fear (the most common and often extremely intense), depression, anger, and irritability. Euphoria and erotic thoughts have also been described. Dreamy states and feelings of depersonalization commonly occur. Déjà vu, déjà entendu, and other abnormalities of memory such as recollections of childhood or even former lives can also be present with this form of epilepsy.

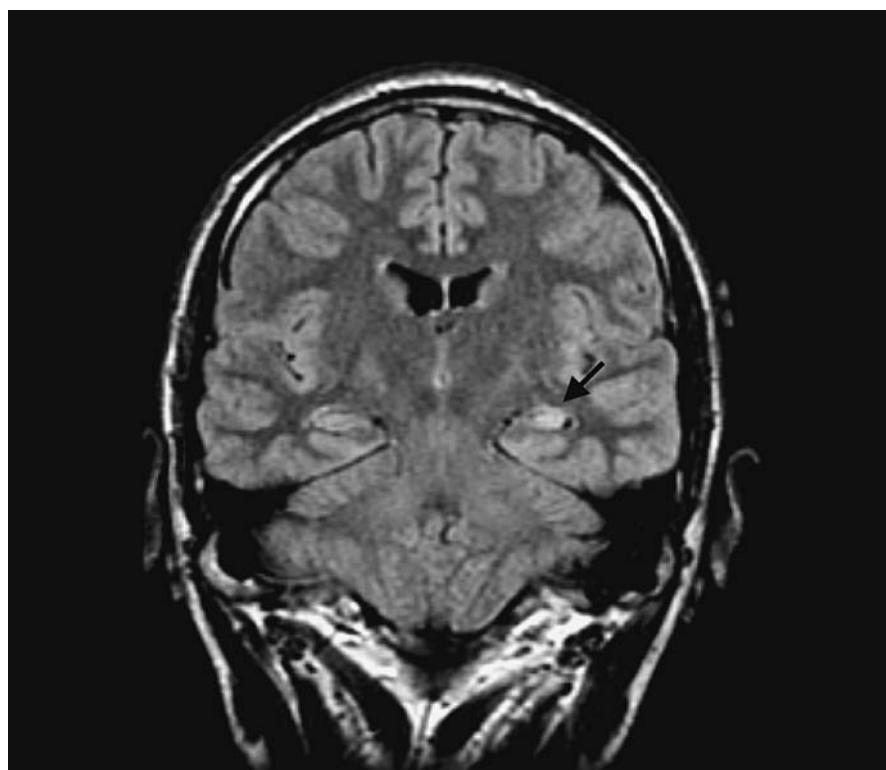

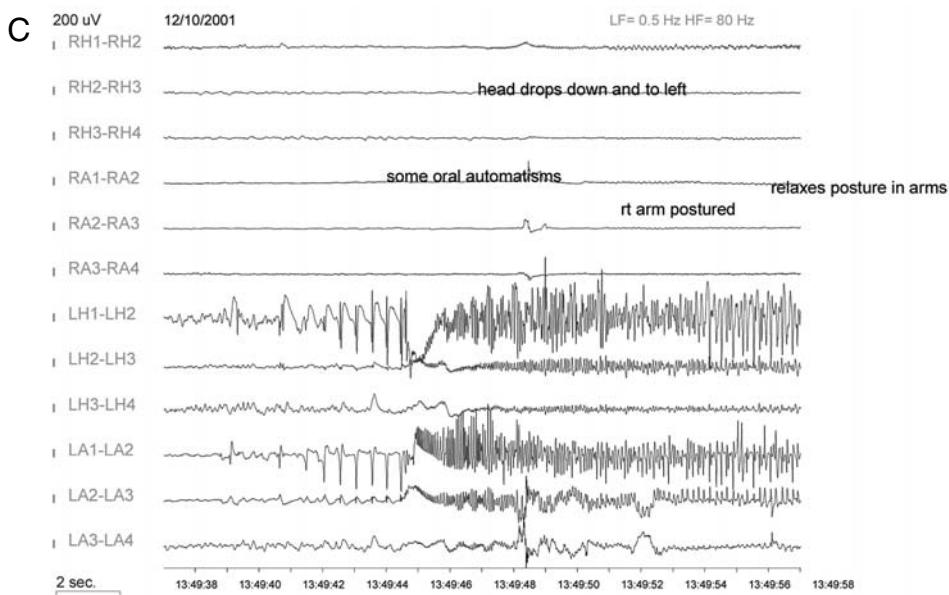

After the aura and in the early stages, motor arrest and absence are prominent. Typically, this is followed by marked automatisms. The automatisms of mesiobasal TLE can be prolonged and are characteristically orointerpersonal (e.g., lips-macking, chewing) and/or gestural (e.g., fidgeting, undressing, walking). Typically, the automatisms are more marked ipsilaterally and may be associated with contralateral posturing. There may be some apparent responsiveness, and "conscious behavior" can occur during nondominant temporal lobe seizures. During the seizure, speech with recognizable words lateralizes the focus to the nondominant temporal lobe. Secondary generalization is less common than in extratemporal lobe epilepsy. Postictal confusion is typical, and postictal dysphasia can occur following dominant temporal lobe seizures. Postictal headache and postictal psychosis have also been described. There is profound amnesia for the absence and automatism (Walker and Shorvon, 1997).

### EEG Characteristics

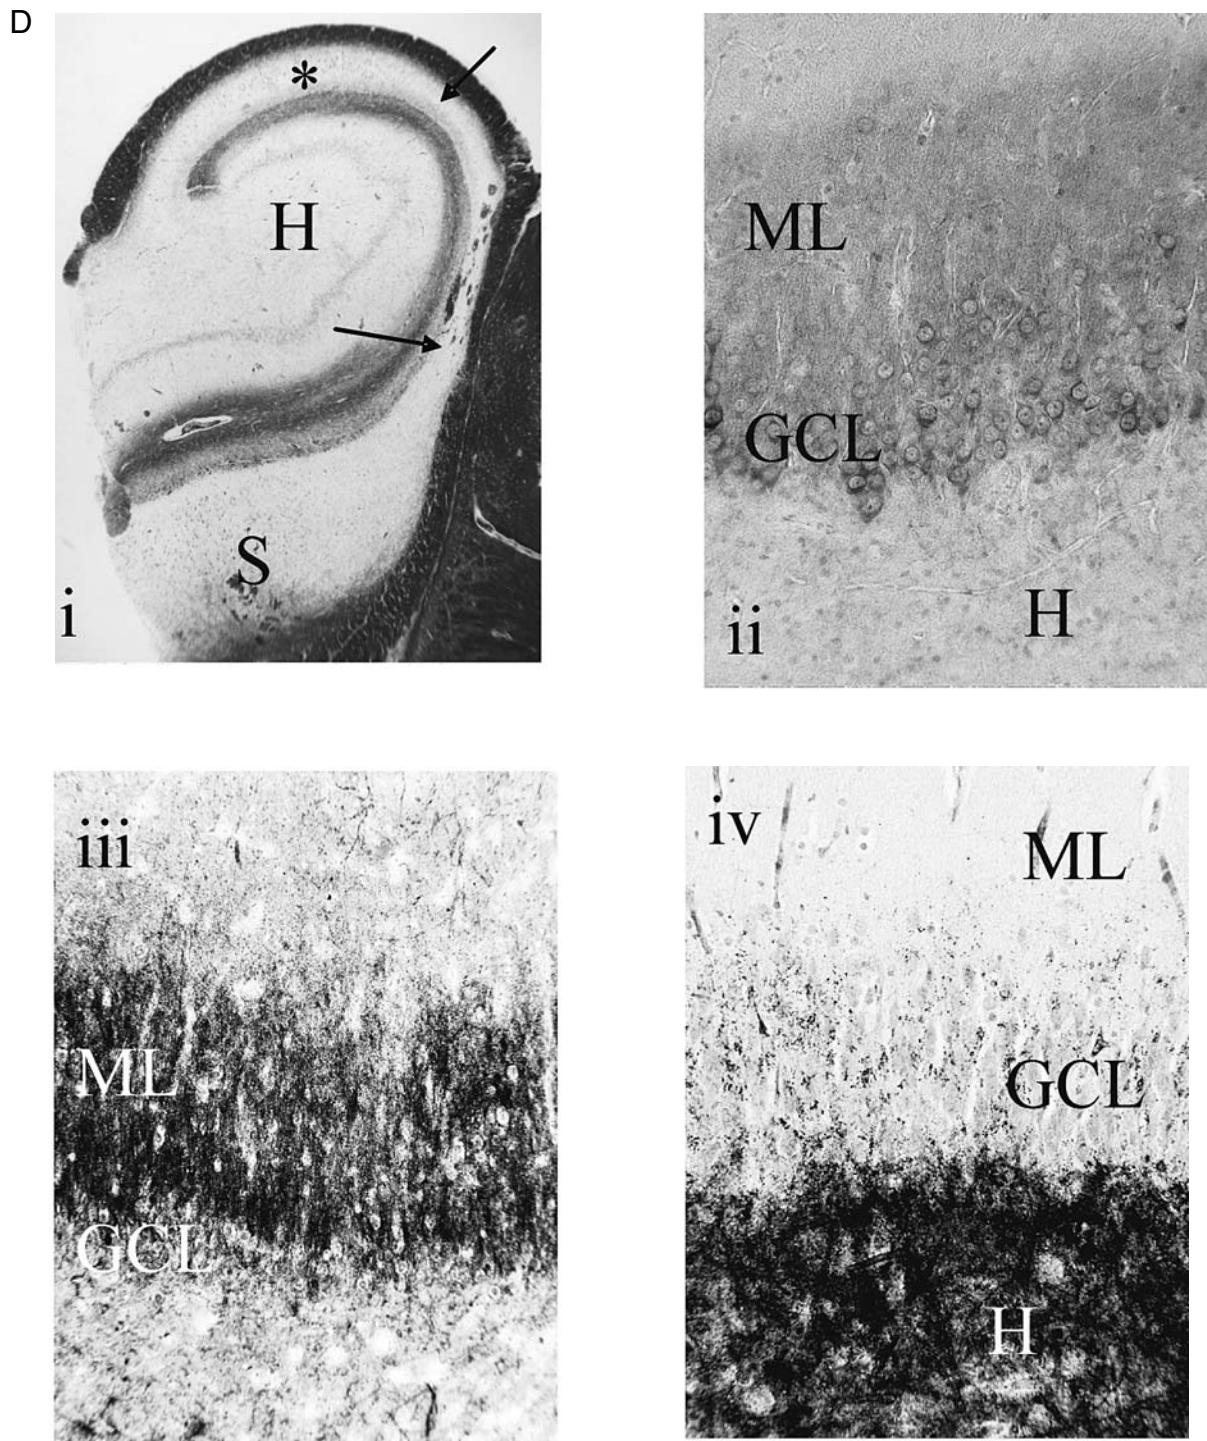

Scalp EEG recordings usually demonstrate interictal epileptiform abnormalities (spikes, sharp waves) over the mid/anterior temporal region, but it is common for these epileptiform

**A**

A 32-year old man presented with refractory partial epilepsy. He had a prolonged febrile seizure at the age of 18 months, and spontaneous seizures began at the age of 8 years. These seizures have continued despite trying all available antiepileptic drugs. The seizures take the form of simple partial seizures in which he perceives a sense of fear rising from his stomach, and complex partial seizures in which he has an aura as above and then loses touch with his surroundings. During the complex partial seizure he is described as making chewing movements, his right hand is postured and he fiddles with his clothes with his left hand. The seizure lasts a couple of minutes, and he is then confused and dysphasic afterward for approximately 5 minutes.

**B****C**

**Figure 16-1.** Clinical features of mesial temporal lobe epilepsy. *A*. Typical history. *B*. Magnetic resonance imaging (MRI) findings of left hippocampal sclerosis with high T2 signal in shrunken hippocampus (arrow). *C*. Intracranial recordings from left (LH) and right (RH) hippocampus and left (LA) and right (RA) amygdala demonstrate well localized 1- to 2-Hz spikes in left hippocampus and amygdala that evolve to low-amplitude fast activity at seizure onset.

**Figure 16-1.** (Continued) D. Histology of left hippocampal sclerosis. i. Loss of cells in hilus (H) and CA1 (arrows) with preservation of CA2 (star) and subiculum (S); ii. Dynorphin staining demonstrating many fiber sprouting in granule cell layer (GCL) and molecular layer (ML); iii. Mossy fiber sprouting illustrated with Timm's stain; iv. Hippocampus with minimal mossy fiber sprouting for comparison with iii.

abnormalities to occur bilaterally or independently over both temporal regions (reasons why this may be so are discussed below) (Williamson et al., 1993). Ictal scalp recordings usually demonstrate a build-up of 5- to 10-Hz sharp activity localized to the mid/anterior temporal region. This activity may remain

localized or commonly spreads to involve a wider field including the contralateral temporal lobe.

Depth electrode studies have further confirmed the electrographic origin of these seizures in the hippocampal formation (King and Spencer, 1995). Although interictal spikes may

occur independently from either the hippocampus or extrahippocampal sites (see below), the ictal discharges are usually relatively well localized. Preictal abnormalities can occur with well localized 1- to 2-Hz spikes that recur over seconds or minutes (Fig. 16–1C, see color insert). With clinical seizure onset, there is a 10- to 15-Hz low-amplitude discharge that is initially confined to hippocampal electrodes (Fig. 16–1C, see color insert) but grows in amplitude and then spreads to other regions (King and Spencer, 1995). A second pattern has also been described in which the seizure begins as a low-amplitude, high-frequency discharge without the preictal spiking. These two types of onset can occur in the same patient. The exact location for seizure onset can vary not only from patient to patient but also within the same patient. This suggests that seizure onset and generation is not from a single area in mesial temporal structures but from a distributed network.

### Hippocampal Resection

Surgery has provided the most compelling evidence of hippocampal sclerosis as the substrate for the epilepsy. Surgical outcome for intractable TLE is most successful when mesial temporal structures are included in the resection. In patients with drug-resistant epilepsy in whom there is concordance between neuroimaging, electroclinical characteristics of the seizure, and neuropsychological tests, there is a better than 80% chance of “curing” the epilepsy with temporal lobe resection (Arruda et al., 1996). Furthermore, over 80% of patients without tumors rendered seizure-free by temporal lobectomy have hippocampal sclerosis as their main pathology (French et al., 1993). In these patients depth electrode recordings also localized the seizure onset to the sclerosed hippocampus. There is thus a strong correlation between resection of a sclerosed hippocampus and cure of the epilepsy. Temporal lobe surgery, however, also involves removal of or damage to structures outside the hippocampus, including the amygdala and parahippocampal structures and temporal neocortex. Furthermore, many patients, despite successful surgery, remain dependent on antiepileptic drugs. These observations argue that structures beyond the hippocampus are involved in the epileptic network.

### 16.2.3 Etiology

#### Pathogenesis of Hippocampal Sclerosis and Developmental Aspects

There are predictable patterns of cell loss and alterations to the intrinsic circuitry of hippocampal sclerosis. However, the factors critical to the initiation of the cell loss and hippocampal reorganization are still debated, and the precise etiology of hippocampal sclerosis remains elusive.

A significant cerebral insult (or initial precipitating injury) occurring early in life, such as a febrile or prolonged seizure, is often reported (30–50% of cases—but up to 80% in one surgical series) in retrospective studies of patients with hip-

pocampal sclerosis (French et al., 1993). The “injury” hypothesis implies that this insult irreversibly damages or alters the hippocampus, resulting in a template for the progression to hippocampal sclerosis following a “latent” interval. There appears to be age-specific sensitivity for this injury, with more severe neuronal loss demonstrated with earlier onset of epilepsy (Davies et al., 1996). The most direct evidence of the association is the observation with serial neuroimaging that hippocampal sclerosis occurs following prolonged febrile convulsions (Van Landingham et al., 1998). Febrile seizures have been modeled in animals by inducing hyperthermic seizures in rats by blasts of hot air or water. The similarities between the animal model and the human condition are that seizures occur in response to high body temperature and that increasing age confers resistance to these seizures (Baram et al., 1997; Walker and Kullmann, 1999). Although fever in humans is associated with other physiological changes, reducing the body temperature is an effective way to reduce the likelihood of seizures; thus, hyperpyrexia is probably the main trigger. There are, however, major differences between hyperthermic seizures in rats and febrile convulsions in humans. Inducing hyperthermia in young Sprague-Dawley rats apparently results in seizures in most of these animals (Baram et al., 1997), but convulsions are relatively rare in children with fever. In experimental models, prolonged hyperthermic seizures in immature rats did not cause spontaneous seizures during adulthood but did increase seizure susceptibility following administration of a convulsant (a “second hit”) (Dube et al., 2000). However only 2% to 7% of children with a history of febrile convulsions go on to develop epilepsy (i.e., unprovoked seizures) later in life (Annegers et al., 1987). Because many children with febrile convulsions may have a predisposing susceptibility to seizures, the low incidence of subsequent epilepsy could be explained by a protective effect of febrile seizures. Alternatively, febrile seizures alone are not sufficient to result in development of epilepsy. (Walker and Kullmann, 1999).

Other insults can result in hippocampal sclerosis including neonatal hypoxia and head injuries. In rat models, fluid percussion injury to the dura results in hilar interneuron loss in the hippocampus (Lowenstein et al., 1992). The mechanism by which this occurs is unknown. The neuronal loss is accompanied by enhanced excitability of the hippocampus but again no spontaneous seizures (Lowenstein et al., 1992). These experimental and human studies do not, however, address two fundamental questions: (1) Why is hippocampal sclerosis predominantly a unilateral disease process in humans (see below) following a “global” cerebral insult? (2) What is the nature of the “second hit” that results in the expression of epilepsy?

The second hit does not necessarily have to be environmental but could be the coexistence of various genetic factors or concomitant developmental abnormalities. Temporal lobe epilepsy is generally regarded as an acquired disorder with only a small genetic contribution. There are familial cases of febrile seizures, which are associated with ion channel mutations: sodium channel subunit and  $\gamma$ -aminobutyric acid

ionotropic receptor family A ( $\text{GABA}_A$ ) subunit mutations) (Table 16–1) (Kullmann, 2002). However, these families usually present with a heterogeneous group of epilepsies that are distinct from the typical history of hippocampal epilepsy. More recently, the leucine-rich, glioma-inactivated 1 gene has been associated with familial neocortical temporal lobe epilepsies, although the mechanisms by which this mutation results in epilepsy are unknown (Kullmann, 2002). We are at present ignorant of the genetic mutations underlying most of the genetically determined epilepsies, let alone those that contribute to other epilepsies. Genetic predisposition to some forms of temporal lobe epilepsy and febrile convulsions have been described, and there are familial cases of febrile convulsions and TLE but without hippocampal sclerosis (Baulac et al., 2001).

More recent attention has focused on an underlying maldevelopment of the hippocampus as a primary abnormality predisposing to hippocampal sclerosis and to febrile seizures. In an MRI study of families with familial febrile convulsions, a subtle preexisting hippocampal abnormality was detected (Fernandez et al., 1998), and hippocampal sclerosis has also been reported in patients in association with isolated malformations of the hippocampus (Baulac et al., 1998). In addition, an abnormal persistence of calretinin positive Cajal-Retzius cells in the hippocampus has been reported in hip-

pocampal sclerosis specimens (Blumcke et al., 1999b). Cajal Retzius cells, through secretion of the reelin protein, play a critical role in neuronal organization in the developing brain. Higher numbers of Cajal-Retzius cells were particularly prominent in patients with hippocampal sclerosis and a history of febrile seizures. It is plausible that such an injury occurring early in life disrupts normal hippocampal development and maturation (one manifestation of which is an excess of Cajal-Retzius cells), which in turn predisposes to hippocampal sclerosis. As it has been suggested that reelin in the adult cortex has a role in plasticity and axonal remodeling, an increased number of these cells may also be important for the reorganization of circuitry occurring in hippocampal sclerosis (described below).

The final argument supporting a maldevelopmental basis for hippocampal sclerosis comes from the observation that hippocampal sclerosis is often observed in association with subtle cytoarchitectural malformations in the neocortex, also termed microdysgenesis (Hardiman et al., 1988). This may be indicative of a more widespread maldevelopmental process involving both mesial and lateral temporal lobe structures. One cytoarchitectural feature observed in microdysgenesis is also an excess of Cajal Retzius cells in the molecular layer (Garbelli et al., 2001), which interestingly seems to parallel findings in hippocampal sclerosis.

**Table 16–1.**  
**Monogenic Epilepsies and Ion Channels Implicated in Human Epilepsy**

Syndrome	Gene	Locus	Protein
<b>Autosomal Dominant Inheritance</b>			
Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)	CHRNA4	20q13.2-q13.3	Nicotinic ACh receptor subunit
	CHRN2	1p21	Nicotinic ACh receptor subunit
Benign familial neonatal convulsions (BFNC)*	KCNQ2	20q13.3	Potassium channel subunit
	KCNQ3	8q24	Potassium channel subunit
Generalized epilepsy with febrile seizures plus (GEFS†)	SCN1A	2q24	Sodium channel subunit
	SCN1B	19q13.1	Sodium channel subunit
	GABRG2	5q33.1-q33.1	$\text{GABA}_A$ receptor subunit‡
	GABRA1	5q34	$\text{GABA}_A$ receptor subunit
Juvenile myoclonic epilepsy (JME)	LGI1	10q24	Leucine-rich, glioma-inactivated 1 [unknown function—not an ion channel]
Autosomal dominant partial epilepsy with auditory features [ADPEAF]‡			
<b>Sporadic</b>			
Severe myoclonic epilepsy of Infancy (SMEI)	SCN1A	2q24	Sodium channel subunit
<b>Other Ion Channel Genes Implicated in Epilepsy§</b>			
Febrile and afebrile seizures	SCN2A	2q23-q24.3	Sodium channel subunit
Episodic ataxia type 1 with partial epilepsy	KCNA1	12p13	Potassium channel subunit
Episodic ataxia type 2 with spike-wave epilepsy	CACNA1A	19p13	Calcium channel subunit
JME	CACNB4	2q22-23	Calcium channel subunit¶

ACh, acetylcholine;  $\text{GABA}_A$ ,  $\gamma$ -aminobutyric acid ionotropic receptor family A;  $\text{GABA}_B$ , GABA ionotropic receptor family B.

\*A 15% risk of epilepsy continuing beyond infancy.

†Also associated with febrile seizures and absences.

‡Also known as autosomal dominant lateral temporal epilepsy.

§Mutations identified in small number of patients, so role in epilepsy is less clear.

¶Also associated with generalized epilepsy with praxis-induced seizures.

