## Preface

The hippocampus is one of the most widely studied regions of the brain and is of interest to a wide spectrum of neuroscientists, ranging from those who study its normal structure and function to others who study its malfunction in various diseases and pathological conditions. Information about it has accrued across a considerable span of time and is spread over a wide variety of publications. It seems all the more remarkable, therefore, given the explosion of texts on every conceivable topic in neuroscience, that there is no single, comprehensive source of information on the hippocampal formation. It would clearly be helpful to the community of hippocampologists to have the essential information about hippocampal neurobiology gathered together in one volume. This book is our attempt at a reasonably comprehensive survey of hippocampal research, as viewed through many eyes and collected with a wide variety of methods. We hope that the book will be useful at several levels. For those new to the arena of hippocampal research, we hope it will act as a primer pointing to the important advances of the past decades and suggesting important research paths to be pursued; for hippocampal veterans, we hope that by laying bare the many uncertainties and open questions that remain, it will provide ample stimulus to see old problems with new eyes and to pursue them with renewed vigor.

The hippocampus is a structure eminently worthy of study in its own right, but it has also been seen by many as a model structure for the study of cortical function and plasticity in general. The twin aims of the book therefore are to discuss hippocampal structure and function in its own terms and to highlight how study of the hippocampus has revealed ideas and advances that are of wider significance and generality for neuroscience.

The inception of *The Hippocampus Book* occurred many years ago, at the end of a symposium in the beautiful, stimulating city of Palermo in Sicily. We ended up at a street-side cafe, each with a glass of birra glowing in the setting Mediterranean sun. We were four old friends, all long-term

card-carrying hippocampologists. Inevitably, our conversation turned to our favorite brain structure and in particular to the lack of reviews and surveys to which we could direct fledgling hippocampologists. Eventually, Per Andersen threw out the challenge: Could the four of us write a treatise on the hippocampal formation that captured the essentials, derived as they were from so many branches of neuroscience? He wondered whether, among us, we could cover the entire field from synapse to behavior by way of the cells and the nerve nets in between. The original crew had a not inconsiderable breadth of experience from physiology, psychology, and behavioral science, but we quickly realized the essential need for structural information as one of the foundations of such a book. We were happy to bring on board a neuroanatomist with great knowledge and experience of the hippocampus, and the gang of four became five.

Over the next 10 years, the Editors met in numerous delightful venues in the United States and Europe to read each other's work and to confer on the book. Although much writing was done during this phase, it gradually dawned on us that two formidable obstacles made our objective significantly more difficult than we had originally anticipated. First, the material on the hippocampus was even more extensive than we had expected and, with the explosion of neuroscience, was growing rapidly day by day. A recent PubMed search elicited more than 73,000 references to the target word "hippocampus." More daunting still, the breadth of the field had expanded with the introduction of new methods and information, not least from the rapidly developing fields of molecular biology, genetics, and development. To cover these important fields adequately, we decided to ask a set of colleagues with the appropriate specialist knowledge to join us in the effort. We were fortunate to attract a powerful team, and the Editors are extremely grateful to these colleagues for their important contributions.

We hope that *The Hippocampus Book* will prove useful to its readers. We are confident that many share our affection for

this uniquely fascinating structure. If the book helps future neuroscientists in their planning and execution of hippocampal studies, our project will have been a success. If, in addition, the book facilitates new lines of thought and experimental approaches that challenge existing ideas and concepts, our reward will be even greater. With its important role in mem-

ory and its involvement in a host of psychological and psychiatric conditions, the hippocampal formation will undoubtedly continue to be an active focus of energetic research. Our hope is that *The Hippocampus Book* will act as a springboard and a guide for some of that research.