Hippocampal sclerosis is also well recognized to occur in association with more severe cortical malformations, vascular malformations, and low-grade glioneuronal tumors (Cendes et al., 1995; Li et al., 1999). It is possible that in these cases the epileptogenic extrahippocampal lesion “kindles” the hippocampal neuronal loss (i.e., the hippocampal sclerosis in these cases is a secondary event) (see below). It has been shown, however, that in patients with dual pathologies removal of both the lesion and the abnormal hippocampus has the best outcome in terms of seizure control (Li et al., 1999), emphasizing the role of the hippocampus in temporal lobe seizures even when there is a second pathology.

### **Animal Models of Mesial Temporal Lobe Epilepsy**

The interpretation of many of the pathological findings and the electrophysiologic studies in human postsurgical specimens is confounded by: (1) the influence of treatment; (2) the difficulty differentiating cause from effect (i.e., it is possible that the changes are the result, not the cause, of the seizures); and (3) the lack of adequate control tissue for comparison. To overcome these handicaps, animal models of mesial TLE are used. The two most studied are the kindling model and the poststatus epilepticus model. Intrahippocampal injection of tetanus toxin also results in spontaneous seizures even after clearance of the toxin, and this model has also contributed to our understanding of the pathophysiology of mesial TLE (Mellanby et al., 1977). This model does not result in hippocampal sclerosis (Jefferys et al., 1992), and the seizures usually abate, in contrast to the human condition. We discuss the kindling and the poststatus epilepticus models in more detail, as these models possibly have human correlates.

**Kindling.** Kindling is the repetition of tetanic (trains of) stimuli that initially evoke after-discharges but not seizures (Goddard, 1967; McNamara et al., 1993). Repetition of the same trains of stimuli results in gradual lengthening of the after-discharges, eventually leading to progressively more severe seizures. Once an animal has been kindled, the heightened response to the stimulus seems to be permanent, and spontaneous seizures can occur (McNamara et al., 1993). The hippocampus and amygdala are easily kindled, resulting in a well described progression of limbic seizures. Kindling shares several characteristics with NMDA-dependent long-term potentiation (LTP) of excitatory synaptic transmission. This has led to the suggestion that kindling and LTP have similar underlying mechanisms. In support of this, the rate at which kindling occurs is retarded in rodents treated with NMDA receptor antagonists. There are, however, several differences between kindling and LTP. Although NMDA receptor antagonists can completely block the induction of LTP, they are unable to block kindling completely (Cain et al., 1992). Perhaps a more fundamental difference is that the kindling process requires after-discharges; the repeated induction of LTP without after-discharges does not induce kindling. LTP of

glutamatergic synaptic transmission may contribute to kindling by increasing the excitatory synaptic drive and the likelihood of evoking after-discharges but is alone insufficient to explain the cellular mechanisms of kindling (Cain, 1989; Cain et al., 1992).

Kindling alone is unlikely to explain the occurrence of hippocampal sclerosis in association with other pathology because kindling itself usually results in no or minimal hippocampal damage and sclerosis (Tuunänen and Pitkänen, 2000). Kindling could, however, explain the progression of mesial temporal epilepsy. Eventually spontaneous seizures in the kindling model result in progressive neuronal loss in the hippocampus (Cavazos et al., 1994). Indeed, even following single seizures there is evidence of both apoptotic cell death and neurogenesis in the dentate granule cell layer (Bengzon et al., 1997). This suggests that recurrent seizures may cause further structural and functional changes in the hippocampus. Human evidence for this has mainly been indirect. Epilepsy duration correlates with hippocampal volume loss and progressive neuronal loss and dysfunction (Theodore et al., 1999). There has also been a case reported of hippocampal volumes decreasing with time in hippocampal sclerosis (Van Paesschen et al., 1998) and the appearance of hippocampal sclerosis de novo following secondary generalized brief tonic-clonic seizures (Briellmann et al., 2001).

**Poststatus Epilepticus.** Seizures are usually self-terminating and brief. Occasionally seizures persist unabated, or repeated seizures can occur without recovery; this situation is termed status epilepticus. Although status epilepticus may occur in individuals with preexisting epilepsy, more than half of patients who present with status epilepticus have no history of seizures (DeLorenzo et al., 1996). In these patients, the status epilepticus is often acutely precipitated by a central nervous system (CNS) infection, cerebral vascular accident, hypoxia, or alcohol. The probability of then developing epilepsy (unprecipitated seizures) is 41% within 2 years compared with 13% for those with acute symptomatic seizures but no status epilepticus (Hesdorffer et al., 1998). This suggests a relation between the prolonged seizures of status epilepticus and subsequent epileptogenesis, although a relation between the length of the seizure and the nature and severity of the precipitant cannot be discounted. In humans, status epilepticus has been shown to result in hippocampal damage and subsequent hippocampal sclerosis. The hippocampus thus has a dichotomous role: as the substrate for epilepsy and as the structure susceptible to damage by prolonged seizures. Animal models of generalized convulsive as well as limbic status epilepticus have supported these findings. Limbic status epilepticus has been induced by the systemic or local administration of kainic acid, systemic administration of pilocarpine (a muscarinic receptor agonist), or protocols using electrical stimulation of limbic areas (Walker et al., 2002). Status epilepticus in these models in adult animals results in hippocampal damage similar to that observed in humans. Following these acute episodes of limbic status epilepticus,

many of the animals go on to develop spontaneous limbic seizures after a latent period lasting days to weeks (Walker et al., 2002).

#### 16.2.4 Pathophysiology

One of the major points of confusion in understanding the pathophysiology of epilepsy is the differentiation of a seizure (*ictus*) from interictal discharges and, indeed, from epilepsy itself. Although obviously linked, they are separate entities. An epileptic seizure is a transient paroxysm of excessive discharges of neurons in the cerebral cortex causing a clinically discernible event. Brief synchronous activity of a group of neurons leads to the interictal spike, and as we discuss, this shares some mechanisms with seizure generation; spikes should, however, be recognized as a distinct phenomenon (de Curtis and Avanzini, 2001). Epilepsy, on the other hand, is the propensity to have seizures; and epileptogenesis is the development of a neuronal network in which spontaneous seizures occur.

##### Interictal Spike

Epileptiform interictal EEG abnormalities include spikes, which are fast electrographic transients lasting less than 80 ms, and sharp waves, which last 80 to 120 ms (de Curtis and Avanzini, 2001). That these abnormalities are pathological is supported by their rare occurrence (< 1%) in healthy individuals (Gregory et al., 1993) and their strong association with epilepsy (Ajmone-Marsan and Zivin, 1970). Spikes and sharp waves are often followed by a slow wave lasting hundreds of milliseconds. As discussed below, this slow wave probably represents a period of relative refractoriness. It has been established from concomitant field potential and intracellular recordings that the intracellular correlate of the interictal spike is the paroxysmal depolarizing shift (PDS) (Matsumoto and Ajmone-Marsan, 1964), a slow depolarizing potential with a high-frequency (> 200 Hz) burst of action potentials.

In hippocampal slices from healthy animals, PDSs can be observed if GABA<sub>A</sub> inhibition is reduced or if "excitability" is increased by increasing potassium, reducing magnesium, reducing calcium, or blocking potassium channels with 4-aminopyridine (de Curtis and Avanzini, 2001). The PDS is characterized by an early phase that is maintained by intrinsic properties of the neuron followed by a later phase that is secondary to recurrent excitation. Thus, the generation of interictal spikes is dependent on two phenomena: the intrinsic burst properties of neurons and the synchronization of neuronal populations. Within the hippocampus, pyramidal cells in area CA3 and some in area CA1 demonstrate burst properties (see Chapter 5). The mechanisms underlying this are different for neurons from these two subfields. The bursting in CA3 pyramidal cells appears to be dependent on regenerative dendritic potentials secondary to activation of calcium and sodium channels (Traub and Jefferys, 1994), whereas the burst properties of some CA1 pyramidal cells is probably due to

persistent sodium currents (Su et al., 2001). The effect of a burst of action potentials is to increase synaptic reliability; within the excitatory network of the CA3 pyramidal cells, burst firing in a single CA3 pyramidal cell can generate a synchronized burst throughout the whole network (Miles and Wong, 1983). Because of the propensity for the CA3 pyramidal cells to generate this synchronized burst, this region has often been considered the "pacemaker" for seizure activity. Synchronized bursts can, however, also occur in the CA1 subfield (Karnup and Stelzer, 2001). In some situations the synchronization of CA1 pyramidal cells is secondary to a CA3 generated burst, but synchronization can also occur through a combination of nonsynaptic mechanisms including gap junctions, ephaptic transmission, and changes in the extracellular milieu. The importance of these nonsynaptic mechanisms in neuronal synchronization has been emphasized by the "zero" calcium model of ictal discharges, in which reducing extracellular calcium in a hippocampal slice preparation below that necessary for synaptic transmission results in synchronized epileptiform discharges due to increased axonal excitability and ephaptic transmission (Jefferys, 1995). Furthermore, decreasing extracellular space (indirectly increasing ephaptic transmission) can promote bursting (Roper et al., 1992), whereas intracellular acidification with sodium propionate—indirectly decreasing electrotonic coupling (Perez and Carlen, 2000)—inhibits epileptiform bursts (Xiong et al., 2000). Synchronization of principal cells can occur secondary to oscillations in the inhibitory interneuron network; indeed, single basket cells have been shown to synchronize the discharges of pyramidal cells through synchronized somatic inhibition (Cobb et al., 1995). Although the precise mechanisms of neuronal synchronization in the hippocampus are still unclear, the observation of high-frequency oscillations superimposed on spike discharges has led to the hypothesis that the same physiological mechanisms that subtend fast oscillations in the hippocampus are also responsible for pathological synchronization (Perez and Carlen, 2000; Traub et al., 2001).

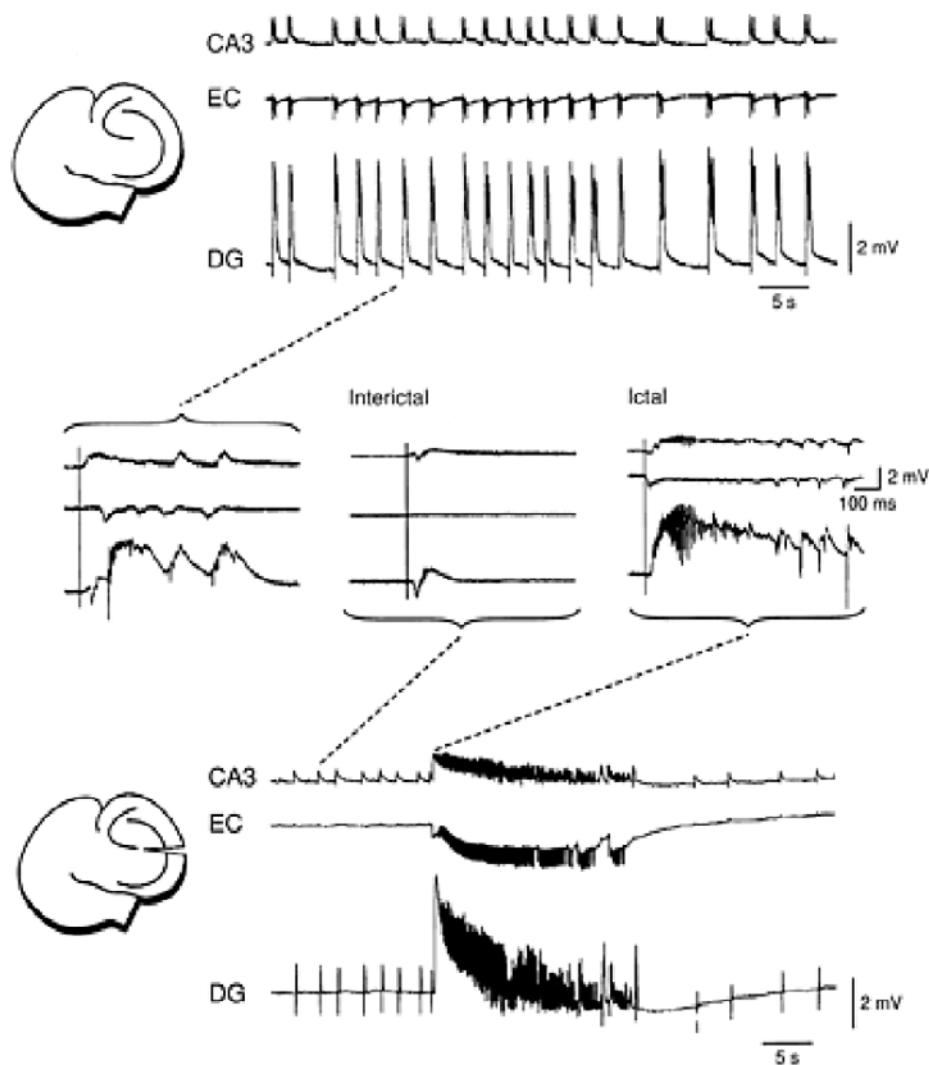

The interictal spike is terminated by activation of hyperpolarizing GABA<sub>A</sub> and GABA<sub>B</sub> receptor-mediated currents and calcium-dependent potassium currents (Alger and Nicoll, 1980; Domann et al., 1994; Scanziani et al., 1994). There is also some evidence of a contribution by other potassium currents, such as the sodium-dependent potassium current (Schwindt et al., 1989). Blocking the after-hyperpolarization, however, only results in moderate prolongation of the burst in CA3; and exhaustion of the immediately releasable pool of glutamate has also been proposed to be a critical process in burst termination (Staley et al., 1998). Furthermore, large depolarizations (rather than hyperpolarizations) herald the termination of brief epileptic after-discharges (Bragin et al., 1997). This depolarization can be replicated by focal microinjection of potassium, and it has been hypothesized that potassium ions released by discharging neurons result in propagating waves of depolarization, which block spike generation in neurons akin to spreading depression (Bragin et al., 1997).

Nevertheless, interictal spikes activate hyperpolarizing currents resulting in a postspike refractory period, during which neuronal activity is inhibited (de Curtis and Avanzini, 2001). The effective activation of these currents by the interictal spike thus raises the possibility that spikes can be anti-ictogenic. There is evidence that this may be the case or at least that spikes are intrinsically different from a seizure. Depth EEG recordings in humans suggest that the interictal spike can originate from a much wider field than the ictal zone (see above). Therefore, it is not uncommon to find spikes originating in either hippocampus, whereas seizure activity is confined to one hippocampus.

A seizure is not the evolution of spike discharges but can begin as a distinct high-frequency rhythm (see above). Spike discharges can precede the seizure with progressively less effective after-hyperpolarizations, but ictal activity remains a distinct phenomenon. Furthermore, activation of interictal spikes occurs after the seizure, raising the possibility that this is a compensatory antiepileptic response (de Curtis and Avanzini, 2001). Critical experiments in entorhinal cortex-

hippocampal slice preparations, in which there is partial preservation of the trisynaptic loop, have confirmed the antiepileptic potential of spikes. Spike discharges generated in CA3 inhibited epileptic activity in the entorhinal cortex, so sectioning of the Schaffer collaterals led to potentiation of entorhinal cortex seizure activity (Fig. 16–2) (Barbarosie and Avoli, 1997).

Most of the ictal activity described thus far in the hippocampal slice preparation has been brief and difficult to relate to seizures *in vivo* that last tens of seconds. Can such prolonged activity be mimicked in the slice, and does it differ from briefer discharges? Prolonged ictal activity (seizure-like activity) has been induced in the slice with high extracellular potassium (Traynelis and Dingledine, 1988). In this preparation, the CA3 subfield generates regular interictal spikes, which “drive” the generation of prolonged rhythmic “seizure” activity in the CA1 region; interestingly, the CA3 region in this preparation is resistant to generating this ictal activity (Traynelis and Dingledine, 1988). Inducing seizure-like activity in brain slices by other means (e.g., the lowering magne-

**Figure 16-2.** Interictal spikes inhibit seizure activity. Spontaneous epileptiform activity induced by  $Mg^{+2}$ -free artificial cerebrospinal fluid (ACSF) before and after a Schaffer collateral cut. Before the lesion (*top*), synchronized interictal discharges are recorded in the CA3, entorhinal cortex (EC), and dentate gyrus (DG). Sectioning the Schaffer collaterals (*bottom*) abolishes interictal discharges in the EC and discloses ictal epileptiform activity that is recorded in the three areas. Expanded traces of the experiment shown in the *top* and *bottom* are illustrated in the *middle*. Note that before the Schaffer collateral cut  $Mg^{+2}$ -free-induced interictal discharges consist of multiple components, whereas after the cut (Interictal) they are markedly reduced in duration and number of events. (Source: Adapted from Barbarosie and Avoli, 1997.)

sium level or GABA<sub>A</sub> receptor blockade) can result in the generation of such activity in other regions in the hippocampal/parahippocampal formation such as the subiculum (Behr and Heinemann, 1996), area CA3 (Borck and Jefferys, 1999), and the entorhinal cortex (Jones, 1989). That small areas can generate seizure-like activity in the slice supports the hypothesis that a network of only a few thousand neurons is necessary to sustain seizure activity (Borck and Jefferys, 1999). That the maintenance of seizure-like activity is different from the mechanisms underlying briefer epileptiform discharges is suggested by their differing pharmacology; NMDA receptor antagonists can terminate brief epileptiform discharge but are ineffective during the “maintenance phase” of seizure-like activity (Borck and Jefferys, 1999).

So how do spontaneous seizures (epilepsy) occur *in vivo*? The brain slice studies can give us an insight into specific questions concerning the generation of epileptiform discharges. The interpretation and the *in vivo* extrapolation of such studies are, however, complicated by certain observations: Seizure-like activity can be generated *in vitro* by quite disparate means, and the mechanisms and structures involved in the generation of such activity can differ from study to study. Seizure activity relies on oscillatory synchronization; thus, mechanisms similar to those described in Chapter 8 undoubtedly contribute to the emergence of *in vivo* seizure activity. Furthermore, it is likely that mechanisms similar (but not necessarily identical) to those that underlie spike discharges and longer “epileptic after-discharges” promote *in vivo* seizure activity. The transition from normal, physiological oscillatory behavior to epileptiform behavior is likely to be due to greater spread and neuronal recruitment secondary to enhanced connectivity, enhanced excitatory transmission, or a failure of inhibitory mechanisms. Indeed, in human studies,

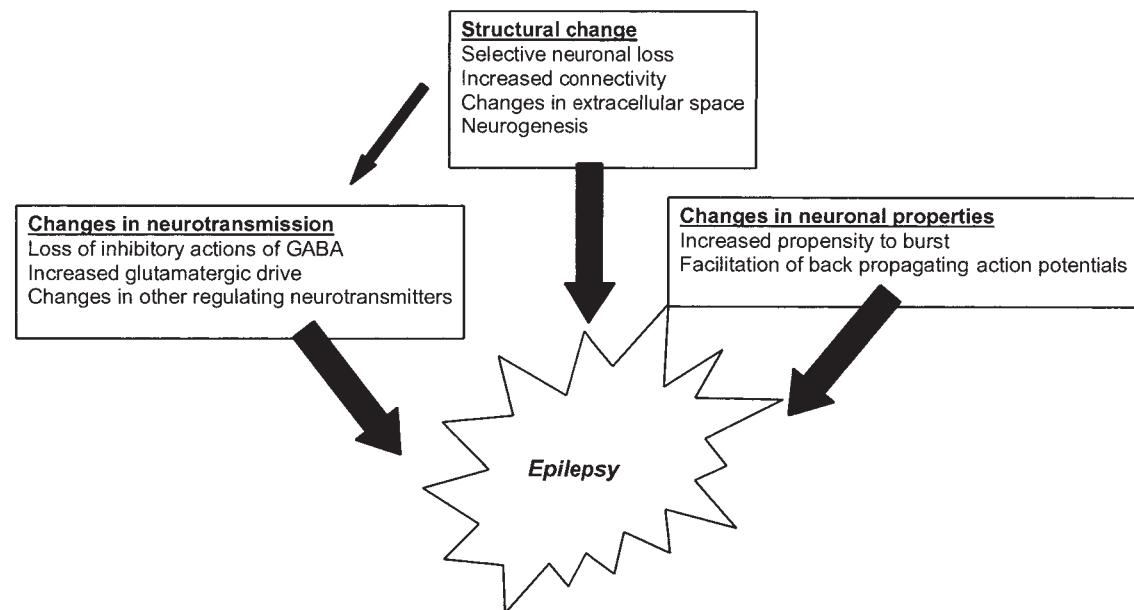

the EEG becomes less chaotic in large areas of cortex at the start of an ictus, suggesting that widespread synchronization is occurring (Martinerie et al., 1998). To understand how a network that usually maintains oscillatory behavior becomes “epileptic,” it is paramount to consider the changes that occur in the hippocampus during epileptogenesis.

One problem with much that has been described is that it is associational (i.e., changes are observed and are assumed to contribute to the epileptogenic process). This may not hold true for many of the changes, which could be compensatory (i.e., protecting against the epileptogenic process). Unfortunately, it has been difficult to distinguish between these possibilities, and we are far from a comprehensive model of epileptogenesis. The changes that occur can be divided into structural change (neuronal loss, reorganization, synaptic reorganization, changes in glia and extracellular space), changes in neurotransmission, and lastly changes in neuronal properties. We discuss how each of these changes may contribute to the epileptogenic process (Fig. 16–3).

### Structural Change

**Neuronal Loss.** Hippocampal sclerosis is typically a unilateral process, affecting either hemisphere equally, with involvement of the whole length of the hippocampus. In some cases more focal damage may be observed (Babb et al., 1984), and in others there is bilateral sclerosis (Van-Paesschen et al., 1997a). In so-called classic hippocampal sclerosis, selective loss of pyramidal cells is seen in the CA1 subfield and in the hilar region with accompanying astrocytic gliosis. In some patients neuronal loss is restricted to the CA1 subfield (de Lanerolle et al., 2003). Pyramidal cells of CA2 and dentate granule cells appear more resistant (Bruton, 1988). In severe hippocampal

**Figure 16–3.** Structural changes, changes in neurotransmission, and changes in the intrinsic properties of neurons all contribute to the development of epilepsy.

sclerosis almost total neuronal loss is seen in all hippocampal subfields and may be accompanied by marked deposition of corpora amyacea. In the pattern of hippocampal sclerosis termed “end folium gliosis,” encountered in 3% to 4% of surgical cases (Bruton, 1988), the neuronal cell loss appears confined to the hilus and includes loss of both principal cells and interneurons. This pattern of hippocampal atrophy is less easily detected on preoperative MRI and is associated with a later onset of epilepsy than classic hippocampal sclerosis and a worse postoperative seizure outcome (Van Paesschen et al., 1997b).

Quantitative histological studies have been carried out in hippocampal sclerosis series, and pathological grading systems have been proposed to categorize the severity of neuronal loss in hippocampal sclerosis; for example, in one system, grade I hippocampal sclerosis correlates with less than 10% of neuronal dropout in CA1 up to grade IV hippocampal sclerosis, which shows more than 50% neuronal loss in all subfields (Wyler et al., 1992). This is based on a semiquantitative assessment of neuronal loss in histological sections. Such analyses have proved useful as they allow pathological correlation with clinical parameters (e.g., the age of the patient at epilepsy onset and the duration of seizures) (Davies et al., 1996) and with neuroimaging features. These grades may also reflect a progressive evolution of hippocampal sclerosis from grades I to IV, mirroring ongoing hippocampal atrophy that has been occasionally reported in sequential neuroimaging studies.

Marked cytological alterations have been observed in surviving neurons in hippocampal sclerosis using immunohistochemistry, electron microscopy, and confocal imaging techniques (Blumcke et al., 1999a). These changes include enlargement and accumulation of neurofilaments in end folial neurons, abnormal dendritic nodular swellings, and ramifications of these cells. These features more likely represent secondary or adaptive cellular changes due to the altered connectivity in the reorganized hippocampus rather than a primary cellular abnormality.

Neuronal loss and gliosis may also be present in adjacent limbic structures, including the amygdala (Yilmazer-Hanke et al., 2000) and parahippocampal gyrus, which along with hippocampal sclerosis are collectively referred to as mesial temporal sclerosis. Neuronal loss may also involve the entorhinal cortex, and volume loss has been demonstrated in the entorhinal cortex with quantitative MRI studies (Salmenpera et al., 2000). Neuropathological studies of this cortical region in patients with hippocampal sclerosis have suggested significant loss of layer III cells (Du et al., 1993), although other studies have suggested a more variable pattern of cell loss involving all layers, including loss of pre-alpha cells (Yilmazer-Hanke et al., 2000). The observed loss of entorhinal neurons could indicate either primary or secondary involvement of this region in the pathophysiology of temporal lobe seizures. An important observation, however, has been the demonstration of entorhinal cortex neuronal loss in the absence of hippocampal sclerosis (Yilmazer-Hanke et al., 2000; Bernasconi et al., 2001).

This and the observation that the entorhinal cortex can alone maintain seizure-like activity (Jones, 1989) perhaps implicate a more specific role for this region in seizure generation.

The extent of any temporal neocortex neuronal loss does seem to correlate with the severity of hippocampal damage (Bruton, 1988). Neocortical neuronal loss also appears to be layer-specific, with cortical layers II and III more severely affected.

**Mechanisms of Neuronal Death in Status Epilepticus.** The pattern of neuronal death in hippocampal sclerosis is mirrored by neuronal death seen in postmortem specimens following status epilepticus (DeGiorgio et al., 1992). Imaging studies have demonstrated the occurrence of hippocampal sclerosis following status epilepticus and prolonged seizures, further emphasizing the vulnerability of the hippocampus to neuronal damage. Insights into the mechanisms underlying this damage have largely been derived from animal models of status epilepticus (Meldrum, 1991). They have shown that although a certain amount of neuronal damage is secondary to physiological compromise that occurs during status epilepticus (e.g., hypoxia, hypoglycemia, hypotension) a large proportion of the damage is independent of these factors. This neuronal damage is due to excitotoxicity in which the presence of epileptic activity mediates neuronal death through the activation of glutamate receptors. Excessive influx of calcium (and zinc at mossy fiber synapses) through primarily NMDA receptors, but also through  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors lacking the GluR2 subunit, results in a cascade of reactions leading to cell death (Weiss et al., 2000; Lipton and Rosenberg, 1994; Tanaka et al., 2000).

**Specific Neuronal Vulnerability in Hippocampal Sclerosis.** Loss of the principal pyramidal cells in hippocampal sclerosis is established, but it is difficult conceptually to conceive how removal of principal excitatory neurons can contribute to a state of hyperexcitability. Undoubtedly, neuronal loss may contribute to synaptic rearrangements and perhaps increased connectivity, but more important perhaps is the vulnerability of specific subsets of interneurons in the hippocampal formation, which may influence the intrinsic circuitry of the hippocampus and seizure propagation. Most interneurons contain the neurotransmitter GABA but can be further subdivided according to their connectivity, calcium-binding protein content, and neurotransmitter receptor status (Freund and Buzsaki, 1996).

Neuropeptide Y (NPY)- and somatostatin-containing inhibitory interneurons are normally numerous in the hilus and form a dense plexus of fibers in the outer molecular layer of the dentate gyrus which co-localizes with glutamic acid decarboxylase (GAD) (Amaral and Campbell, 1986). Loss of these interneuronal subtypes in the hilus was noted in hippocampal sclerosis (deLanerolle et al., 1989; Mather et al., 1995a). NPY-containing axons also appeared to be reorganized in the dentate molecular layer in hippocampal sclerosis, and ectopic expression of NPY in granule cells has been

observed following seizures (Vezzani et al., 1999). This is likely to represent plasticity in NPY inhibitory mechanisms in the epileptogenic hippocampus. A more recent quantitative study using *in situ* hybridization however, has suggested that NPY and somatostatin neurons in the fascia dentata are lost in proportion to the overall cell loss and are not specifically “targeted” in the disease process (Sundstrom et al., 2001).

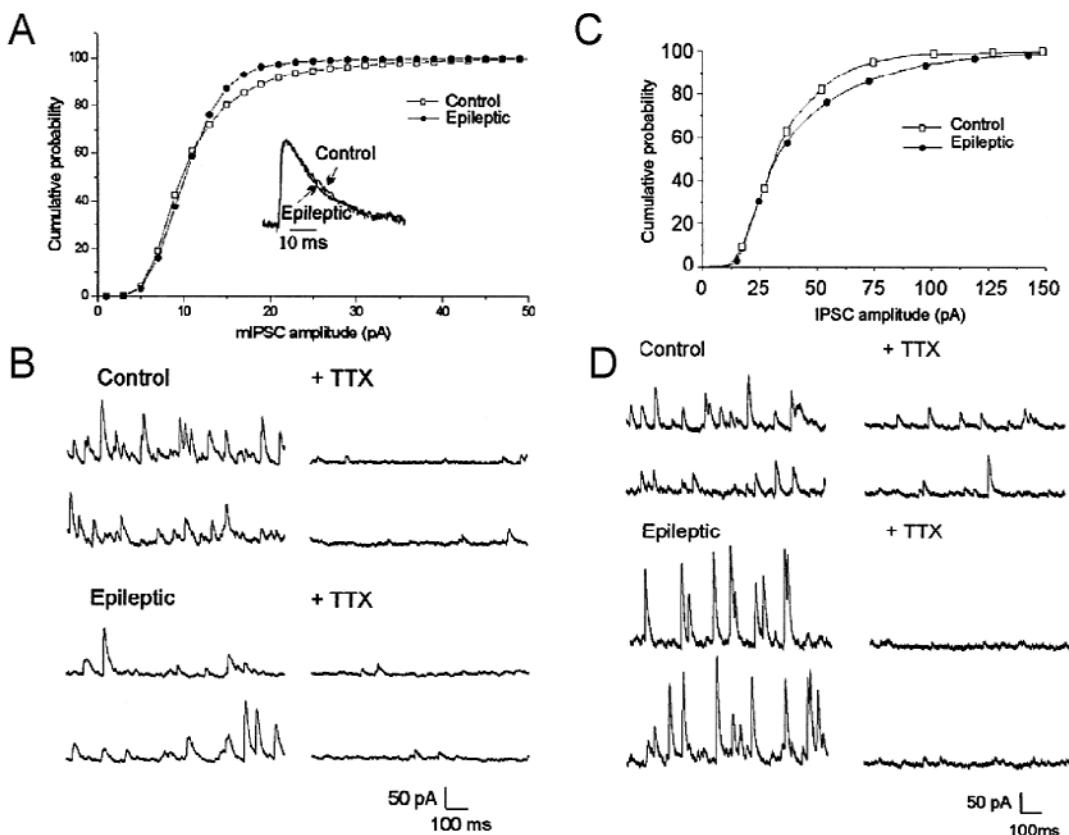

The calcium-binding proteins calbindin D-28-K, parvalbumin, and calretinin label different, nonoverlapping subsets of inhibitory hippocampal interneurons, and the resistance or susceptibility of these cell populations in hippocampal sclerosis may directly affect hippocampal epileptogenesis. The normal distribution of calbindin is not restricted to interneurons but is also present in the dentate gyrus granule cells, mossy fibers, and CA2 pyramidal cells; parvalbumin and calretinin are present only in interneurons. Calbindin-positive interneurons are mainly involved in the inhibition of principal cells in the dendritic region, whereas calretinin-positive interneurons probably selectively innervate other interneurons (Magloczky et al., 2000). An early study had suggested preferential survival of calbindin and parvalbumin immunoreactive neurons in hippocampal sclerosis (Sloviter, 1991). Furthermore, increased complexity of the terminal processes of powerful inhibitory interneurons, the chandelier cell (which may be parvalbumin- or calbindin-positive) has also been demonstrated in hippocampal sclerosis (Arellano et al 2004). More recent quantitative studies, however, have shown selective loss of parvalbumin-immunoreactive neurons in the hilus disproportionate to the overall cell loss (Zhu et al., 1997). The distribution of calbindin-positive interneurons in the dentate gyrus in hippocampal sclerosis was shown not to differ from controls in one study but striking enlargement of their cell bodies with enhanced expression of calbindin and modification of the dendritic trees and synapses of these cells was noted (Magloczky et al., 2000). Marked plasticity and reorganization of calbindin-positive interneurons in the CA1 subfield in the hippocampus has also been shown, which may predate the pyramidal cell loss (Wittner et al., 2002). The findings support a complex set of changes in interneuronal anatomy with changes in interneuron targets. Calretinin cells do not appear to show abnormal distribution in hippocampal sclerosis (Blumcke et al., 1996); but increased numbers of a subset of calretinin-positive neurons, the Cajal-Retzius cells, occurs in hippocampal sclerosis in some patients (Blumcke et al., 1999b). Studies have demonstrated an expansion of calretinin-positive axonal networks in the molecular layer of the dentate gyrus in hippocampal sclerosis (Blumcke et al., 1996, 1999b; Magloczky et al., 2000). These fibers are likely to represent those of the excitatory supramamillary pathway terminating on granule cells rather than local axons. This observation may indicate enhanced excitation of granule cells by this pathway (Magloczky et al., 2000).

The observed relative resistance of certain calbindin-containing neurons to neuronal damage has led to the suggestion that calbindin itself may be neuroprotective (Leranth and Ribak, 1991). However, in calcium-binding protein knockout

mice, the absence of these proteins does not appear to affect the numbers of interneurons or excitotoxic-mediated cell loss in epilepsy (Bouilleret et al., 2000). Furthermore, in hippocampal sclerosis there is loss of calbindin expression by granule cells (Magloczky et al., 2000). Granule cells are typically more resistant to damage in hippocampal sclerosis than other principal neurons and it has controversially been proposed that the calbindin loss actually protects these cells from  $\text{Ca}^{2+}$ -mediated neuronal damage (Nagerl et al., 2000). The proposed mechanism underlying this proposal is that lack of calbindin results in larger intracellular free calcium transients that inactivate calcium channels, thus limiting intracellular calcium accumulation; on the other hand, buffering of free calcium transients with calcium-binding proteins permits greater accumulation of intracellular calcium. Thus, although these calcium-binding proteins may identify neurons that are resistant to damage, the calcium-binding protein itself is probably not neuroprotective.

Selective loss of hilar mossy cells, an excitatory interneuron with distinctive dendritic arborizations, has been described in hippocampal sclerosis cases compared to patients with generalized seizures (Blumcke et al., 2000b). These excitatory interneurons project to inhibitory basket cells, and their loss may result in reduced feedforward granule cell inhibition supporting the experimental “dormant basket cell hypothesis” (Sloviter, 1991). However it is recognized in animal models that basket cells also receive direct excitatory input from the granule cells and perforant path fibers, thus bypassing the mossy cells (Kneisler and Dingledine, 1995).

**Pathophysiological Role of Neuronal Damage.** Are epileptogenesis and neuronal damage directly related? Following status epilepticus, those animals that develop spontaneous seizures have greater hilar interneuronal loss, perhaps resulting in decreased inhibitory drive (Gorter et al., 2001). It has also been suggested that damage to CA3 and the Schaffer collaterals may prevent spikes generated in CA3 from inhibiting epileptic activity in the limbic system (see above). Selective neuronal death can also result in a change in the nature of inhibition. Dendritically expressed inhibitory postsynaptic potentials (IPSPs) modify the transmission of excitatory postsynaptic potentials (EPSPs) to the soma, whereas somatic and perisomatic IPSPs depress the excitability of the neuron (Cossart et al., 2001). Basket cells, which make multiple perisomatic and somatic synapses, have extensive axonal arborizations leading to connection of one basket cell with many pyramidal cells. By synchronously modulating the excitability of a group of pyramidal neurons, one basket cell can synchronize pyramidal cell activity (Cobb et al., 1995). The loss of oriens/lacunosum-moleculare interneurons in CA1 results in loss of distal dendritic inhibition, whereas the preservation and increased connectivity of basket cells may result in greater pyramidal cell synchronization (Fig. 16–4) (Cossart et al., 2001). The selective loss of certain interneuronal populations in hippocampal sclerosis is thus probably pro-epileptogenic; but is neuronal loss necessary for epileptogenesis? That there is a distinction

**Figure 16-4.** Inhibition is decreased in dendrites but increased at the soma. *A, B*, Recordings from the apical dendrites of CA1 pyramidal cells. *A*, The cumulative probability plot of the amplitudes of miniature events was shifted to the left, indicating decreased frequency of amplitudes larger than 15 pA in epileptic animals. The kinetics of miniature events (normalized averages) did not seem modified (*inset*). *B*, Whole-cell recordings of spontaneous (control) and miniature (TTX, 1  $\mu$ M) inhibitory postsynaptic currents obtained at the reversal potential of glutamatergic events in a control and a kainate-treated animal. Continuous 4-s recordings are shown. The frequency of spontaneous events is lower in the epilep-

tic tissue. *C, D*, Somatic recordings from CA1 pyramidal cells. *C*, The cumulative probability plot of the amplitudes of spontaneous IPSCs was shifted to the right, indicating an increased frequency of large-amplitude events in experimental animals ( $n = 6$  cells) as compared to controls ( $n = 6$  cells). *D*, Whole-cell recordings of spontaneous (control) and miniature (TTX, 1  $\mu$ M) inhibitory postsynaptic currents obtained at the reversal potential of glutamatergic events. The frequency of spontaneous events was similar in control and epileptic neurons, but the number of large-amplitude events seemed to be increased in the epileptic neuron. (Source: Adapted from Cossart et al., 2001, with permission.)

between neuronal damage and epileptogenesis is indicated by kindling, in which epileptogenesis occurs in the setting of no or minimal neuronal damage, and similarly in the intrahippocampal tetanus toxin model (see above). Indeed, kindling may protect against neuronal damage induced by kainic acid (Kelly and McIntyre, 1994), raising the intriguing possibility that epilepsy itself can be neuroprotective.

**Granule Cell Dispersion.** The observation of disorganization or dispersion of granule cells into the molecular layer of the dentate gyrus in hippocampal sclerosis was first described in detail by Houser (Houser, 1990; Houser et al., 1992). Dispersed granule cells appear separated from the normally compact cell layer, which gives the impression of an undulated irregular border with the molecular layer. In some cases the deep (hilar border) of the granule cell layer is also ill-defined. As a result, in hippocampal sclerosis the cell layer appears broadened with a mean width of 180  $\mu$ m in TLE patients

compared to 100  $\mu$ m in control subjects (Houser, 1990). The dispersed cells often appear elongated or fusiform in shape, reminiscent of migrating neurons. Less often a bilaminar arrangement of granule cells is observed (Houser et al., 1992; Thom et al., 2001) or nests of GCs are present in the hilus (Houser, 1990; Thom et al., 2001). The incidence of granule cell dispersion in hippocampal sclerosis surgical series is of the order of 40% (Houser, 1990; Thom et al., 2001).

It has been suggested that granule cell dispersion represents a primary abnormality of neuronal migration or an underlying hippocampal malformation (Houser et al., 1992). There are occasional reports of granule cell dispersion in association with cortical malformations in the absence of a history of seizures and with bilateral hippocampal involvement (Harding and Thom, 2001). Disorganization of the granule cell layer and ectopic localization of neurons have also been noted in several animal models with cortical malformations such as the reeler, and *p35* mutant mice. The presence of gran-

ule cell dispersion in human hippocampal sclerosis has also been correlated with epileptic events occurring early in life, including febrile seizures (Houser, 1990), suggesting a vulnerability of these neurons during this time period. It has further been shown that the presence of granule cell dispersion correlates well with the severity of hippocampal neuronal loss (Thom et al., 2001). This suggests that granule cell dispersion represents an epiphenomenon of hippocampal sclerosis rather than a primary abnormality, the migration of granule cells perhaps being influenced by neurotrophin secretion during seizures or other cellular signals. Interestingly, an inverse correlation between the levels of reelin protein and the extent of granule cell dispersion in the hippocampus has been shown, suggesting a possible functional role for Cajal Retzius cells in this process (Frotscher et al., 2003).

In animal models of epilepsy, such as the pilocarpine model, there is evidence to suggest that abnormally migrated granule cells are newly generated cells, neurogenesis being stimulated by the seizures (Parent et al., 1997) (see Chapter 9). Rapid dispersion of granule cells has been demonstrated following injury (Omar et al., 2000) and it has been shown that newly generated cells can migrate as far as CA3 and integrate into the CA3 neuronal network (Scharfman et al., 2000). Abnormal connections formed by new cells may contribute to seizure development (Parent et al., 1997), although experimental inhibition of neurogenesis does not prevent granule cell axon reorganization (see below) in epilepsy models (Parent et al., 1999). Studies have confirmed that neurogenesis also occurs in adult human dentate gyrus (Eriksson et al., 1998), and neuronal progenitor cells have been isolated from the dentate gyrus (Roy et al., 2000). This pool of precursor cells may have important physiological roles, but it is conceivable that in human epilepsy, stimulated by seizures, an increased rate of granule cell neurogenesis occurs, leading to the abnormal cell localization and reorganization observed in hippocampal sclerosis. There is also evidence emerging that radial glial cells in this region could act as neuronal precursors, and neurogenesis may be stimulated by NPY (Howell et al., 2003).

Another study has demonstrated the stem cell intermediate filament protein nestin in granule cell neuronal precursors in young patients with mesial TLE and surgery before the age of 2 years (Blumcke et al., 2001). Similar cells were not found in adults with hippocampal sclerosis; whether the nestin-positive cells represent newly generated cells or a delay in hippocampal development in these younger patients is not clear. Studies of cell cycle proteins, including Ki67, showed low expression in the dentate gyrus subgranular layer in adult hippocampi from patients with epilepsy (Del Bigio, 1999). Although this is an insensitive technique for measuring cells with a low turnover rate, it does imply that neurogenesis in hippocampal sclerosis is a rare event and likely to be dependent on age.

Even if migrated granule cells do represent newly generated cells, it is unknown whether there are any differences in the physiological properties of these less mature cells. Electrophysiological studies in human hippocampal sclerosis

have already demonstrated the existence of distinct populations of granule cells, with one group showing abnormal excitability (Dietrich et al., 1999). We also know from animal studies that there is considerable potential for adaptability and plasticity of granule cells, such as increased basal expression of GAD (Sloviter et al., 1996), NPY induction (Vezzani et al., 1999), loss of calbindin expression (Magloczky et al., 1997), and altered ionotropic and metabotropic glutamate and GABA neurotransmitter receptor profiles on granule cells (Loup et al., 2000). It is plausible that such plasticity could be enhanced in newly generated granule cells and that it could contribute to seizure propensity.

**Mossy Fiber Sprouting.** In 1974, using Golgi techniques, Scheibel and colleagues identified aberrant axons from granule cell neurons ascending into the molecular layer of the dentate gyrus in hippocampal specimens from patients with epilepsy (Scheibel et al., 1974). It has long been considered that reorganization of the excitatory glutamatergic mossy fiber pathway is a key event in the development of chronic seizures (Sutula et al., 1989). Mossy fiber sprouting in human hippocampal sclerosis specimens results in aberrant innervations of other granule cells and also of CA3 pyramidal neurons, resulting in both feedback and feedforward excitation (Babb et al., 1991; Mathern et al., 1995b). In addition, aberrant mossy fibers in animal models innervate interneurons, suggesting that new inhibitory circuits are established (Kotti et al., 1997).

Mossy fiber sprouting in the supragranular layer of the dentate gyrus can be demonstrated using the Timms histochemical method, which highlights the zinc-rich mossy fiber synaptic terminals (Babb et al., 1991), or with dynorphin immunohistochemistry (Houser et al., 1990). Increased expression of growth-associated protein GAP-43 in the supragranular layer is thought to be indicative of active mossy fiber sprouting in hippocampal sclerosis specimens (Proper et al., 2000). Similarly increased synaptogenesis in this region has been demonstrated by studying the distribution of 5' nucleotidase activity, which localizes in regions with more active synaptic turnover (Lie et al., 1999). Overall reorganization of synaptic terminals in hippocampal sclerosis has also been demonstrated in human specimens using immunohistochemistry for synaptic antigens such as synaptophysin, which shows a loss in the hilus and increased labeling in the dentate gyrus molecular layer (Honner et al., 1994; Davies et al., 1998; Proper et al., 2000). Similarly, prominent immunolabeling for chromogranins (neuropeptide precursors that can be co-released with catecholamines and peptides) in the inner molecular layer of the dentate gyrus has been shown to correspond with reorganized mossy fibers in patients with epilepsy (Kandlhofer et al., 2000). In parallel with increased synaptogenesis, elaboration and increased complexity of granule cells dendrites in the inner molecular layer has been demonstrated in hippocampal sclerosis patients (von Campe et al., 1997). The hypothesis that mossy fiber collaterals form granule cell–granule cell synapses has been confirmed by visualizing

dentate granule cells and their mossy fibers after terminal uptake and retrograde transport of biocytin in epileptic rats secondary to status epilepticus (Okazaki et al., 1995).