## Acknowledgments

Over the years, several individuals and institutions have helped us in various ways with the creation of this book. An important planning session took place at The Institute for Neuroscience, then at The Rockefeller University. We thank its Director Gerald Edelman and Research Director Einar Gall for their generous support. Twice we were accommodated for writing sessions at the Centre for Advanced Studies at the Academy of Science and Letters in Oslo, and we thank the director of the Centre Vigdis Ystad and the President of the Academy Bjarne Waaler for their hospitality. At other times we met in La Jolla, California, Overstrand, Norfolk and in London at the Royal Society and the Novartis Institute. We enjoyed several editorial meetings in Edinburgh at the Centre for Neuroscience. To all these institutions we express our gratitude.

Many dozens of our colleagues have been badgered with questions over the years and have replied with patience and dispatch. Per Andersen particularly thanks Theodor Blackstad, Gyorgyi Buzsaki, Leif Gjerstad, Vidar Jensen, Edward Jones, Bruce Piercy, Geoffrey Raisman, Eric Rinvik, Thomas Sears, and Jon Storm-Mathisen. Finally, we express our particular gratitude to Fiona Stevens, at Oxford University Press, New York for keeping faith with our project through too many fallow periods and, also at OUP to Joan Bossert and Mallory Jensen for the graceful pressure they applied during the final months while shepherding the book to publication. Finally, we are deeply grateful for the efficient, yet gracious manner, in which Berta Steiner at Bermedica Production helped us to bring the book to fruition.

# Contents

## ❖ Chapter 1

- The Hippocampal Formation 3  
*Per Andersen, Richard Morris, David Amaral, Tim Bliss, and John O'Keefe*
- 1.1 Overview 3
  - 1.2 Why Study the Hippocampal Formation on its Own? 4
  - 1.3 Defining the Contemporary Era 5
  - 1.4 Organization and Content of the Book 6

## ❖ Chapter 2

- Historical Perspective: Proposed Functions, Biological Characteristics, and Neurobiological Models of the Hippocampus 9  
*Per Andersen, Richard Morris, David Amaral, Tim Bliss, and John O'Keefe*
- 2.1 Overview 9
  - 2.2 The Dawn of Hippocampal Studies 9
    - 2.2.1 *A Famous Dispute About the Significance of the Hippocampus* 9
  - 2.3 Early Ideas About Hippocampal Function 10
    - 2.3.1 *The Hippocampal Formation and Olfactory Function* 10
    - 2.3.2 *The Hippocampal Formation and Emotion* 11
    - 2.3.3 *The Hippocampal Formation and Attention Control* 12
    - 2.3.4 *The Hippocampal Formation and Memory* 13
    - 2.3.5 *More Direct Evidence for Hippocampal Involvement in Memory* 13
    - 2.3.6 *The Hippocampus as a Cognitive Map* 16
    - 2.3.7 *Conclusions* 16
  - 2.4 Special Features of Hippocampal Anatomy and Neurobiology 16
    - 2.4.1 *Early Neuroanatomical Studies of the Hippocampus* 17
    - 2.4.2 *New Fiber Tracing Methods* 18

- 2.4.3 *New Anatomical Techniques that Revolutionized Connectivity Studies* 18
- 2.4.4 *Predominantly Unidirectional Connectivity Between Cortical Strips* 20
- 2.4.5 *New Tracing Studies Using Axonal Transport* 20
- 2.4.6 *Electron Microscopy Offers New Opportunities* 21
- 2.4.7 *Hippocampal Synapses Are Highly Plastic: Early Studies of Sprouting* 21
- 2.4.8 *Hippocampal Neurons: Transplantable with Retention of Many Basic Properties* 22
- 2.4.9 *Hippocampal Cells Grow Well in Culture* 22
- 2.4.10 *Development of Hippocampal Slices: From Seahorse to Workhorse* 22
- 2.5 Several Neurophysiological Principles Have Been Discovered in Hippocampal Studies 23
  - 2.5.1 *Identification of Excitatory and Inhibitory Synapses* 23
  - 2.5.2 *Gray Type 2 Synapses are Inhibitory and are Located on the Soma of Pyramidal and Granule Cells* 23
  - 2.5.3 *Gray Type 1 Synapses are Excitatory and are Located on Dendritic Spines* 24
  - 2.5.4 *Long-lasting Alterations of Synaptic Efficiency After Physiological Stimulation* 24
  - 2.5.5 *Hippocampal Systems: Exhibiting Several Types of Oscillatory Behavior* 25
  - 2.5.6 *Studies of Epileptiform Behavior* 25
- 2.6 Development of Methodological Procedures for General Use 26
  - 2.6.1 *Hippocampus as a Test Bed for Microelectrode Work* 26
  - 2.6.2 *Pioneers of Intracellular Recording* 26
  - 2.6.3 *Tetrode Development* 27
  - 2.6.4 *Field Potential Analysis* 27
  - 2.6.5 *Histochemistry: Pioneered in the Hippocampus* 30
  - 2.6.6 *Pharmacological Analysis of Cellular Properties* 30
  - 2.6.7 *Development of Computational Models of Neural Networks* 31