Sprouting of mossy fibers is thought to result from epilepsy-induced loss of target cells (e.g., hilar mossy cells). However, in animal models it may be an early event, occurring within 4 weeks following the start of kindling (Elmer et al., 1996) and independent of hippocampal cell loss, possibly regulated by neurotrophic factors (Adams et al., 1997). Preliminary studies also indicate that mossy fiber sprouting is likely to be independent of any granule cell neurogenesis (Parent et al., 1997).

**Pathological Role of Mossy Fiber Sprouting.** It has long been considered that reorganization of the excitatory glutamatergic mossy fiber pathway is a key event in the development of chronic seizures. The dentate granule cells of the hippocampus probably act as a brake against seizure propagation through limbic circuitry (Perlin et al., 1992; Lothman and Bertram, 1993). This is mediated by the relative inexcitability of dentate granule cells through strong tonic GABAergic inhibition and relatively hyperpolarized membrane potentials. Dentate granule cells do not show the burst properties characteristic of hippocampal pyramidal cells in response to reduced GABAergic inhibition. Furthermore, dentate granule cell synchronization is difficult to achieve because of the low rate of connectivity between the granule cells.

Epileptogenesis may change the properties of dentate granule cell receptors (see below); but, importantly, mossy fiber sprouting greatly increases their connectivity. Even with sprouting, it is difficult to recruit dentate granule cells into epileptiform activity perhaps because of the extensive and increased synaptic input from GABAergic interneurons. Epileptiform activity can be induced in the dentate granule cells when mossy fiber sprouting is present by increasing extracellular potassium or by reducing GABA<sub>A</sub> receptor-mediated inhibition (Cronin et al., 1992; Wuarin and Dudek, 1996). This has led to the compelling hypothesis that epileptogenesis results in a potentially hyperexcitable granule cell layer that can be recruited into epileptic activity either by a rise in extracellular potassium, which could occur secondary to a sustained discharge from the entorhinal cortex, or through breakdown of inhibition (see below).

Is mossy fiber sprouting necessary for epileptogenesis? Blocking mossy fiber sprouting with the protein synthesis inhibitor cycloheximide does not prevent epileptogenesis (Longo and Mello, 1998). The interpretation of these experiments is confounded, however, by the likelihood that inhibiting protein synthesis inhibits other antiepileptogenic processes. In a recent study, the presence (or not) of dynorphin-positive mossy fiber sprouting in hippocampal sclerosis correlated with the postsurgical outcome; those with sprouting more often having a seizure-free outcome (de Lanerolle et al., 2003). It is also becoming increasingly apparent that there is sprouting of axons from other neuronal populations, includ-

ing sprouting of CA1 pyramidal cell axons, resulting in an increase in interconnectivity that results in increased excitability of the CA1 subfield (Esclapez et al., 1999). Sprouting of excitatory axons leading to increased interconnectivity may be a powerful means of generating hyperexcitable circuits that can maintain and propagate epileptic activity.

**Dormant Basket Cell Hypothesis.** Immediately following 24 hours of perforant path stimulation, there is loss of paired-pulse inhibition to perforant path stimulation in the dentate granule cell layer (Sloviter, 1987). The mechanism underlying this change was proposed to be the loss of excitatory input onto basket cells due to excitotoxic loss of mossy cells (Sloviter, 1987). However, application of NBQX, an AMPA receptor antagonist, was shown to inhibit the loss of mossy cells but to have no effect on the loss of paired-pulse inhibition (Penix and Wasterlain, 1994). Similarly, in the tetanus toxin model, disinhibition occurs in the absence of hilar cell loss (Whittington and Jefferys, 1994). Other factors are therefore likely to be responsible for the loss of paired-pulse inhibition, such as loss of affinity and activity of GABA<sub>A</sub> receptors in the hippocampus or a shift in the chloride reversal potential to more positive values (Kapur et al., 1994). These changes may be due in part to altered phosphorylation of GABA<sub>A</sub> receptors (Kapur et al., 1994) but could also be due to altered GABA<sub>A</sub> receptor subunit composition and expression (Sperk et al., 1998). Perhaps one of the main mechanisms is decreased recruitment of basket cells by excitatory inputs from dentate granule cells, the perforant path, and CA3 pyramidal cells through upregulation of presynaptic metabotropic glutamate receptor activity (Doherty and Dingledine, 2001).

Loss of paired-pulse inhibition was proposed to be an epileptogenic phenomenon, but subsequent studies have shown that paired-pulse inhibition becomes increased during the latent period (i.e., with epileptogenesis) and that epileptogenesis is associated with increased recruitment of basket cells (Milgram et al., 1991; Sloviter, 1992).

Synaptic rearrangement also occurs in CA1; and the hyperexcitability in CA1 with epileptogenesis has been proposed to be secondary to reduced recruitment of inhibitory interneurons (Bekenstein and Lothman, 1993). The main evidence for this is the loss of the IPSP from the EPSP–IPSP sequence on distant stimulation of the Schaffer collaterals. This evidence is perhaps flawed because this study does not adequately differentiate loss of the IPSP from prolongation of the EPSP. Subsequent data have shown increased excitability of CA1 interneurons following epileptogenesis (Sanabria et al., 2001). There are, however, other mechanisms underlying possible disinhibition in the CA1 region including changes in the pattern of inhibition (see above) and postsynaptic changes (see below).

**Glial Cells and Extracellular Space.** There are alterations in astrocytic function in the gliotic hippocampus. Astrocytes show physiological changes characteristic of immature astro-

cytes, including prolonged depolarization, that may contribute to seizure generation (Hinterkeuser et al., 2000; Schroder et al., 2000). Indeed, there is altered expression of ionotropic glutamate receptors on astrocytes in hippocampal sclerosis which may facilitate seizure spread (Seifert et al., 2004). In another study of rat and human hippocampi in TLE, the proliferation of glial cells in areas of neuronal loss were associated with alterations in extracellular potassium, which also may affect conduction of seizure activity (Heinemann et al., 2000). Altered levels of glial glutamate transporters (e.g., EAAT2), which has been shown in hippocampal sclerosis (Proper et al., 2002), may also influence the extracellular pool of glutamate. Furthermore, calcium oscillations in astrocytes can result in glutamate release, which may contribute to epileptic activity (Tian et al., 2005).

During seizures there is considerable shrinkage of the extracellular space due to intracellular accumulation of sodium chloride; indeed, a single seizure can result in a 10% to 30% decrease in extracellular space (Lux et al., 1986). This may result in increased nonsynaptic transmission through ephaptic and ionic mechanisms. Indeed, decreased extracellular space during seizures has been indirectly shown to have a role in seizure maintenance and spread; hypotonic extracellular solutions that decrease extracellular space are proconvulsant, whereas hypertonic solutions (increasing the extracellular space) can terminate seizure discharges (Roper et al., 1992). Although overall there is an expansion of the extracellular space in hippocampal sclerosis (Hugg et al., 1999; Wiesemann et al., 1999), how this relates to local changes in extracellular space and neurotransmission are unknown.

### Neurotransmitter Systems

**GABAergic Mechanisms.** Alteration in the distribution of neurotransmitter receptors has been extensively investigated as a pathogenic mechanism in the hyperexcitability of the hippocampus in TLE. The “GABA” hypothesis proposes that a deficit in inhibitory GABAergic transmission is implicated in seizures. GABA<sub>A</sub> and to a lesser extent GABA<sub>B</sub> receptor subtype expression (Barnard et al., 1998) and reuptake mechanisms have been studied in human hippocampal sclerosis tissues. Many alterations in GABA transmission may represent an adaptive mechanism in the brain in response to repetitive seizures, and increased expression of GABA<sub>A</sub> receptors has been documented in animal models of epilepsy as a compensatory mechanism (Fritschy et al., 1999). There is also upregulation of GAD, the main GABA-synthesizing enzyme, in interneurons following acute seizures. GABA and GAD are also upregulated in the mossy fibers and dentate granule cells (Sloviter et al., 1996). The finding of a mossy fiber-like GABAergic signal has raised the possibility that mossy fibers co-release glutamate and GABA (Walker et al., 2001); seizures may upregulate the GABAergic component (Gutierrez and Heinemann, 2001). In human hippocampal sclerosis, selective upregulation of GABA<sub>A</sub>α2 subunit in granule cells has been

observed, highlighting the plasticity of this neurotransmitter system in hippocampal sclerosis (Loup et al., 2000). The changes that are observed differ with time and between regions. Thus, specific GABA<sub>A</sub> receptor changes occur during acute seizures. As acute seizures continue they can become less responsive to benzodiazepines, which is mirrored by decreased potency of benzodiazepines on GABA-mediated synaptic currents in dentate granule cells (Kapur and Macdonald, 1997). In contrast, the potency of GABA itself and pentobarbitone remained unaltered, suggesting that rapid changes in GABA receptor properties occur during seizures. Although the pathophysiological consequences of these changes are difficult to predict, they have implications for the treatment of acute, prolonged seizures. During epileptogenesis the GABA<sub>A</sub> receptor changes are more complex and are region-specific. In the dentate granule cells, there is an increase in the number of GABA<sub>A</sub> receptors per synapse, leading to increased quantal size (Nusser et al., 1998). An especially interesting finding is that the increased GABA receptor-mediated signaling to dentate granule cells becomes more sensitive to zinc (Buhl et al., 1996; Brooks et al., 1998). To understand the potential involvement of zinc in epilepsy, it is necessary to consider the role of the sprouted mossy fibers. Mossy fiber terminals contain zinc and release it during synaptic activity (Assaf and Chung, 1984; Howell et al., 1984). Thus, it is conceivable that in the epileptic hippocampus zinc released from mossy fibers results in disinhibition, unmasking the potentiated excitatory dentate granule cell circuits (Buhl et al., 1996). This hypothesis is confounded by the observation that the zinc released from sprouted mossy fibers failed to affect GABA<sub>A</sub> receptor-mediated currents induced by local release of caged GABA (Molnar and Nadler, 2001). Furthermore, mice that lack the zinc transporter (ZnT3) and so lack synaptically available zinc have an exaggerated response to a convulsant; this observation does not, however, preclude a role for zinc in epileptogenesis (Cole et al., 2000).

Decreased sensitivity of GABA<sub>A</sub> receptor-mediated signals to zolpidem (a selective benzodiazepine agonist) has also been noted (Brooks et al., 1998). Using a combination of patch-clamp recording and single-cell mRNA amplification, it was found that the increased zinc sensitivity and decreased benzodiazepine sensitivity of the GABA<sub>A</sub> receptor was associated with (and possibly explained by) decreased expression of the α1 subunit and increased expression of the α4 subunit (Brooks et al., 1998). In addition, there were changes in β subunit expression that may affect benzodiazepine efficacy and the efficacy of barbiturates, steroids, zinc, and lorcetazole, a new antiepileptic drug (Brooks et al., 1998). These changes were seen during the latent period that predicated the onset of epilepsy, suggesting a role in the epileptogenic process. GABA<sub>A</sub> receptor-mediated transmission in CA1 undergoes different changes. In contrast to dentate granule cells, GABA<sub>A</sub> receptors on CA1 pyramidal cells are less responsive to applied GABA following epileptogenesis (Gibbs et al., 1997). There are also changes that suggest there may be a decrease in the presynap-

tic GABA reserve, although the synaptic consequences of this are unknown (Hirsch et al., 1999).

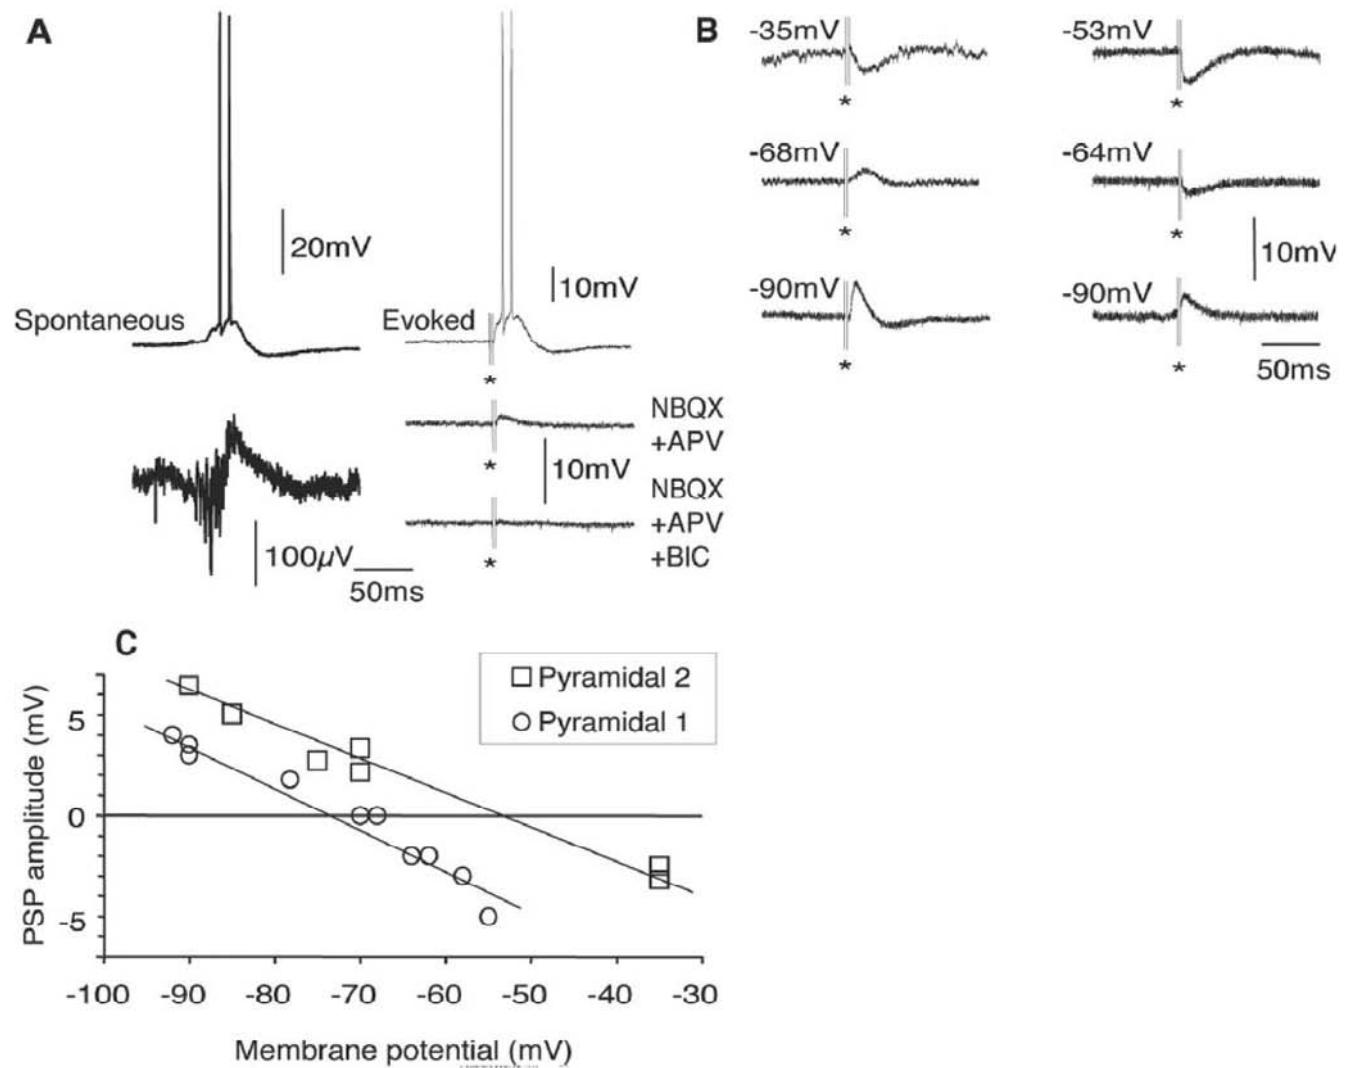

The effects of GABA<sub>A</sub> receptor activation on membrane potential depend on the chloride reversal potential. High internal chloride such as occurs developmentally can result in depolarizing GABA<sub>A</sub> receptor-mediated potentials. Could such depolarizing GABA<sub>A</sub> receptor-mediated potentials occur in epileptic tissue and contribute to epileptogenesis? Evidence from a study of hippocampal slices from patients who underwent temporal lobectomy suggest that this is so (Cohen et al., 2002). Synchronous rhythmic activity was found to be generated in the subiculum of slices of temporal lobe from patients with temporal lobe epilepsy, and this synchronous rhythmic activity was abolished by the GABA<sub>A</sub> receptor antagonist bicu-

culline and by glutamate receptor antagonists, suggesting that both excitatory and inhibitory signaling contributed to the spontaneous interictal-like events. Further studies in these cells demonstrated that the GABAergic synaptic events reversed at depolarized potentials (Fig. 16–5). Thus, depolarizing GABAergic responses potentially contributed to human ictal activity in the subiculum. The mechanism by which such depolarizing GABA<sub>A</sub> receptor-mediated potentials occur is unknown, but might be downregulation of the K<sup>+</sup>/Cl<sup>-</sup> co-transporter KCC2 that maintains the low intracellular chloride.

GABA<sub>B</sub> receptor changes have also been demonstrated in human hippocampal sclerosis tissue. GABA<sub>B</sub> receptors inhibit neurotransmitter release from presynaptic terminals and

**Figure 16–5.** Depolarizing  $\gamma$ -aminobutyric acid-A (GABA<sub>A</sub>) receptor-mediated potentials may contribute to seizure generation. Pyramidal cells active during interictal-like events showed excitatory GABAergic transmission. A. Discharges in pacemaker cells were triggered by orthodromic stimulation (right, upper trace). Depolarizing synaptic potentials persisted when glutamatergic transmission was suppressed (middle trace). They were suppressed

by blocking GABA<sub>A</sub> receptors (lower trace). BIC, bicuculline. B, C. Reversal potential for GABAergic transmission in cells that fired during interictal events was more depolarized than at rest (B, left; C, squares). Reversal in inhibited cells was hyperpolarized from rest (B, right; C, circles). Records were obtained in NBQX and APV. Linear fits are indicated. PSP, postsynaptic potential. (Source: Adapted from Cohen et al., 2002, with permission.)

cause late inhibitory synaptic potentials (Barnard et al., 1998). Increased expression of GABA<sub>B</sub>1 receptor has been shown in the subiculum of hippocampal sclerosis cases and in surviving CA1 neurons and granule cells with augmented receptor binding in CA3 (Billinton et al., 2001), although functional interpretation of these findings is difficult. The upregulation could represent a greater number of inhibitory synapses, increased postsynaptic GABA<sub>B</sub> receptors, or increased presynaptic GABA<sub>B</sub> receptor number, leading to decreased neurotransmitter release mainly from inhibitory axonal terminals. More recently, downregulation of mossy fiber presynaptic GABA<sub>B</sub> receptors has been found in tissue from epileptic animals. It resulted in decreased mossy fiber heterosynaptic depression, and may contribute to increased signal flow through the hippocampus (Chandler et al., 2003). Decreased presynaptic GABA<sub>B</sub> receptor activity on interneurons has also been proposed to underlie the enhanced inhibition that occurs in the dentate gyrus during epileptogenesis (Haas et al., 1996).

Changes in GABA uptake have also been described in the dentate gyrus (During et al., 1995; Patrylo et al., 2001). Both animal and human data support a decrease in clearance of synaptically released extracellular GABA, perhaps owing to decreased expression or impairment of GABA transporters (During et al., 1995; Mathern et al., 1999; Patrylo et al., 2001). This has been speculated to lead to increased interictal inhibitory "efficacy." Because the rises in extracellular potassium that occur during seizures may result in reversal of GABA uptake, decreased GABA transporter function results in impairment of extracellular GABA rises during seizure activity, possibly resulting in impaired inhibition during seizure activity. The change in GABA<sub>A</sub> receptor subunits resulting in a greater response to endogenously applied GABA (Brooks et al., 1998) could compensate for decreased extracellular GABA rises. Nevertheless, these data raise the possibility that decreased GABA transporter function could be pro-epileptogenic during times of seizure activity but promote inhibitory transmission during the interictal period.

**Glutamatergic Mechanisms.** Upregulation of excitatory metabotropic glutamate receptors (mGluR1 subunit) has been observed in the dentate gyrus in both human and animal models of hippocampal sclerosis, and it could contribute to the development of chronic seizures through increased excitatory transmission (Blumcke et al., 2000a). In addition, upregulation of the presynaptic inhibitory metabotropic receptor subunit mGluR4 in the dentate gyrus and granule cells in hippocampal specimens was also observed, which may contribute to the dampening of seizure activity (Lie et al., 2000). In studies employing *in situ* hybridization techniques, increases in pyramidal and granule cell AMPA receptor mRNA (Mathern et al., 1997) and in granule cell NMDAR1 and NMDAR2 subunit mRNA have been shown, results that are supported by autoradiographic studies (Brines et al., 1997). Studies in kindled models have supported the hypothesis that during epileptogenesis there is enhanced transmission from the entorhinal cortex to dentate granule cells (Behr et al., 2001).

One of the major mechanisms underlying this is undoubtedly an increase in NMDA receptor-mediated neurotransmission (Mody and Heinemann, 1987). Kindling results in fast, long-lasting posttranslational modifications in the function of dentate granule cell NMDA receptor channels, leading to increases in the mean open time and burst and cluster duration and to decreases in the channel-blocking effect by magnesium (Kohr et al., 1993). Similar changes in NMDA channels have been reported in human epileptic tissue (Lieberman and Mody, 1999). Modification of the NMDA receptor channels probably results from a decrease in the activity of intracellular phosphatases, leading to increased phosphorylation of the receptors (Kohr et al., 1993; Lieberman and Mody, 1994).

There is more uncertainty concerning changes in AMPA receptor neurotransmission. Certainly, changes in AMPA receptor subunit composition are seen in animal models prior to neurodegeneration; there is a decrease in the expression of the GluR2 subunit in vulnerable cells (Grooms et al., 2000). This evidence supports a role for calcium flux through GluR2 lacking AMPA receptors in mediating neuronal death (Grooms et al., 2000). Conversely, there appears to be upregulation of GluR2 in less vulnerable neurons such as the dentate granule cells (de Lanerolle et al., 1998).

Changes in glutamate uptake during epileptogenesis could also have an important role. There is burgeoning evidence that glutamate may escape from the synaptic cleft to activate extrasynaptic receptors, or even receptors at neighboring synapses (Kullmann and Asztely, 1998). Glutamate "spillover" can activate presynaptic glutamate receptors on GABAergic terminals, resulting in decreased inhibitory drive, and can increase NMDA receptor-mediated signaling (Min et al., 1999; Semyanov and Kullmann, 2000). Extrasynaptic accumulation of glutamate may play a role in epilepsy: Rodents lacking the gene coding for the glial glutamate transporter GLT-1 (EAAT2) show lethal spontaneous seizures (Tanaka et al., 1997). Rather surprisingly, chronic administration of anti-sense oligonucleotide to knock down the same transporter produces a different phenotype, characterized by neurodegeneration rather than seizures (Rothstein et al., 1996). Reduction of expression of the neuronal transporter EAAC1 (EAAT3), however, also causes seizures in rats. Subtle alterations in transporter levels have been reported in hippocampal tissue taken from patients with TLE (Mathern et al., 1999), although it is difficult to determine to what extent this reflects selective neurodegeneration. In an animal model of hippocampal sclerosis there was downregulation of the glial glutamate transporter that could contribute to glutamate spillover but upregulation of the neuronal glutamate transporter, which has been hypothesized to play a dominant role in reversed glutamate uptake (Ueda et al., 2001). Furthermore, marked extracellular glutamate rises have been recorded in humans using *in vivo* microdialysis prior to seizure onset, leading to the suggestion that these glutamate rises are an initiating factor in spontaneous seizures (During and Spencer, 1993).

**Other Neurotransmitters.** Alterations of many other transmitter systems have been described in association with acute limbic seizures and with hippocampal sclerosis. Perhaps one of the most intriguing roles for many of these transmitters is in seizure termination, and acute alterations have been implicated in the progression of seizures to status epilepticus. Adenosine, opioids, NPY, and galanin have all been proposed to play an important role in seizure termination (Young and Dragunow, 1994; Mazarati et al., 1998, 1999; Vezzani et al., 1999), whereas accumulation of substance P has a pro-epileptogenic effect (Mazarati et al., 1999).

Adenosine is a potent inhibitor of neurotransmitter release and has been shown to be effective for terminating brief seizures. Indeed, accumulation of adenosine seems to be a credible contender for a prominent role in seizure termination, as seizures promote adenosine release (Berman et al., 2000). Adenosine antagonists shorten the stimulation protocol or lessen the chemoconvulsant dose necessary to induce status epilepticus (Young and Dragunow, 1994). Also, adenosine agonists are effective at stopping both the induction and maintenance of status epilepticus (Handforth and Treiman, 1994). To what degree changes in adenosine anticonvulsant activity contribute to epileptogenesis or to the failure of seizure termination (status epilepticus) is unknown. Although regional changes in adenosine receptor density have been described during epileptogenesis (Ekonomou et al., 2000), it may reflect cell loss and synaptic rearrangement.

Opioid release has also been suggested as a major mechanism underlying the termination of seizures. The observed loss of dynorphin-like immunoreactivity in the hippocampus during sustained seizure activity is consistent with loss of a potent endogenous antiepileptic (Mazarati et al., 1999). Opioid antagonists facilitate the establishment of status epilepticus, and agonists inhibit both the induction and maintenance of status epilepticus.

In addition to opioids, a variety of other modulatory neuropeptides exist. NPY is such a peptide that has potent effects on neurotransmission. Cloning has revealed five NPY receptors, Y1–Y5 (Vezzani et al., 1999). In human hippocampal sclerosis, there is increased NPY, upregulated presynaptic Y2 receptors that inhibit neurotransmitter release, and downregulated Y1 receptors that are expressed postsynaptically and are excitatory (Furtinger et al., 2001). Furthermore, Y5 receptor knockout mice and NPY knockout mice have an exaggerated response to kainic acid with prolonged seizures (Baraban et al., 1997; Marsh et al., 1999).

Galanin is another bioactive peptide that is widely distributed throughout the CNS. Galanin in the hippocampus is predominantly inhibitory, decreasing the release of excitatory amino acids. In the hippocampus, galanin immunoreactivity is confined to axons, the bulk of which are the axons of medial septal neurons (Mazarati et al., 1998). Status epilepticus in two models—perforant path stimulation and lithium pilocarpine—resulted in the disappearance of galanin immunoreactive fibers in the hippocampus; this may have resulted from loss of medial septal neurons or through exhaustion of galanin

stores (Mazarati et al., 1998). This would have a disinhibitory effect. Soon after the status epilepticus, however, galanin immunoreactive-positive neurons appeared in the hilus; they increased in number after the first day but gradually declined a few days later. This increase in galanin-immunoreactive neurons in the hippocampus is possibly a compensatory response to prolonged ictal activity and depletion of galanin from septal afferents. Galanin injected into the hilus prevented the induction of status epilepticus and also stopped established status epilepticus. Conversely, antagonists of galanin receptors facilitated the development of status epilepticus (Mazarati et al., 1998). Further confirmatory evidence of the importance of galanin comes from studies of transgenic mice in which overexpression of galanin had an antiepileptic effect, and galanin knockouts were more susceptible to the induction of status epilepticus (Mazarati et al., 2000).

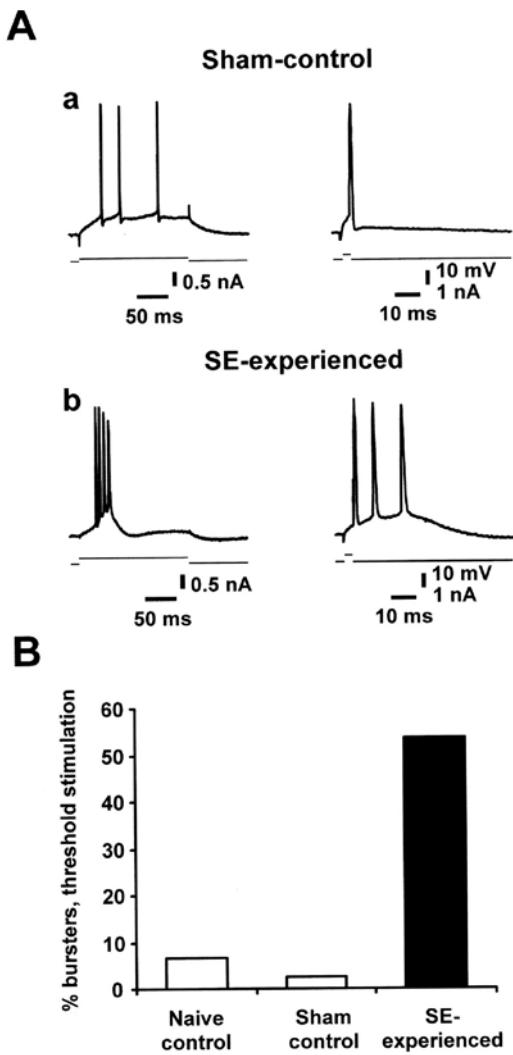

### Changes in Neuronal Properties

Although most recent research into epileptogenesis and seizure generation has concentrated on changes in the neuronal network, alterations in intrinsic neuronal properties could also contribute to this process. Importantly, ion channel mutations in which there may be only subtle changes to the kinetics of ion channels can result in epilepsy.

As discussed in the section on the interictal spike, CA3 pyramidal cells can generate burst firing, whereas few pyramidal cells in CA1 demonstrate such firing properties. Alterations in intrinsic membrane properties can dramatically affect the firing properties of such neurons and could promote burst firing. Such burst firing in a dense excitatory network has the potential to generate synchronized bursts and may thus promote epileptic activity. In the pilocarpine model of epileptogenesis, the proportion of bursting CA1 pyramidal cells increases dramatically, such that more than half demonstrate bursting properties (Fig. 16–6) (Su et al., 2002). This may be due to upregulation of a T-type calcium channel that can produce a significant calcium tail current following an action potential, resulting in significant afterdepolarization (Su et al., 2002). Persistent sodium currents may also contribute to this propensity for bursting.

More recently, downregulation of dendritic A-type potassium channels has been found in the pilocarpine epilepsy model (Bernard et al., 2004). This downregulation is partly due to increased channel phosphorylation by extracellular signal-regulated kinase but also to decreased transcription. These potassium channels limit the back-propagation of action potentials from the soma into the distal dendrites. The functional consequence of back-propagating action potentials is likely to be an amplification of EPSPs and thus increased excitation. The effect of downregulation of A-type potassium channels on dendritic calcium spikes and burst firing is unknown.

Epileptogenesis can thus lead to an acquired channelopathy in neurons that may promote burst firing and hyperexcitability.

**Figure 16-6.** Upregulation of intrinsic burst-firing in CA1 pyramidal cells from SE-experienced versus control animals. *A*. Representative responses of CA1 pyramidal cells from sham-control (a) and SE-experienced animals (b) 30 days after pilocarpine treatment. In each panel, the responses of CA1 pyramidal cells to long (leftmost traces) and brief (rightmost traces) depolarizing current pulses (injected through the recording microelectrode) are shown. Top and bottom traces depict the neuronal response and the current stimulus, respectively. *B*. Most of the CA1 pyramidal cells in the sham-control group ( $n = 42$ ) and in the naive-control group ( $n = 15$ ) were regular firing cells, with only a small fraction displaying burst discharges to threshold stimulation (white bars). In contrast, CA1 pyramidal cells in the SE-experienced group showed a high incidence of intrinsic bursting (54%,  $n = 97$ ), with bursting neurons displaying all-or-none bursts of three to four clustered spikes in response to either brief or long current injection (Ab). (Source: Adapted from Su et al., 2002, with permission.)

### 16.2.5 Conclusion

The hippocampus through its physiological role can initiate and maintain oscillatory behavior. It is this property along with the plasticity of the hippocampus and its vulnerability to neuronal damage that contribute to the pathological role of

the hippocampus in epileptic activity. In association with neuronal damage associated with hippocampal sclerosis, there is a vast array of changes in organization, connectivity, receptors, intrinsic neuronal properties, and astrocyte function that can contribute to epileptogenicity. The great challenges are to differentiate pro-epileptogenic changes from antiepileptogenic, compensatory changes, and to determine which are the critical processes. It is likely that epileptogenesis is not a single process but that many diverse processes can result in the expression of epilepsy.

## 16.3 Alzheimer's Disease

### 16.3.1 Introduction

Alzheimer's disease (AD) is the most common cause of dementia worldwide. AD is a neurodegenerative disorder in which the accumulation of amyloid plaques and neurofibrillary tangles represents the pathological hallmark of the disease. Five million people in the United States and 400,000 in the United Kingdom are estimated to have AD, with a disease onset typically occurring early in the eighth decade of life. Disease prevalence increases with age: 1 in 2000 people aged below 60 years are affected and 1 in 200 aged over 60 years. In the elderly population the prevalence rises dramatically, with AD occurring in 20% of those aged  $\geq 80$  years and in 50% of those  $\geq 90$  years of age.

Memory loss is the predominant feature of AD. Impairment of episodic memory occurs early during the course of the disease and is usually the most prominent symptom throughout the disease course. Progressive dysfunction of other cognitive domains is also observed in AD, and the final stages of the disease are characterized by severe global impairment of cognitive function.

The neuropathological changes in AD are thought to be manifest initially in the entorhinal cortex (EC), progressing from there to the hippocampus, with increasing involvement of the neocortex as the disease progresses (Braak and Braak, 1991). However, significant neocortical pathology is already present by the time dementia is clinically diagnosed, which has prompted efforts to identify the clinical manifestations of AD in its earliest stages, when the pathological changes are primarily restricted to the medial temporal lobe structures. This has resulted in the introduction of the concept of "mild cognitive impairment" (MCI), representing the predementia stage of AD. Within the broad overview of AD provided in this chapter, particular attention is devoted to the involvement of the hippocampal formation in AD and MCI and on the implications that improved identification of this involvement has for earlier diagnosis and treatment of AD.

### 16.3.2 Clinical Features

Memory impairment of insidious onset typifies the initial stages of AD. Patients exhibit poor memory for autobiographical events, current affairs, and the names and faces of acquain-

tances. Frequently they exhibit difficulty remembering familiar routes, and “getting lost” is a commonly experienced symptom early in the disease. These early symptoms may be attributed initially to cognitive decline as a consequence of normal aging; but as the disease progresses the memory impairment becomes severe enough to disrupt activities of daily living, and patients begin to lose their functional independence. The central nature of the memory problem in AD is reflected in the National Institute of Neurological and Communicative Diseases and Stroke/Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA) criteria (McKhann et al., 1984) for the diagnosis of probable AD, which state that the presence of progressive memory impairment and impairment of at least one other cognitive function are required for a clinical diagnosis of AD. However, atypical forms of AD are well recognized, in which the prevailing symptomatology reflects dysfunction of nonmemory cognitive domains, such as speech or visuoperceptual function, but these are much less common than the classic amnestic presentation.

Impairment of other cognitive functions becomes increasingly prominent during the course of the disease. Word-finding difficulty is a relatively frequent early symptom, and speech output is often diminished. Executive functions, such as problem solving and abstract reasoning, decline progressively. Later in the disease there is impairment of word comprehension, reflecting a breakdown in semantic memory function. Other characteristic early symptoms include limb apraxias (higher order motor disorders affecting the execution of skilled or learned limb movements), impaired calculation skills, and disorders of visuospatial and visuoperceptual function. The progressive involvement of multiple cognitive domains in AD reflects the accumulation of pathological changes predominantly in the frontal, temporal, and parietal lobes; the occipital lobes are usually relatively spared in the early stages of AD.

The disorders of cognitive function are accompanied by a variety of neuropsychiatric symptoms, which include depression, changes in personality, delusions, and hallucinations, with depression often preceding diagnosis. Behavioral disturbances such as aggression, agitation, and nocturnal wandering increase with disease severity. Loss of insight is common. In the late stages of the disease, parkinsonian signs (e.g., limb rigidity, motor slowing) and various involuntary limb movements are observed, and seizures may also be observed in severe AD. Finally, patients become bedbound and entirely dependent on caretakers, and in this state they are vulnerable to intercurrent medical complications such as sepsis.

From the time that AD is diagnosed initially, the disease runs approximately 5 to 10 years until the time of death, with a mean survival of 8 years.

### Mild Cognitive Impairment

There is increasing awareness that AD may be associated with a prolonged prodromal or “preclinical” phase, during which the cognitive dysfunction is relatively subtle and circum-

scribed and insufficiently severe to warrant a diagnosis of dementia. The introduction of drug treatments for AD, in the form of the acetylcholinesterase inhibitors, has helped stimulate efforts to identify this prodromal phase in AD, culminating in the introduction of the concept of mild cognitive impairment (MCI) (Smith et al., 1996). Although there exists a degree of debate about the defining criteria for MCI, the most widely accepted criteria for the diagnosis of MCI are based on the presence of significant objective memory decline in the context of normal activities of daily living and intact function in other cognitive domains.

Figures for the prevalence of MCI in the population vary considerably, ranging from 3.0% to 16.8% depending on definitions (DeCarli 2003). Epidemiological data support the notion that MCI represents a precursor state of AD: Patients with MCI “convert” to AD at a rate of approximately 12% per annum, compared with an annual rate of 1% to 2% in the normal elderly population.

The current definition of MCI is predicated on impaired memory. However, the heterogeneity in the clinical presentation of AD suggests “amnestic MCI” that may represent a particular precursor state of AD. Future efforts to categorize the initial clinical phases of AD will include the identification of equivalent MCI states affecting other cognitive domains and will aim to differentiate MCI (due to AD) from cognitive impairment as a consequence of other cognitive disorders, as well as from the memory decline that accompanies the normal aging process. In this context, the fact that the pathological damage in the earliest phases of AD is largely restricted to the entorhinal cortex and hippocampus may be used to direct diagnostic investigations, including structural and functional neuroimaging techniques and clinical neuropsychological assessments of memory.

### Pattern of Cognitive Deficits in AD

The deficit in memory that characterizes early AD is primarily impaired episodic memory. Patients are unable to learn new material and have difficulty recalling recent events. A number of factors contribute to this disruption of episodic memory, including deficiencies in encoding and storing new information and heightened sensitivity to the disruptive effects of proactive interference. AD patients also exhibit impaired priming performance (facilitated performance by prior exposure to stimuli); patients with AD, Huntington’s disease, and Korsakoff syndrome are equally impaired on tests of verbal recognition and recall, but only AD patients show additional impairment of verbal priming, indicating that AD is also associated with a deficit of implicit memory.

Studies on the rate of long-term forgetting, or the rate of loss of memory after successful learning, have yielded conflicting results. Some studies have shown that AD patients have faster forgetting rates than either controls or patients with depression or Korsakoff syndrome (Hart et al., 1987), but others have failed to demonstrate accelerated forgetting in AD (Becker et al., 1987). Studies of retrograde amnesia in AD have

revealed that recent memories are more affected than remote memories.

The diagnostic utility of memory tests in AD varies according to the severity of cognitive impairment. In the presymptomatic phase of the disease, the tests currently considered to predict with greatest accuracy the progression to AD are tests of verbal learning and immediate visual recall. By contrast, for established AD, tests of delayed recall are most sensitive at differentiating between early AD and normal controls but are of limited value in tracking disease severity in AD because performance on these tests often declines rapidly to a plateau. Recognition memory tests, involving verbal and visual subtests, are less sensitive than recall tasks for detecting early AD but are more useful for staging disease severity.

Disorders of speech and language also occur early in the course of AD. Word-finding difficulty is often the first problem to become manifest, and it is associated with compensatory circumlocution. Naming is initially preserved but becomes progressively more impaired during the course of the disease. Neologisms, verbal and literal paraphasias, also become more prominent and are accompanied by loss of word comprehension, reflecting a breakdown of verbal semantic knowledge. Severe AD may be associated with palilalia (the repetition of words and phrases) and logoclonia (repetition of the final syllable of a word), and speech may deteriorate into unintelligibility. Ultimately, some patients may become entirely mute.

Topographical disorientation is another characteristic early feature of AD. Patients complain of “getting lost,” initially only in unfamiliar environments, but subsequently they experience difficulty finding their way around familiar places, including their own homes. The presence of topographical disorientation may help differentiate early AD from other dementias; for instance, patients with frontotemporal lobe degeneration, typified by focal atrophy of the frontal and anterior temporal lobes, typically do not get lost. This topographical disorientation in AD has been variously ascribed to impaired visuospatial function as a result of damage to the parieto-occipital region; to topographical agnosia, representing an impairment of the ability to recognize those cues or landmarks that are required to permit successful navigation through an environment; and to an impaired memory for places as a consequence of damage to the hippocampus or parahippocampal regions. The last possibility is consistent with the observation that the medial temporal lobe structures are preferentially affected in the earliest stages of the AD disease process.

Apraxia (impairment of sensorimotor integration due to disorders of higher cerebral function) is observed in most patients with mild to moderate AD. Ideational apraxia, in which there is an inability to construct the idea of a purposeful movement, such that patients are unable to perform these movements (e.g., using a manual tool), may occur as a result of damage to the parietal and frontal association areas, particularly in the left hemisphere. Ideomotor apraxia, in which the construct of a purposeful movement is intact but the execution of the movement is faulty, is associated more

with damage to the parietal association areas as well as damage to the premotor cortex and the supplementary motor areas.

Visual agnosia (inability to recognize objects) is a common feature of AD in its more advanced stages and results from damage to the visual association areas. Subtypes of visual agnosia include apperceptive agnosia, in which the disorder of object perception is exemplified by difficulty recognizing unusual views of common objects; it is typically associated with damage to the right parietal lobe. In associative agnosia, there is no perceptual deficit but, instead, inability to assign the correct semantic meaning to the perceived objects, resulting again in misidentification of objects. In this instance, the cortical damage most frequently involves the left occipitotemporal region. More specific forms of agnosia include prosopagnosia, in which there is impairment of familiar face recognition, typically associated with damage to the right temporal lobe.

Together, amnesia, aphasia, apraxia, and agnosia form the core disorders of cognitive function in AD. However, the global nature of the cortical involvement in established AD is reflected in a multitude of additional cognitive deficits, prominent among which are disorders of attention and calculation. The involvement of the frontal lobes in the pathological process results in “neurological” symptoms such as impaired executive function and reduced problem-solving ability, as well as a variety of “neuropsychiatric” symptoms including changes in personality and disturbances of social conduct.

### Structural Imaging

Generalized cerebral atrophy is a characteristic gross pathological feature of AD. The utility of cerebral atrophy as a biomarker of disease is reflected in the NINCDS-ADRDA diagnostic criteria (McKhann et al., 1984), which state that the diagnosis of probable AD is supported by “evidence of cerebral atrophy on CT or MRI and progression documented by serial observation.” The presence of cerebral atrophy in AD may be determined using a variety of techniques. Qualitative assessment of brain atrophy (visual inspection of brain scans) has the benefit of general applicability but the disadvantage of wide interobserver variability. Of the various quantitative techniques currently in use, volumetric analyses have been shown to have greater diagnostic specificity and sensitivity than linear measurements of atrophy. Analyses may be cross-sectional (i.e., based on a single scan) or longitudinal (repeated measurements performed over serial scans). The diagnostic utility of data obtained from cross-sectional imaging studies is limited by the variability in brain size among individuals, reflecting differences in head size in the normal population, and by the reduction in total brain volume that occurs as a consequence of normal aging. Longitudinal studies have greater diagnostic specificity and sensitivity than cross-sectional studies but are necessarily disadvantaged by the need for at least two scans and as a consequence cannot

provide corroborative information at the time of the initial diagnostic inquiry.