2.6.8 *The Hippocampal Formation: A Test Bed for Several Types of Neural Dysfunction and Neuropathology* 31

## ❖ Chapter 11

Hippocampal Neurophysiology in the Behaving Animal 475

*John O’Keefe*

- 11.1 Overview 475
- 11.2 Hippocampal Electroencephalogram Can Be Classified into Distinct Patterns, with Each Providing Information About an Aspect of Hippocampal Function 477
  - 11.2.1 Hippocampal EEG Can Be Classified into Four Types of Rhythmic and Two Types of Nonrhythmic Activity 477
  - 11.2.2 Each EEG Pattern Has Distinct Behavioral Correlates 477
- 11.3 Hippocampal Theta Activity 479
  - 11.3.1 Hippocampal Theta Activity: Historical Overview 479
  - 11.3.2 Hippocampal Theta Activity Is Comprised of Two Components, *a*-Theta, and *t*-Theta, Which Can Be Distinguished on the Basis of Behavioral Correlates and Pharmacology 480
  - 11.3.3 Both Types of Theta Activity Are Dependent on the Medial Septal/DBB but Only *t*-Theta Is Dependent on the Entorhinal Cortex 480
  - 11.3.4 *t*-Theta Occurs During Movement Through Space 481
  - 11.3.5 *a*-Theta Occurs During Arousal and/or Attention as well as Movement 481
  - 11.3.6 Theta and Sleep 481
  - 11.3.7 Theta Activity in Nonhippocampal Areas 481
  - 11.3.8 Does the Hippocampal EEG in Monkeys and Humans Have a Theta Mode? 482
  - 11.3.9 Functions of Theta 482
- 11.4 Non-theta EEG Patterns in the Hippocampal EEG: LIA, SIA, Ripples, Beta, and Gamma 483
  - 11.4.1 Sharp Waves, Ripples, and Single Units During Large Irregular Activity 483
  - 11.4.2 Dentate EEG Spikes During LIA 484
  - 11.4.3 Pharmacology of LIA 484
  - 11.4.4 Behavioral Correlates and Functions of LIA 484
  - 11.4.5 Small Irregular Activity 485
  - 11.4.6 Beta/Gamma Activity in the Hippocampus 485