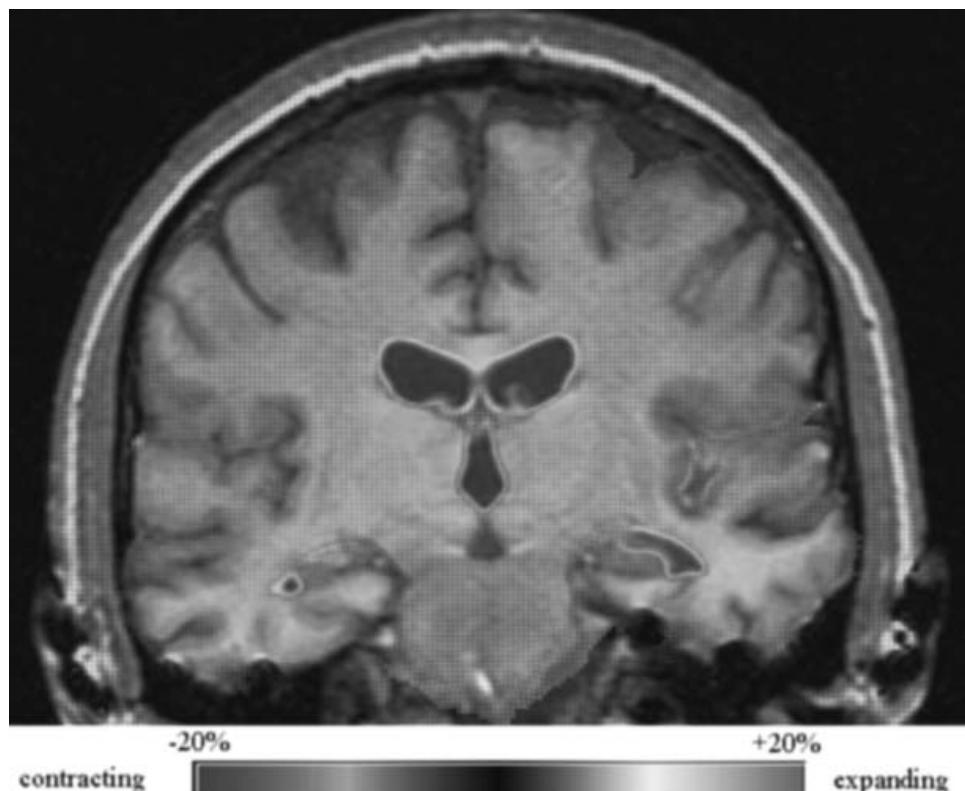

Most volumetric MRI studies have relied on manual segmentation of brain regions of interest. Information on the structural brain changes in AD can also be obtained using semiautomated, increasingly sophisticated techniques such as voxel-based morphometry, in which the distribution of atrophy in the AD brain is determined by comparison with a nonatrophied "template" brain (Good et al., 2002), and fluid registration MRI, in which longitudinal patterns of atrophy throughout the brain can be observed by tracking the brain changes over time on a voxel-by-voxel basis (Fox et al., 2001) (Fig. 16-7, see color insert).

Prior understanding of the pattern of pathological involvement of the cerebral cortex has prompted the assessment of regional brain volume measurements in AD as an alternative to measurements of whole-brain volume. Most studies have concentrated on the medial temporal lobe, but other researchers have investigated structures such as the frontal lobes, the cingulate gyrus, the superior temporal gyrus, and the corpus callosum. As with the measurement of whole-brain atrophy, there are several methods for assessing atrophy of the medial temporal lobe structures. They include the use of a visual rating scale for medial temporal lobe atrophy, in which

the degree of atrophy is classified according to a five-point grading scale following visual inspection of MRI scans (Wahlund et al., 2000). Linear measures of atrophy include measuring the height of the hippocampus and parahippocampal gyrus, the interuncal distance, and the width of the temporal horn of the lateral ventricle. Area measurements include changes in the cross-sectional area through the hippocampus and in the surface area of the entorhinal cortex. Of these various measurement techniques, perhaps the most useful in the clinical domain is that based on visual rating of medial temporal lobe atrophy, which has benefits in terms of ease of use and widespread applicability and compares favorably with quantitative volumetric analysis in the diagnostic differentiation of patients with AD.

**Hippocampus.** In recent years increasing emphasis has been devoted to volumetric analyses of structural change derived using quantitative MRI techniques, with the hippocampus representing the primary region of interest in most instances. The use of volumetric MRI measures of hippocampal atrophy as surrogate markers of disease in AD is validated by the demonstration of a strong correlation between MRI-determined hippocampal volumes and neuronal numbers in the hippocampus in AD (Bobinski et al., 1999). A number of

**Figure 16-7.** Coronal MRI at the mid-hippocampal level using voxel-compression mapping overlay to show the change in brain volume over 12 months in a patient with Alzheimer's disease (AD). Particular features to note are the marked involvement of the temporal lobes including the hippocampi, the relative symmetry of the structural changes, and the diffuse involvement of both gray and white matter.

studies have demonstrated that AD is associated with significant hippocampal volume loss. Data from cross-sectional studies are complemented by longitudinal data indicating that AD is associated with an increased rate of hippocampal atrophy (Jack et al., 1998). Although most of these studies have concentrated on the structural changes in patients with established dementia, hippocampal atrophy has also been found to be present in the presymptomatic stage of AD, as determined by scan data acquired on familial AD (FAD) patients prior to symptom onset (Convit et al., 1997).

Determination of hippocampal atrophy can distinguish AD from normal aging with a high degree of specificity and sensitivity. At a fixed specificity of 80%, the sensitivity of hippocampal volumetric measurements for differentiating patients with mild-to-moderate AD is approximately 88% (Jack et al., 1997).

Several imaging techniques have been applied to the hippocampus in recent years. MRI-based high-dimensional brain mapping (Csernansky et al., 2000) is a technique in which a control MRI template is transformed onto individual scans in such a way that changes in the shape of the hippocampus are detectable. Using this technique, AD was found to be associated with a symmetrical deformity of hippocampal shape that differentiated it from the morphological changes seen with normal aging. The particular deformities affecting the head of the hippocampus and along the lateral aspect of the body of the hippocampus are consistent with pathological changes affecting the CA1 field in AD. A similar technique was subsequently used by the same authors to demonstrate hippocampal deformations in patients with mesial TLE (Hogan et al., 2004).

A technique has also been developed for visualizing neuritic plaques in autopsy-acquired human brain tissue using magnetic resonance (MR) microscopy, which provides greater spatial resolution than MRI (Benveniste et al., 1999). Technical limitations currently militate against *in vivo* application, but advances in scan technology may permit the future use of a similar technique in the antemortem diagnosis of AD.

**Entorhinal Cortex.** In view of the early, severe involvement of the EC in the AD pathological process, it has been argued that EC atrophy may be a more sensitive marker of AD than hippocampal atrophy. However, the theoretical benefits of assessing EC volume changes in AD are partially offset by the difficulty of determining with confidence the boundaries of the EC on MRI scans, which have led some to undertake measurements of the parahippocampal gyrus (which contains the EC in its entirety) instead, with the presence of atrophy in this structure taken as a surrogate marker of EC atrophy. Despite these perceived difficulties, a technique for delineating the EC from volumetric MRI scans was developed (Insausti et al., 1998) using the cytoarchitectonic boundaries of the EC as the guidelines for segmentation of the EC volume. In various modified forms (modifications in segmentation protocol resulting primarily from the difficulty of establishing the medial border of the EC at the junction with the perirhinal

cortex along the medial lip of the collateral sulcus), this technique has been used to demonstrate significant bilateral EC atrophy in established AD (Fig. 16–7, see color insert). Longitudinal studies on AD patients, with volume measurements of the EC and the hippocampus performed on scans with an average scan interval of 21 months, reveal a significantly greater rate of atrophy affecting the EC (mean annual volume loss 7.1% per annum) than the hippocampus (mean annual volume loss 5.9%), which would support the idea that the pathological changes in AD are more severe in the EC than in the hippocampus.

**Structural Imaging in MCI.** Neuroimaging studies reveal that MCI is also associated with atrophy of the EC and the hippocampus. Volumetric MRI analysis indicates that there is a progression of atrophy of these structures from normal aging through MCI to AD; the degree of atrophy in these structures is sufficiently great to differentiate effectively between MCI patients and age-matched controls and between MCI and AD patients, with significantly greater atrophy observed in the latter group. The etiological relation between MCI and AD is underlined further by the observation that the presence of hippocampal atrophy in MCI patients is predictive of future conversion to AD (Jack et al., 1999).

A comparison of hippocampal and EC volumes in normal control subjects, patients with MCI, and patients with early AD revealed that assessment of EC volumes is most effective for discriminating between control subjects and MCI patients, whereas measurement of hippocampal volumes provided better discrimination between patients with MCI and those with AD, which suggests that atrophy of the EC precedes that of the hippocampus and is more pronounced in the initial stages of AD (Pennanen et al., 2004).

**Medial Temporal Lobe Atrophy in Non-Alzheimer Dementias.** Atrophy of medial temporal lobe structures discriminates effectively between AD and age-matched controls but is less effective at differentiating between AD and other diseases that cause dementia. Hippocampal atrophy has been found in other neurodegenerative disorders such as dementia with Lewy bodies and frontotemporal lobar degeneration (FTLD), as well as in vascular dementia. With regard to the latter, the determination of hippocampal atrophy to differentiate between different dementias is complicated further by the frequent coexistence of AD and vascular pathology. With regard to other temporal lobe structures, atrophy of the EC has also been observed in FTLD and, in particular the clinical subtype of FTLD described as semantic dementia (SD). In this instance, the severity of EC atrophy exceeds that noted in AD patients of comparable disease severity, although the atrophy is predominantly left-sided, in keeping with the language dominance of the left hemisphere (Chan et al., 2001).

The fact that the presence of hippocampal or EC atrophy alone is insufficiently specific to discriminate effectively between these disorders suggests that greater diagnostic differentiation may require evaluation of the particular distribution

of atrophy in these regions. One example of this is provided by the left/right asymmetry of medial temporal lobe atrophy in SD, which contrasts with the symmetrical atrophy that is typical of AD. An alternative approach is to examine the distribution of atrophy in regions of interest. For instance, in AD there is an even distribution of atrophy along the rostrocaudal length of the hippocampus, whereas in SD there is asymmetrical atrophy affecting primarily the rostral portion of the left hippocampus.

**Memory Impairment and Medial Temporal Lobe Atrophy in Alzheimer's Disease.** Deficits of episodic memory correlate with atrophy of the hippocampus but not with atrophy of structures outside the medial temporal lobe, such as the caudate nucleus and the lateral temporal cortex. Although differing results have been observed across a number of studies, partly as a consequence of differences in methodology and in data interpretation, most studies have revealed that performance on tests of memory correlate with hippocampal volume but not with the volumes of the amygdala or of the whole temporal lobe. Hemispheric differences are also found; the volume of the left hippocampus has been found to correlate with verbal recall, whereas the volume of the right hippocampus correlates with performance on tests of visual or spatial recall. Studies of the relation between hippocampal volume and immediate and delayed recall have yielded differing results: In one study, hippocampal volumes correlated with both recall tasks (de Toledo-Morrell et al., 2000), whereas in another a positive correlation was observed between the volumes of the hippocampus and parahippocampal gyrus with delayed, but not immediate, recall (Kohler et al., 1998). The volume of the right parahippocampal gyrus was positively associated with delayed visual recall. Hippocampal and parahippocampal gyrus volumes have also been found to correlate with a different verbal learning task (Libon et al., 1995).

In summary, most studies attempting to correlate the memory deficits in AD with atrophy of specific brain regions have implicated the hippocampus as the main region of interest. The difficulty of establishing the nature of the memory task that provides the best correlation with hippocampal volume in AD are reminiscent of the problems experienced in the clinical setting with identifying the memory tests that are most able to detect early AD.

### Functional Imaging

The neuronal death and the dysfunction of surviving neurons in affected brain regions in AD results in a reduction in neuronal activity, which in turn produces an alteration in metabolic demands, with a lowering of glucose metabolism and oxygen uptake. Cerebral blood flow (CBF) to affected brain regions is likewise reduced. Cerebral hypometabolism and hypoperfusion are detectable using various functional imaging techniques, and the information derived from functional imaging complements the structural data obtained from com-

puted tomography (CT) and MRI. To date, most of the functional imaging studies in AD have compared patients with AD with age-matched normal control subjects rather than with patients with other neurodegenerative disorders.

**Positron Emission Tomography.** Cerebral glucose metabolism can be measured by positron emission tomography (PET) imaging of the radioactive tracer  $^{18}\text{F}$ -fluorodeoxyglucose ( $^{18}\text{F}$ -FDG). PET can also be used to measure oxygen metabolism or CBF using  $^{15}\text{O}_2$ - or  $^{15}\text{O}_2$ -labeled water. Statistical parametric mapping (SPM) (Friston et al., 1995) is commonly used to analyze scan data on a voxel-by-voxel basis.

Positron emission tomography (PET) scans in AD demonstrate bilateral temporoparietal hypometabolism and hypoperfusion. The reductions in CBF and oxygen uptake have been found to correlate with the severity of the dementia. A number of studies have demonstrated correlations between memory scores and metabolism or blood flow in AD, and an association between hippocampal atrophy and regional glucose metabolism has also been demonstrated. In advanced AD, hypoperfusion changes are more widespread and additional reductions in CBF are seen in the frontal lobes.

The efforts to identify the earliest structural abnormality in AD using MRI are mirrored by studies performed using functional imaging paradigms. These have shown that hypoperfusion of the EC in cognitive normal elderly subjects is predictive of progression to MCI (de Leon et al., 2001), indicating that abnormalities of brain function may be detected at the very earliest stages of the disease.

The relation between the functional imaging data obtained from PET studies and data from structural imaging studies remains unclear. Although both imaging modalities have identified abnormalities involving the EC in the earliest stages of AD, PET studies have also shown hypofunctioning of the temporoparietal regions and the posterior cingulate cortex in early AD, whereas structural scans have revealed atrophy predominantly affecting the medial temporal lobe regions at this stage of the disease process. Given that these regions receive significant inputs from the hippocampal formation, it is possible that the PET data reflect a disconnection syndrome, in which deficits are observed in regions with disturbed activity due to reduced afferent input from damaged regions upstream in the projection. An alternative explanation for this apparent discrepancy might rest with methodological considerations. With regard to the structural imaging data, reproducible and easily validated protocols for the measurement of brain volumes are primarily restricted to the temporal lobe structures, within which atrophy is also readily detected on visual inspection. By contrast, the anatomical landmarks of regions such as the posterior cingulate gyrus are less easily identified on MRI, as a consequence of which volume loss in these regions is more difficult to detect and may therefore be underreported. In terms of the PET data, the absence of observed hypometabolism in the hippocampus and parahippocampal regions in early AD may reflect in part the low spa-

tial resolution of the current generation of PET scans. Finally, the nature of the relation between regional brain atrophy and detection of regional hypofunction has yet to be established fully for progressive degenerative disorders such as AD.

In one study, Klunk et al. (2004) employed PET imaging using a novel tracer, named Pittsburgh compound-B (PIB), designed as a marker for brain amyloid. In patients with early AD, PET scans demonstrated increased retention of PIB (compared with control subjects) in regions of association cortex that are known to contain significant numbers of amyloid deposits. By contrast, there was no significant difference in PIB retention between AD patients and controls in those brain regions largely devoid of amyloid deposition, such as the cerebellum. The evidence from this study that PET, in conjunction with targeted tracer compounds, may be used to provide quantification of the pathological changes in AD raises the possibility that PET may be used in the future to detect, and possibly to track over time, the key pathological changes in AD.

**Single Photon Emission Computed Tomography.** Single photon emission computed tomography (SPECT) has an advantage over PET in that it is less expensive and more widely available, but it is less informative in that it provides only semiquantitative perfusion images and has poorer spatial resolution. CBF is measured by detection of radioactive tracers such as the lipophilic technetium  $^{99m}\text{Tc}$ -hexamethyl propyleneamine oxamine ( $^{99m}\text{Tc}$ -HMPAO). There is a reduction in CBF in the temporoparietal regions of patients with mild-to-moderate AD (Battistin et al., 1990), with a correlation between the reduction in blood flow and hippocampal atrophy. However, the low diagnostic sensitivity and relatively poor spatial resolution of SPECT has limited its use as a diagnostic tool.

**Functional MRI.** The different magnetic properties of oxygenated and deoxygenated blood can be measured using the technique of blood oxygen level-dependent (BOLD) functional MRI (fMRI), with increased levels of blood oxygenation resulting in greater signal intensity. As with PET, fMRI scan data can be analyzed using SPM.

During a verbal episodic memory task patients with mild AD showed reduced activation of anterior prefrontal cortex when compared with control subjects and, instead, exhibited increased activation in a number of other brain regions, with the latter believed to represent compensatory reallocation of brain resources in response to the frontal lobe dysfunction. In a cued recall task, AD patients failed to demonstrate any increased activity in the left hippocampus—a phenomenon observed in control subjects—but, instead, were found to have increased activity in other cortical regions. These observations of increased functional activation during cognitive tasks as compensation for dysfunction of brain regions normally associated with those tasks raises the possibility that fMRI may be used in the diagnosis of AD. Functional brain changes have also been detected prior to the clinical onset of AD; subjects at

risk for AD exhibit different patterns of brain activation in the absence of any clear cognitive impairment.

Particular attention has been devoted to the regional activation patterns with the hippocampal formation in view of the early pathological involvement of the hippocampus in AD. A comparison of the fMRI activation patterns in patients with AD and patients with isolated memory decline reveals that AD patients exhibit reduced activation in all hippocampal regions. By contrast, patients with selective memory impairment either exhibited diminished activation in all hippocampal regions (similar to the pattern observed in AD) or reduced activation affecting only the subiculum. In the latter cases, the preferential involvement of the subiculum in these cases may reflect neuronal loss in the subiculum or loss of input to the subiculum in patients at risk of developing AD.

The observation that regional BOLD fMRI activation correlates with excitatory input, as manifested by the EPSP, rather than the regional output (spiking activity), suggests that reductions in regional fMRI activation patterns in AD may reflect damage in upstream neuronal populations providing excitatory inputs to the region in question (Logothetis et al., 2001). However, several outstanding issues remain with regard to the association of abnormal fMRI activation and structural pathology in AD. Specifically, the relation between fMRI activation and cerebral atrophy, as demonstrated on structural MRI, remains unclear, particularly in terms of the potential confounding effect of atrophy on fMRI activation patterns. In addition, the presence of vascular pathology in AD may represent another confounding factor in fMRI analysis in that changes in activation may be attributable to alterations in hemodynamic response as well as to changes in neural activity.

**Magnetic Resonance Spectroscopy.** Detection of changes in the concentration of brain metabolites using magnetic resonance spectroscopy (MRS) represents an alternative imaging modality that can be applied to disease states affecting the brain. Two metabolites that are of greatest interest are *N*-acetyl aspartate (NAA) and myoinositol (MI), which are markers of neuronal and glial cell metabolism, respectively. MRS has demonstrated levels of NAA that are reduced by 10% to 15% in AD, with the magnitude of metabolite reduction correlating with disease severity. Other studies (Jessen et al., 2000) have shown a 15% to 20% increase in MI, and a combination of NAA and MI measurements increases the ability of MRS to differentiate AD from normal aging. At present, MRS is less useful for distinguishing AD from other neurodegenerative diseases, and the utility of this imaging technique beyond the research domain has yet to be established.

### 16.3.3 Genetics

Most AD cases occur in sporadic form, with familial AD (FAD) accounting for less than 5% of all cases. Apart from the earlier age at onset (typically before the age of 65 years) no consistent differences in the clinical features of sporadic and

familial AD have been identified. This similarity in clinical presentation has underpinned the belief that greater understanding of the defects occurring as a result of the genetic mutations associated with FAD will, in turn, yield key insights into the mechanisms of disease in AD.

### Amyloid Precursor Protein

Most cases in which the patients have early-onset AD (aged  $\leq$  50 years) are attributable to familial forms of AD. Causative genetic mutations have been identified in these cases. The first reported FAD-associated mutations were those in the amyloid precursor protein (APP) on chromosome 21 (Chartier Harlin et al., 1991). The exact function of APP remains undetermined, with a role in growth promotion, signaling mechanisms, and cell adhesion having been variously suggested (Breen et al., 1991; Milward et al., 1992; De Strooper and Annaert, 2000). APP is cleaved at its N- and C-termini by  $\beta$ - and  $\gamma$ -secretases, respectively, to produce the peptide A $\beta$ , comprising 40 to 42 amino acids, which is the main constituent of the amyloid plaques in AD. Despite the uncertainty over the role of APP, its role in the pathogenesis of AD appears unequivocal; all currently identified mutations of the APP gene result in an increased amount of A $\beta$  or an increased proportion of A $\beta$  containing 41 or 42 amino acids, which are more amyloidogenic and therefore predispose to the formation of amyloid plaques.

### Presenilins

The APP mutations account only for a small proportion of early-onset FAD. Most of these cases are caused by mutations of the *PS1* gene on chromosome 14, coding for the protein presenilin 1 (PS1). In all, *PS1* mutations are responsible for 30% to 50% of all cases of familial AD. Shortly after the discovery of the *PS1* gene, a second presenilin gene, *PS2*, on chromosome 1 was identified (Li et al., 1995). Known *PS2* mutations account for less than 10% of all FAD cases. More than 50 different mutations of *PS1* have been described, but to date only two causative *PS2* mutations have been identified.

The presenilins are transmembrane domain proteins. As with APP, the function of the presenilins remains unclear, although some clues can be derived from understanding the function of the homologous proteins SEL-12 and SPE-4 in *Caenorhabditis elegans*. SEL-12 is involved in receptor trafficking and localization, mediated via the *lin-12/Notch* pathway, and SPE-4 plays a role in intracellular protein sorting during spermatogenesis. The demonstration of a relation between PS1 and  $\gamma$ -secretase function (De Strooper et al., 1999) has fueled speculation that PS1 represents  $\gamma$ -secretase or that PS1 and  $\gamma$ -secretase form part of a macromolecular complex that mediates the cleavage of APP. Accordingly, presenilin mutations may alter the membrane conformation of APP, resulting in a different position of cleavage by  $\gamma$ -secretase; and thus generation of the more amyloidogenic forms of A $\beta$ . The

observation that mice underexpressing PS1 exhibit a reduction in LTP following repeated tetanic stimulation of the CA1 region (Morton et al., 2002) suggests that PS1 is also implicated in the maintenance of LTP.

### Apolipoprotein E

Linkage to chromosome 19 was observed in families with late-onset FAD (Pericak-Vance et al., 1991). The responsible susceptibility gene was found to encode for apolipoprotein E (ApoE), a 299-amino-acid lipid transport protein that mediates the intracellular uptake of lipids through binding to the low density lipoprotein (LDL) receptor. Three alleles for the ApoE gene exist: *APOE- $\epsilon$ 2*, *APOE- $\epsilon$ 3* (the common form), and *APOE- $\epsilon$ 4*. The likelihood of developing AD has been found to correlate with the number of *APOE- $\epsilon$ 4* genes (Saunders et al., 1993);  $\epsilon$ 4 heterozygotes had a greater risk and earlier disease onset than non- $\epsilon$ 4 individuals, and  $\epsilon$ 4 homozygotes had the greatest risk of all. Homozygous  $\epsilon$ 4 patients were also found to have a greater number of amyloid plaques than patients homozygous for the  $\epsilon$ 3 allele. When compared with age-matched normal controls (in whom the  $\epsilon$ 4 allele is found in 16% of cases), the presence of the  $\epsilon$ 4 allele is more frequent in both late-onset AD with a positive family history (52% of all cases) and sporadic AD (40% of all cases).

One theory concerning the role of ApoE4 in the pathogenesis of AD proposes that ApoE4 binds more easily to A $\beta$  than ApoE3, resulting in increased deposition of amyloid in plaques. Another theory is based on the observation that ApoE4 binds less well to the microtubule-associated protein tau than ApoE3 or ApoE2. This has the effect of destabilizing microtubules, which in turn results in the formation of neurofibrillary tangles.

### 16.3.4 Pathophysiology

#### Neuropathology

On macroscopic examination, the AD brain can vary in appearance from normal to severely atrophic, with cases of early-onset AD often exhibiting the most marked atrophy. Typically, the AD brain features widening of the sulci and ventricular enlargement, which is most prominent in the lateral ventricles. There is generalized atrophy of the cerebral cortex, but closer inspection of the temporal lobes may reveal a greater degree of atrophy affecting the amygdala, hippocampus, and parahippocampal gyrus.

The definitive diagnosis of AD relies on the demonstration of histological features that were first described around the turn of the twentieth century. Most prominent among them are the amyloid plaques and neurofibrillary tangles, and their significance is reflected in the various published criteria for the pathological diagnosis of AD, which are based on an evaluation of the frequency of neuritic plaques, on quantitative assessment of both plaques and tangles, and most recently on the number of tangles and neuropil threads in the cerebral

cortex. Other pathological changes in AD include granulovacuolar degeneration and Hirano bodies, both of which primarily affect the hippocampus, as well as amyloid angiopathy and in severe AD mild spongiosis. Little is known about the pathogenesis of granulovacuolar degeneration or Hirano bodies or their relation to the natural history of AD, but the predominance of hippocampal involvement in both instances may provide another explanation for the prominence in AD of symptoms of hippocampal dysfunction.

**Amyloid Plaques.** Extracellular amyloid plaques (APs) are visualized best using silver stains or immunohistochemical techniques using an antibody to A $\beta$ . APs are divided into two main types: diffuse plaques and neuritic plaques. Diffuse plaques are composed of homogeneous deposits of fibrillary material but contain only scant numbers of amyloid fibrils and do not stain with the Congo red stain for amyloid. Neuritic plaques are more heterogeneous in composition, with a central dense core of amyloid fibrils surrounded by glial and abnormally swollen neuritic processes, occasionally containing paired helical filaments. Neuritic plaques stain with Congo red. The two types of plaque differ crucially in that the A $\beta$  in neuritic plaques occurs in the form of insoluble, possibly neurotoxic  $\beta$ -pleated sheets. APs are observed mainly in the neocortex, with only small numbers seen in the hippocampal formation during the early stages of AD; plaque density in the cortex increases with disease severity, although the progression of AP deposition does not follow a clear hierarchical pattern (Arriagada et al., 1992).

**Neurofibrillary Tangles.** Neurofibrillary tangles (NFTs) are found in the perikarya of neurons. They are stained with the Bielschowsky silver stain (a stain for thioflavine S) and by immunohistochemistry using an antibody to the tau protein. They are commonly flame-shaped in appearance and occupy the cell body and proximal portion of the apical dendrite of the affected neuron. NFTs are usually intraneuronal but occasionally extracellular and represent the insoluble remains of a dead neuron (the “ghost tangle”). Ultrastructural examination reveals that NFTs are primarily comprised of paired helical filaments, which are composed of a number of proteins including tau,  $\beta$ -amyloid, ubiquitin, and neurofilament proteins such as actin.

A hierarchical staging system for the neuropathological changes in AD has been elaborated based on the distribution of NFTs in the cerebral cortex (Braak and Braak, 1991). The first neurons to exhibit NFTs and neuropil threads (NTs)—straight and paired helical filaments composed of abnormally phosphorylated tau protein—are the pre-alpha projection neurons in the transentorhinal cortex, a transition zone between the entorhinal cortex and the adjacent isocortex. Other areas with early development of NFTs are the entorhinal cortex (EC) and field CA1 of the hippocampus. In stages I and II (the “transentorhinal stages”) these minor pathological changes are restricted to the EC and hippocampus. Stages III and IV (the “limbic stages”) are characterized by moderate

numbers of NFTs and NTs in the transentorhinal cortex, EC, and CA1, with additional scant numbers of NFTs in CA4, the subiculum, and the parasubiculum. Small numbers of NFTs and NTs are also found in association cortices. In stages V and VI (the “isocortical stages”) all hippocampal subfields and isocortical association areas are severely affected. The progression of these pathological changes is depicted in Figure 16–8, see color insert.

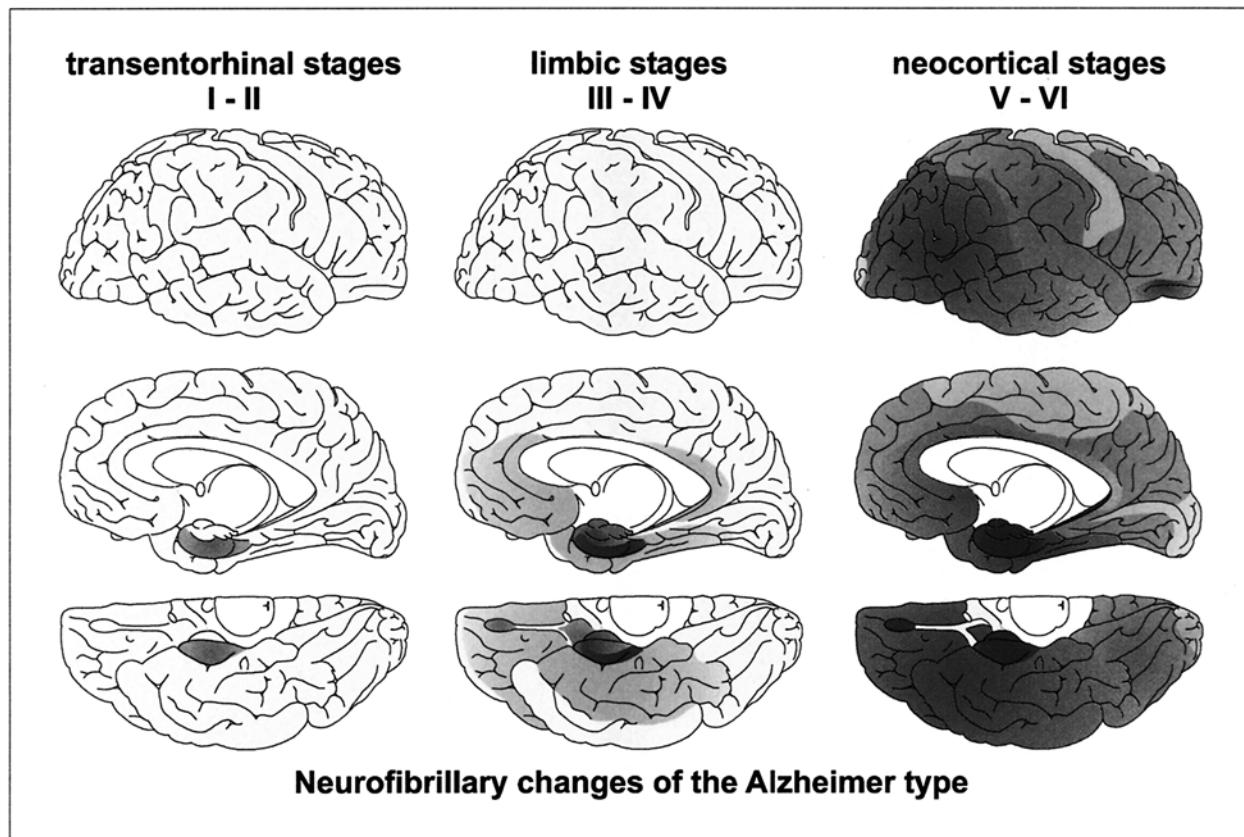

**Granulovacuolar Degeneration.** In marked contrast to the widespread distribution of APs and NFTs, granulovacuolar degeneration is restricted primarily to one neuronal population: the pyramidal cells of the hippocampus. This pathological change is observed in up to 50% of AD cases. Vacuoles (3–5  $\mu\text{m}$  diameter) are found in the cytoplasm of the pyramidal neurons, either singly or in combination. Within each vacuole is an electron-dense granular core. These features can be seen on light microscopy using either silver staining or hematoxylin and eosin (H&E) preparations.

Granulovacuolar degeneration is not specific to AD. It is also a pathological feature of other neurodegenerative disorders such as amyotrophic lateral sclerosis (ALS) and the Parkinson-dementia–ALS complex of Guam and has been found in young adults with Down’s syndrome.

**Hirano Bodies.** Hirano bodies are ovoid eosinophilic inclusions about 10 to 30  $\mu\text{m}$  in length. They can be visualized using the H&E stain. They are most commonly observed adjacent to the hippocampal pyramidal cells, when they indent the neuronal perikaryon, although they can also be found in isolation in the stratum lacunosum. Electron microscopy reveals that Hirano bodies are comprised of parallel filaments 60 to 100 nm in length.

Hirano bodies have been observed in many disorders as well as in the aged normal brain. Although they are most commonly seen in the hippocampus, Hirano bodies have been observed in most other structures of the CNS.

**Medial Temporal Lobe Pathology in Alzheimer’s Disease.** *Entorhinal cortex:* Within the EC, the stellate cells of layer II are the first to exhibit NFTs and NTs. These cells are consistently involved in AD. In one study of patients with pathological diagnoses of definite AD, severe infiltration of stellate cells by NFTs was observed in 100% of cases (Hyman et al., 1990). These degenerative changes are accompanied by neuronal loss, which is prominent even in the early stages of AD. By late AD, severe loss of layer II cells is observed. Examination of the perforant path reveals a number of associated changes. Myelin cuffing and argyrophilic degenerative changes are seen throughout the course of the perforant path as well as in its termination zone in the outer two-thirds of the molecular layer of the dentate gyrus. Increased acetylcholinesterase staining in the outer two-thirds of the dentate molecular layer suggests that there is partial cholinergic reinnervation of the hippocampus in response to the deafferentation of the dentate gyrus.

**Figure 16-8.** Distribution patterns of neurofibrillary changes in AD, including both neurofibrillary tangles and neuropil threads. In stages I and II the pathological changes are largely restricted to the transentorhinal region (tangles may also be found in CA1). Stages III and IV are characterized by severe involvement of the transentorhinal and entorhinal regions, with additional changes

in CA1 and the subiculum. The isocortex is minimally affected. In stages V and VI the entire hippocampal formation is involved, with severe neuronal loss in CA1. The temporal lobes and cortical association areas are severely affected, but typically there is relative sparing of the primary sensory cortices. (Source: Courtesy of Dr. Heiko Braak.)

Of the other layers of the EC, NFT formation is observed in most of the pyramidal cells of layer IV. By contrast, significantly fewer NFTs are observed in layers III, V, and VI, although in layer III the superficial layer of neurons is more severely affected, compounding the disruption of perforant path input to the hippocampus. Assessment of neuritic plaque density reveals a different pattern of laminar involvement, with most plaques observed in layer III. Layers IV, V, and VI are associated with similar plaque density, but relatively few plaques are seen in layer II. Neither NFTs nor neuritic plaques have been demonstrated in layer I.

**Hippocampus:** Of the hippocampal subfields, NFT and AP density is greatest in CA1 and the subiculum. The CA1/subiculum interface zone is particularly affected, with large number of plaques and tangles observed in all cases. In CA3 and CA4, only small numbers of plaques and tangles are observed. The outer two-thirds of the molecular layer of the dentate gyrus is heavily infiltrated by NFTs and neuritic plaques, and NFTs are also seen in the dentate granule cells. Pathological changes in the mossy fiber zone are negligible. In stark contrast to the subiculum, NFTs and plaques are largely absent from the presubiculum. In terms of the hierar-

chical staging of AD pathology, the CA1 pyramidal cells are the first hippocampal neurons to exhibit changes and, in fact, represent the second neuronal population to be affected in AD, after the stellate cells of the EC. The nonpyramidal cells of CA4 and the subicular neurons are next to be affected; the granule cell layer of the dentate gyrus, CA3, and the presubiculum are involved only in the late stages of AD. Interestingly, NFTs are observed in the inner third of the dentate molecular layer in the most severely affected AD cases, which suggests that in the late disease stages there is additional deafferentation of the input to the dentate gyrus from the hilar cells. Although the hippocampus is affected throughout its extent, morphometric studies have found that there is a proportional increase in the number of neurons exhibiting NFTs and granulovacuolar degeneration in the posterior hippocampus when compared with the distribution of changes observed in the hippocampi of age-matched control subjects (Ball, 1987).

The degree of overall hippocampal pyramidal cell loss in AD has been estimated to be around 43% to 47%, with an increase in neuronal loss correlating with disease severity. Some disagreement exists with regard to the distribution of

neuronal loss affecting the hippocampus proper; some observers have reported that the greatest proportion of neuronal loss occurs in CA1, with additional neuronal loss observed in CA4, the subiculum, and the prosubiculum and relative sparing of the dentate granule cells and neurons in CA3 and CA2 (Doebler et al., 1987; West et al., 1994). In a later study, no significant difference was noted in the amount of cell loss in CA1 in AD and normal aging; instead, the greatest differences in neuronal numbers were observed in the granule cell layer and the subiculum (Simic et al., 1997). An inverse correlation exists between hippocampal neuronal density and the number of neurons with NFT infiltration or granulovacular degeneration. In terms of the clinical significance of the severity of hippocampal involvement, the degree of neuronal loss in CA1, CA4, and the subiculum is found to correlate with the duration and severity of AD.

**Amygdala:** In the amygdala, NFT density is highest in the accessory basal and cortical nuclei and lowest in the medial, lateral, and central nuclei. APs were most prominent in the accessory basal and medial basal nuclei and least numerous in the medial, lateral, lateral basal, and central nuclei. Neuronal loss is greatest in the medial group of nuclei. The projections between the amygdala and the hippocampal formation are severely disrupted in AD: There is a prominent afferent projection from the accessory basal nucleus both to the hippocampus and to layer III of the EC. The return projection to the amygdala arises primarily from CA1, the subiculum, and layer IV of the EC, all of which exhibit marked pathological damage.

**Pathological Changes in MCI.** Postmortem analysis reveals that the pathological changes associated with MCI primarily affect the EC and the hippocampus. Patients with very mild dementia at the time of death exhibit severe neuronal loss primarily affecting layer II, with neuronal numbers being reduced by almost 60% (Gomez-Isla et al., 1996). In layer IV, there is a 40% reduction in neuronal numbers, whereas layers I, III, and V are less affected. The degree of neuronal loss is greater in cases of severe dementia, with the drop in neuronal counts in layers II and IV rising to about 90% and 70%, respectively. These reductions in neuronal numbers are accompanied by increased deposition of NFTs and neuritic plaques. A comparison of the severity of EC pathology in MCI and AD reveals that AD is associated with greater volume loss affecting layer II, but the absence of any corresponding decrease in the number of layer II neurons indicates that the development of frank dementia may be associated with other structural changes, such as alterations in the extent of dendritic arborization.

The distribution of pathological damage in the EC in MCI patients bears comparison with the initial stages of pathology described in AD (Braak stages I and II). Given that the onset of frank dementia in AD is associated with more advanced pathological involvement, equivalent to Braak stages III and IV, it might reasonably be assumed that the syndrome of MCI represents the clinical correlate of the earliest pathological ("transentorhinal") stages of the AD disease process.

#### **Comparison with the Pathological Changes of Normal Aging.**

The APs and NFTs are also observed in the brains of nondemented aged individuals. Diffuse plaques are found throughout the cerebral cortex, with additional plaques in the amygdala, EC, and CA1. Smaller numbers of neuritic plaques are also found in these regions but with proportionally greater quantities in the medial temporal lobe structures. NFTs are commonly present in the nondemented elderly brain and are most prominent in the hippocampus and parahippocampal regions (including the EC), with NFT numbers in CA1 correlating with age.

These AD-like changes have led to the suggestion that some "normal" elderly subjects may in fact have covert, or preclinical, AD. However, the observation that normal aging and AD are associated with different patterns of neuronal loss in the hippocampus suggest, instead, that the two do not share a common pathological substrate. The demonstration of Alzheimer-type pathology in "normal" elderly individuals and the concomitant difficulty distinguishing these changes from those observed in the earliest stages of AD mirrors the problem in clinical practice with respect to the differentiation between individuals exhibiting minor cognitive decline in keeping with increasing age, and patients manifesting the earliest symptoms of AD.

#### **Cholinergic Deficit in AD**

The cholinergic innervation to the hippocampal formation arises from various components of the basal forebrain. The medial septal nucleus and the nucleus of the diagonal band provide most of the inputs, with a smaller afferent projection originating from the basalis of Meynert. By comparison, the cerebral cortex receives its major cholinergic input from the basalis of Meynert, with additional lesser projections from the pedunculopontine and lateral dorsal nuclei. Cholinergic afferents are distributed to all cortical regions, but the limbic and paralimbic cortices (including the parahippocampal areas) are the recipients of a particularly strong projection. As a consequence, lesions of the basal forebrain in monkeys result in widespread behavioral abnormalities, within which disruption of memory functions are particularly prominent (Berger-Sweeney et al., 1994).

In AD, NPs and NFTs are observed in the basalis of Meynert, the nucleus of the diagonal band, and the medial septal nuclei. There is marked neuronal loss in the nucleus basalis and the nucleus of the diagonal band. The severity of the neuropathological changes in the basalis of Meynert have been found to correlate with clinical disease severity. The concomitant depletion of cortical cholinergic axons results in a reduction in the activity of choline acetyltransferase (ChAT) in the cortex and diminished choline uptake in AD. ChAT activity is reduced by 60% in cortical biopsies obtained from patients with AD.

The observation that in AD the basal forebrain nuclei are affected by plaques and tangles, in conjunction with the reduction in cortical cholinergic innervation and the demon-

stration that disruption of the cholinergic system causes impaired learning and memory underpin the “cholinergic hypothesis of AD.” The hypothesis proposes that the cognitive dysfunction associated with AD is at least partly attributable to impairment of cholinergic neurotransmission. Support for the hypothesis comes from studies demonstrating that the reductions in ChAT activity and acetylcholine (ACh) synthesis correlate with dementia severity in AD (Wilcock et al., 1982). However, the primary role of the cholinergic system in the pathogenesis of AD is cast into question by the observation that there is relative preservation of the cholinergic neurons of the nucleus basalis in MCI and early AD (Gilmor et al., 1999). Furthermore, the cholinergic system is not selectively affected in AD; pathological changes are also observed in a number of brain stem nuclei, including the locus coeruleus, the ventral tegmental area, and the rostral raphe nuclei. These nuclei, in turn, provide major components of the noradrenergic, dopaminergic, and serotonergic innervation of the cerebral cortex, and it is likely that their involvement contributes to the cognitive dysfunction observed in AD.

#### **Impairment of Synaptic Function in AD**

Synaptic density microdensitometry performed on pathological specimens obtained from the frontal and temporal lobes has revealed significant reductions in the density of presynaptic boutons in AD (approximately 60% of that observed in control brains). The antemortem Mini Mental State Examination score, employed as a global measure of dementia severity, was more closely correlated with synaptic density than with amyloid plaque density or ChAT activity. Consistent with the known involvement of the entorhinal cortex in AD, there is a reduction in the markers for synaptic vesicle proteins in the termination zone of the perforant path in the outer molecular layer of the dentate gyrus. This is accompanied by a reduction in synaptic density in the inner molecular layer, although this is associated with an expansion in the size of the remaining synapses, resulting in the maintenance of the total synaptic contact area in this region (Scheff et al., 1996).

Abnormalities of synaptic transmission in early AD have been demonstrated using *in vitro* and *in vivo* preparations. *In vitro* studies using hippocampal slices prepared from PDAPP transgenic mice overexpressing human mutant amyloid precursor protein have demonstrated alterations in synaptic transmission and LTP (Larson et al., 1999). Enhanced paired-pulse facilitation of synaptic transmission was observed in slice preparations taken from young PDAPP mice. In addition, there was a small (about 10%) reduction in the size of the CA1 dendritic EPSPs following stimulation of the Schaffer collaterals and commissural fibers. By contrast, slice experiments performed on slices taken from aged mice revealed diminution, rather than enhancement, of paired-pulse facilitation and a marked (around 55%) reduction in CA1 field EPSPs. LTP could be induced in both young and aged prepa-

rations, but this was associated with an abnormally rapid decay function. *In vivo* studies using PDAPP mice have demonstrated impaired induction and maintenance of LTP in CA1 following high-frequency stimulation (Giacchino et al., 2000). PDAPP mice also exhibited attenuation of paired-pulse facilitation, indicating impaired presynaptic function in these animals. Although these changes were most prominent in aged transgenic mice, the demonstration of abnormalities in young transgenic mice prior to the development of AD-related pathological changes indicates that defects of hippocampal synaptic transmission may precede the onset of gross neurodegenerative changes.

#### **Mouse Models of AD**

The discovery of the pathogenic APP mutation in 1991 stimulated efforts to create a mouse model in which the characteristic cognitive and pathological features were expressed. Gene-targeted knockout models provide information on the possible actions of the proteins coded by the mutant genes, whereas studies using transgenic mice explore the consequences of the overexpression of mutant AD genes.

**Knockout Models.** APP knockout mice with functionally inactivated alleles of APP are observed to have mild impairment of forelimb grip strength and decreased locomotor activity associated with reactive gliosis. PS1 knockout mice were found to have disrupted development of the axial skeleton as a result of impaired somitogenesis. Examination of the brains of these mice reveals thinning of the ventricular zone and severe regional neuronal loss. Cerebral hemorrhages were seen in all mouse embryos. PS2 knockout mice were found to have mild pulmonary fibrosis and hemorrhage but no pathological brain changes. Absence of PS2 did not affect APP processing. However, the double homozygous PS1/PS2 knockout mice are more severely affected than the PS1 mice, suggesting that PS1 and PS2 have partially overlapping functions.

**Transgenic Models.** Several lines of transgenic mice are currently in existence. The PDAPP mice overexpressing V717F  $\beta$ -APP (an FAD-associated mutation) exhibit amyloid plaques with dystrophic neurites surrounding  $\beta$ -amyloid cores. Transgenic mice with overexpression of human APP<sub>695</sub> (a 695-amino-acid length APP isoform representing one of the more abundant APP isoforms in the AD brain and a potential source of the A $\beta$  peptide) have abnormally high levels of A $\beta$  and  $\beta$ -amyloid deposits in the amygdala, hippocampus, and cortex between 6 and 12 months of age. Neither of these two lines of mice was found to have significant neuronal loss. None of the APP transgenic mice developed NFTs, although abnormally phosphorylated tau immunoreactivity has been observed. Deficits of spatial memory are noted by 9 to 10 months of age, and APP transgenic mice also exhibit impaired LTP (Chapman et al., 1999). PDAPP mice have been found to exhibit an age-related deficit in learning a succession of spatial locations in the watermaze (Chen et al., 2000). By

contrast, object recognition was normal. In these mice, impaired performance on the watermaze task was found to correlate with amyloid plaque density.

The PS1 transgenic mice have elevated levels of A $\beta_{1-42}$ . In view of the fact that patients with familial AD due to PS1 mutations have amyloid plaques comprised primarily of this longer A $\beta$  peptide, these observations provide further evidence that PS1 is involved in this aspect of plaque deposition.

Earlier studies involving APP and PS1 transgenic mice were able to provide reliable models of amyloid deposition, but the absence of any significant tau pathology meant that these studies were of limited value as realistic models of the human AD disease process. However, subsequent research has now provided evidence of a causal association between amyloid and tau pathology. The observation that bigenic mice expressing both mutant APP and mutant tau are found to have significantly greater quantities of intracytoplasmic tau tangles in the limbic system and olfactory cortex than similarly aged mice expressing the mutant tau gene alone can be taken as evidence that the formation of NFTs is influenced by amyloid protein (Lewis et al., 2001). Furthermore, injection of A $\beta_{1-42}$  fibrils into the hippocampi of transgenic mice expressing the mutant P301L tau gene results in a five-fold increase in the number of NFTs in the amygdala (Gotz et al., 2001), which suggests that NFT deposition may be driven by A $\beta_{1-42}$ . These data represent a significant advance in our understanding of the underlying nature of the neurodegeneration of AD, particularly in terms of the link between the two key aspects of AD pathology:  $\beta$ -amyloid deposition and tangle formation.

### 16.3.5 Treatment Options

The introduction of pharmacological treatments for AD during the last decade has resulted in a fundamental change in the approach to the clinical management of a condition previously considered to be associated with an inexorable and unalterable decline. At present, cholinesterase inhibitors are licensed for use in Europe and the United States, and the NMDA antagonist memantine is currently licensed for use in certain European countries. Both treatment options represent symptomatic therapy aimed at attenuating the rate of cognitive and functional decline by enhancing synaptic function. However, neither of these licensed treatments has been demonstrated to exert any effect on the underlying pathological process and so neither is likely to affect the natural history of the disease. As a consequence, efforts have been directed toward the development of treatments that may interrupt the disease process, in the anticipation that any disease-modifying drug may prove successful in altering the natural history of AD.

#### Enhancement of Cholinergic Function

Therapeutic strategies aimed at redressing the cholinergic deficit have led to the development of AChE inhibitors, which block the breakdown of ACh, thereby increasing ACh concen-

trations in the synaptic cleft. Clinical trials have demonstrated that usage of these drugs results in improved cognitive function. AChE inhibitors are currently licensed for the treatment of mild to moderate AD. There is accumulating evidence that they also attenuate the progression of noncognitive symptoms in AD, such as agitation and aggression, and may serve to maintain activities of daily living. However, meta-analyses of randomized clinical trials relating to the use of AChE inhibitors indicate that these drugs provide only a modest benefit in AD (Doody et al., 2001; Kaduszkiewicz et al., 2005), and to date there is little evidence that these drugs have the capacity to alter the natural history of the disease.

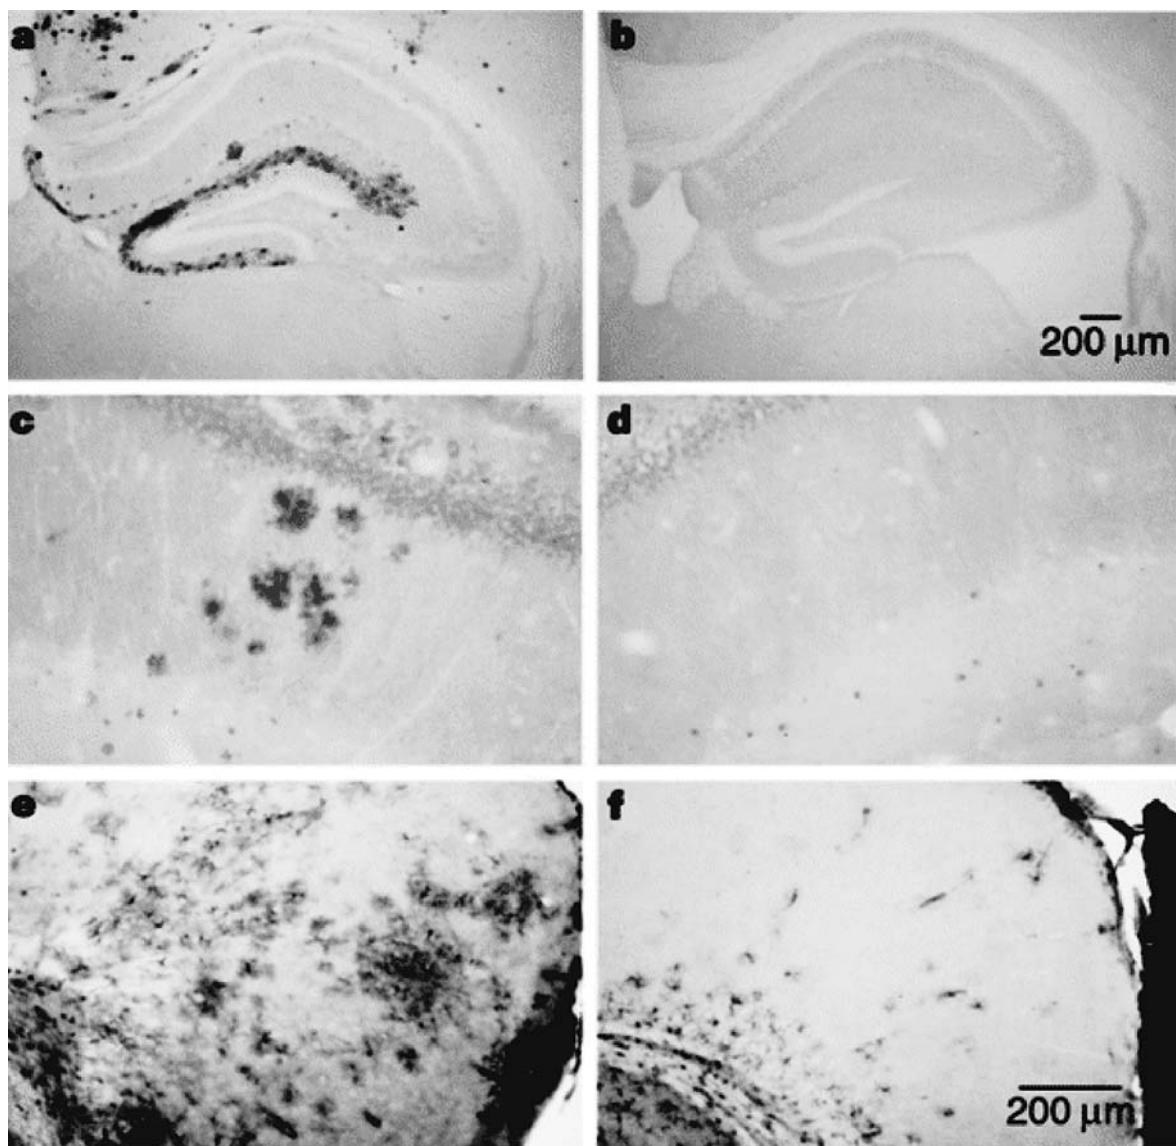

AChE inhibitors are at present the only drugs licensed for the treatment of mild to moderate AD. However, other drugs are being developed that are designed to enhance the cholinergic system by alternative means. They include ACh agonists, m1 muscarinic receptor agonists, and stimulators of ACh release. There have been some reports that cigarette smoking may have a protective effect in AD, which may relate to the effect on nicotinic receptors, but these findings have yet to be fully substantiated. In addition, any potentially beneficial effect on cholinergic transmission is at least partly offset by the increased risk of cerebrovascular disease associated with smoking, which increases not only the risk of AD per se but also the risk of developing concomitant vascular dementia.

#### NMDA Receptor Antagonists

Enhancement of glutamate-mediated synaptic function has been implicated in the pathophysiology of several neurodegenerative disorders including AD, Huntington's disease, and Parkinson's disease. The aminoacidamantane compounds amantadine and memantine have been found to confer neuroprotection by noncompetitive inhibition of glutamate activity at NMDA receptor. The low affinity of both compounds for the NMDA receptor and their fast voltage-dependent channel unblocking kinetics have been cited as the explanation for their low toxicity and good clinical tolerance. This contrasts with the neurotoxicity and psychotogenicity associated with compounds that are more potent NMDA receptor antagonists, such as MK-801 and phencyclidine. A clinical trial involving the use of memantine in patients with severe AD has demonstrated a good safety profile and clinical improvement as measured using cognitive and functional assessment scores (Winblad and Poritis, 1999). As a consequence, memantine has been licensed for use in patients with moderately severe to severe AD.

#### Antiamyloid Immunotherapy

PDAPP mice immunized with A $\beta_{1-42}$  at 6 weeks of age, prior to the development of pathological damage, developed anti-A $\beta_{1-42}$  antibodies and were observed to have significant reductions in amyloid deposition and plaque formation (Fig. 16–9) (Schenk et al., 1999). Injections of A $\beta_{1-42}$  into older mice, in whom AD pathological changes were established, resulted in

**Figure 16-9.** Hippocampal A $\beta$  deposition, neuritic plaque formation, and astrocytosis in 13-month-old mice injected with phosphate-buffered saline (PBS) and A $\beta$ <sub>42</sub>. There is marked A $\beta$  deposition in the outer molecular layer of the dentate gyrus of the PBS-injected mice (*a*), which contrasts with the absence of A $\beta$  observed in the A $\beta$ <sub>42</sub>-injected mice (*b*). Dystrophic neurites

labeled with the APP-specific monoclonal antibody 8ES were found in the hippocampal sections of the PBS-injected (*c*) but not the A $\beta$ <sub>42</sub>-injected mice (*d*). Plaque-associated astrocytosis is abundant in the retrosplenial cortex of the PBS-injected (*e*) but not the A $\beta$ <sub>42</sub>-injected (*f*) mice. (Source: Schenk et al., 1999, with the permission of Dr. Dale Schenk and Nature Publishing Group.)

reduced neuritic plaque burden and associated neuritic dystrophy and gliosis compared with nonimmunized mice. The pattern of amyloid pathology in the hippocampus was strikingly different in the treated mice, with an absence of diffuse deposits and an altered pattern of A $\beta$  immunoreactivity.

Transgenic mice expressing the mutant human APP<sub>695</sub> transgene that were vaccinated with the A $\beta$ <sub>1-42</sub> peptide exhibited a reduction of impairment when tested on a reference memory version of the watermaze task over a number of weeks subsequent to immunization (Janus et al., 2000). However, immunized transgenic mice remained impaired compared with nontransgenic control mice. As with the PDAPP mice, A $\beta$ <sub>1-42</sub> immunization was associated with

reduced amyloid plaque density when compared with nonimmunized mice.

Although initial safety trials of antiamyloid immunization indicated that the treatment could be used in human subjects, a subsequent Phase II safety trial was terminated following the development of subacute meningoencephalitis in 5% of the study population. Interestingly, a pathological study of the brain of the first immunized patient to come to postmortem (Nicoll et al., 2003) revealed large areas of cerebral cortex containing very few amyloid plaques and plaque-associated dystrophic neurites, although quantities of NFTs and neuropil threads were comparable to those observed in nonimmunized cases. Microglial cells were also found to be associated with

immunoreactivity to A $\beta$ , indicating that the immunization had been successful in generating an appropriate immune response, which in turn resulted in clearance of amyloid plaques.

### Secretase Inhibitors

Whereas the vaccination approach is designed to clear amyloid from the brain, an alternative approach is to prevent formation of amyloid plaques by interfering with the production of A $\beta_{1-42}$  from its precursor protein. With this aim in mind, attention has been focused on the discovery of potential inhibitors of the  $\beta$ - and  $\gamma$ -secretase enzymes that cleave APP to form A $\beta_{1-42}$ . Despite extensive animal studies, at present no secretase inhibitor has been put forward openly for clinical trials.

### Other Therapeutic Options

Information derived from epidemiological observations and from research into factors influencing the development of AD pathological changes have stimulated trials with a number of treatments with potentially disease-modifying effects. Following the initial report in 1990 of a reduced incidence of AD in patients with arthritis taking nonsteroidal antiinflammatory drugs (NSAIDs), a number of other reports have drawn attention to the apparent protective effect of long-term NSAID use (in t'Veld et al, 2001). The underlying mechanism for this neuroprotection has not been established, but the observation that amyloid plaques are surrounded by immune cells (e.g., microglia) suggests that NSAIDs may serve to reduce the degree of immune-mediated neuronal destruction. An alternative explanation relates to the suppression by NSAIDs of oxygen free radical-mediated cellular damage. Finally, there may also be a direct effect on the key underlying pathological processes in AD; some NSAIDs have been demonstrated to suppress A $\beta_{1-42}$  formation. Although the epidemiological data are convincing, conclusions arising from clinical trials assessing the value of these drugs in AD must be tempered by the known profile of adverse effects associated with these drugs, particularly the risk of peptic ulceration and gastrointestinal bleeding.

Other long-term studies have documented the beneficial effects of compounds with antioxidant properties; most prominent among them are gingko biloba and vitamins C and E. Preliminary studies have indicated that all three preparations may delay the progression of AD. Similar benefits have been shown for estrogen preparations, but progress in clinical trials has been delayed following the demonstration of an increased risk of breast cancer, stroke, and myocardial infarction in a large study using hormone replacement therapy (Rapp et al, 2003).

The observation that individuals with high serum cholesterol levels are more likely to develop AD, coupled with the results from some studies suggesting that cholesterol promotes the formation of  $\beta$  amyloid, has led to clinical trials involving the use of statins (cholesterol-lowering agents) in

patients with mild AD. The first published reports have indicated that patients on statin therapy experience a small, but not significant, reduction in the rate of cognitive decline over a 6-month period.

Certain metals have been implicated in the AD disease process. Zinc and copper cations play a critical role in the aggregation of  $\beta$  amyloid; in addition, the combination of these cations with  $\beta$  amyloid results in oxidative damage as a consequence of the generation of hydrogen peroxide. Clinical trials involving the use of metal chelators (agents that bind to metal ions) are currently under consideration (Scarpini et al, 2003).

Ultimately, any drug with true disease-modifying potential must fulfill a number of core criteria. First, a reduction in the rate of clinical decline must be demonstrated over several years, in view of the duration of the disease. Second, treatment benefits would have to be observed beyond the period of dosing to exclude the possibility of a symptomatic effect only. Ideally, benefits would be noted not only in memory and other cognitive functions but also in terms of more global measures such as activities of daily living. Finally, it would be desirable to supplement these clinical improvements with some evidence of attenuation of disease progression. In the absence of the ability to monitor directly the effect of treatments on the pathological brain changes, various surrogate markers of disease progression have been proposed, including structural (regional and global cerebral atrophy) and functional (cerebral hypometabolism) markers. Significant, consistent alterations in the longitudinal measurement of these surrogate markers of disease, observed over meaningful time spans, would provide convincing evidence of disease modification.

The discovery of multiple potential treatment avenues has markedly altered the clinical approach to AD. The anticipated development of genetic models of disease that more accurately reflect the core aspects of the AD disease process in conjunction with advances in our understanding of the pathophysiology of the disease are likely to give rise in the future to treatments that have the potential not only for effecting symptomatic alleviation but also for slowing down—perhaps even arresting—the pathological progression of Alzheimer's disease.

### ACKNOWLEDGMENTS

We thank the editors for their help in preparing this chapter. We also thank Eberhard Buhl and Dimitri Kullmann for their helpful comments and criticisms on an earlier version.

- Field effects, 203–204
- Field potentials, 5, 26, 27–30, 28b–29b, 145
- Fight or flight response, 752, 762–763
- Figure-of-eight maze task, 684–685, 685f
- Filopodia  
dendritic, 136  
mossy fiber, 65f, 164, 227
- Fimbria-fornix, 41f, 44, 44f, 47–48, 49  
lesions of, 617–618  
associative memory and, 679  
novel object recognition and, 611  
object-in-place memory and, 680–681  
place memory and, 680–681  
radial maze task and, 628, 629f  
scene memory and, 679–681, 681f  
water maze task and, 639  
species differences in, 44, 44f, 47–48, 49
- Flashbulb memory, 391, 393, 763
- Flood, Per, 23
- Fluvoxamine, long-term potentiation effects of, 404
- Food caching studies, 584, 640–642, 641f, 682–683, 683f, 694f  
window shopping paradigm for, 640
- Food preference task, 584
- Food preference transmission task, in relational processing theory, 667–668, 668f
- Food reward task  
for blocking study, 647  
for vector vs. map study, 649, 649f
- Forgetting, 441–443, 442f
- c-fos  
in cognitive map theory, 624–626, 625f, 626f  
in exploratory behavior, 429  
in long-term potentiation, 388, 390
- Fragment assembly hypothesis, 618
- Free recall task, 552
- Frontal cortex, hypothalamic-pituitary-adrenal axis regulation and, 762
- Frontal lobe, in declarative memory, 594
- Frontotemporal lobar degeneration, 793
- G**
- GABAergic receptor, 138, 218–220, 219f, 219t, 229–231, 274–282
- GABA<sub>A</sub>, 218–220, 219f, 219t, 250f, 274–279  
barbiturate effects on, 220  
basket cell, 278–279  
benzodiazepine effects on, 220, 278  
CA1 pyramidal cell, 277–279  
CA3 pyramidal cell, 279  
cerebellar, 231  
chloride ion gradient of, 220  
dystrophin-associated protein complex and, 282–283  
ethanol modulation of, 277, 278  
genetic analysis of, 283–284  
gephyrin and, 282  
granule cell, 275–277, 279, 283  
hippocampal distribution of, 275–279, 276f, 299–301, 311  
inhibitory postsynaptic current and, 279  
knockout mice for, 283–284  
localization of, 282  
mossy fiber, 277, 279  
plasticity of, 283  
seizure activity and, 283  
steroid modulation of, 277, 283  
stress effects on, 283  
subtypes of, 275, 279  
subunits of, 275, 276f  
in temporal lobe epilepsy, 785–786, 786f  
tonic inhibition and, 231  
trafficking of, 282–283  
zinc modulation of, 277, 278
- GABA<sub>B</sub>, 219f, 219t, 220, 250f, 280–282  
baclofen effect on, 220  
CA1 pyramidal cell, 280, 281, 281f  
CA3 pyramidal cell, 280, 281, 281f  
genetic analysis of, 284  
granule cell, 280, 281f  
hippocampal distribution of, 280–282  
knockout mice for, 284  
mossy fiber, 281  
in NMDA receptor-dependent long-term potentiation, 361–362, 361f, 363f  
subcellular localization of, 281–282  
in temporal lobe epilepsy, 786–787
- Galanin, 221  
in temporal lobe epilepsy, 788
- Gamma, 162, 279, 477, 478f, 485, 728  
basket cell and, 313  
behavioral correlates of, 478f, 479  
in GABA<sub>A</sub> α5 knockout slices, 284

 intracranial recordings in, 772f  
 kindling in, 427, 776, 782  
 long-term potentiation in, 427  
 mossy fiber sprouting in, 783–784  
 nestin-positive cells in, 783  
 neuronal loss in, 779–780  
 neuropeptide Y in, 788  
 neurotransmitters in, 785–788, 786f  
 opioids in, 788  
 paired-associates recall tasks in, 534  
 paired-pulse inhibition and, 784  
 potassium channels in, 788  
 recall memory task in, 533–534  
 recognition memory task in, 533–534  
 seizure duration in, 771, 776  
 semiology of, 771  
 single-unit recording in, 533–534  
 slow wave in, 777  
 status, 776–777, 780, 788  
 structural changes in, 779–785, 779f  
 zinc in, 785  
 Temporal lobectomy, 774, 776  
 Tetrahydrodeoxycorticosterone, GABA<sub>A</sub> receptor function and, 277  
 Tetrodes, 27, 494, 620  
 Thalamus  
 CA1 projection from, 73, 80  
 entorhinal cortex projection from, 93–94  
 head-direction cells of, 520–521, 620  
 parasubiculum projection from, 82  
 presubiculum connections with, 73, 82  
 subiculum connections with, 80  
 Theta, 25, 475, 476, 477, 478f, 479–483  
 amplitude of, 481  
 behavioral correlates of, 477, 478f, 479, 479f, 480, 481  
 clocking function of, 476, 482–483  
 cross-correlation with, 488b, 489f  
 distribution of, 480  
 dual oscillator model of, 507  
 entorhinal pyramidal cell, 176  
 entorhinal stellate cell, 171–172, 171f  
 frequency of, 477, 478f, 481  
 functions of, 475, 476, 482–483, 538–539  
 global synchronizing function of, 482  
 historical perspective on, 12, 25, 479–480  
 in humans, 482  
 long-term potentiation induction and, 476, 483  
 nonhippocampal distribution of, 481–482  
 in primates, 482

- Theta (*Continued*)  
 sleep and, 481  
 stellate cell, 170–172, 171f  
 subiculum, 162  
 subthreshold, 162  
 $\alpha$ -Theta, 475, 480, 490, 538  
 behavioral correlates of, 481  
 movement program activation and, 481  
 pharmacology of, 479f, 480–481  
 $\tau$ -Theta, 475, 490, 538  
 behavioral correlates of, 481  
 movement through space and, 481  
 pharmacology of, 479f, 480–481  
 Theta cells, 476, 486, 490–491  
 action potential of, 486–487, 486f  
 behavioral correlates of, 490–491  
 entorhinal cortex, 537  
 firing of, 490  
 interneuron nature of, 487, 488f, 489f  
 navigation and, 620  
 in nonspatial learning, 523–534, 525f, 527f, 529f, 530f  
 novelty and, 491, 495  
 in operant conditioning, 532–533  
 pharmacology of, 490  
 phasic, 490  
 in rabbit, 523  
 single-unit recording from, 486–487, 486f  
 subiculum, 535  
 theta-off, 490, 491  
 theta-on, 490–491  
 tonic, 490  
 Theta-conditioning experiment, 481  
 Theta-modulated place-by-direction cells, 536, 536f  
 Thiamine deficiency, 555  
 Thirst-related task, in contextual-retrieval theory, 672–674, 673f