- 11.4.7 Olfactory Stimulation Can Elicit Hippocampal Gamma and Beta Waves 485
- 11.5 Single-cell Recording in the Hippocampal Formation Reveals Two Major Classes of Units: Principal Cells and Theta Cells 486
  - 11.5.1 Distinctive Spatial Cells – Complex-spike Place Cells, Head-direction Cells, and Grid Cells – Are Found in Various Regions of the Hippocampal Formation 487
- 11.6 Theta Cells 490
  - 11.6.1 Theta Cells Fire with a Consistent Phase Relation to EEG Theta 490
  - 11.6.2 Pharmacology of Theta Cells 490
  - 11.6.3 Hippocampal Theta Cells Have Behavioral Correlates Similar to Those of the Hippocampal EEG 490
- 11.7 Complex-spike Cells and Spatial Processing 491
  - 11.7.1 Place Cells Signal the Animal’s Location in an Environment 491
  - 11.7.2 Basic Properties of Place Fields 492
  - 11.7.3 Place Fields are Nondirectional in Unrestricted Open-field Environments but Directional When Behavior is Restricted to Routes 495
  - 11.7.4 What Proportion of Complex-spike Cells Are Place Cells? 497
  - 11.7.5 Frame of Reference of Place Fields 498
  - 11.7.6 Place Fields Can Be Controlled by Exteroceptive Sensory Cues 499
  - 11.7.7 Idiographic Cues Can Control Place Fields 502
  - 11.7.8 Are Place Cells Influenced by Goals, Rewards, or Punishments? 504
  - 11.7.9 Temporal Patterns of Place Cell Firing 505
  - 11.7.10 Place Fields in Young and Aged Animals 507
  - 11.7.11 Hippocampal Place Cell Firing Is Influenced by Other Areas of the Brain 509
  - 11.7.12 Primate Hippocampal Units also Exhibit Spatial Responses 510
- 11.8 Place Cells Are Memory Cells 511
  - 11.8.1 Hippocampal Place Cells “Remember” the Animal’s Location for Several Minutes During a Spatial Working Memory Task 512
  - 11.8.2 Place Field Plasticity During Unidirectional Locomotion 512
  - 11.8.3 Cue Control over Hippocampal Place Cells Can Change as a Function of Experience 513
  - 11.8.4 Control of the Angular Orientation of Place Cells in a Symmetrical Environment Can Be Altered by the Animal’s Experience of Cue Instability 514
  - 11.8.5 Complex-spike Cell Firing and Connectivity During Sleep Is Modulated by Prior Spatial Learning Experiences 516
  - 11.8.6 NMDA Receptor Confers Mnemonic Properties on Place Cell Firing 516
  - 11.8.7 Summary of Place Cell Plasticity 517
- 11.9 Head Direction Cells 517

- 11.9.1 Head Direction Cells are Controlled by Distal Sensory Cues 518  
 11.9.2 Angular Distance Between any Given Pair of Head Direction Cells Always Remains Constant 519  
 11.9.3 Head Direction Cells Can also Be Controlled by Idiopathic Cues 519  
 11.9.4 Head Direction Cells Are Found in Different Anatomically Connected Brain Areas 520  
 11.9.5 Dorsal Tegmental Nucleus of Gudden Provides Information About the Direction and Angular Velocity of the Animal's Head Rotation 521  
 11.10 Interactions Between Hippocampal Place Cells and Head Direction Cells 521  
 11.11 Hippocampal Complex-spike Cells Have Been Implicated in Nonspatial Perception and Learning 523  
     11.11.1 Hippocampal Cells Have Been Implicated in the Processing of Nonspatial Sensory Information 523  
     11.11.2 Hippocampal Unit Activity May Show Correlations with Different Aspects of Nonspatial Learning Tasks 524  
     11.11.3 Hippocampal Unit Activity During Aversive Classical Conditioning 524  
     11.11.4 Nictitating Membrane Conditioning in the Rabbit: Role of Theta 525  
     11.11.5 Single-unit Recording in the Hippocampus During Nictitating Membrane Conditioning of Rabbits 526  
     11.11.6 Hippocampal Unit Recording During Operant Tasks 528  
     11.11.7 Comparison of Hippocampal Cells During Operant Conditioning and Place Tasks in Rats 532  
     11.11.8 Hippocampal Units During Nonspatial Learning in Nonhuman Primates 533  
     11.11.9 Hippocampal Units During Nonspatial Learning in Humans 533  
     11.11.10 Conclusions 534  
 11.12 Other Distinctive Cells in the Hippocampal Formation and Related Areas 534  
     11.12.1 Subiculum Region Has Fewer Place Cells than the Hippocampus Proper, and Their Properties Differ 535  
     11.12.2 Presubiculum Contains Several Classes of Spatial Cell 536  
     11.12.3 Parasubiculum 537  
     11.12.4 Spatial Cells in the Entorhinal Cortex 537  
     11.12.5 Cells in the Perirhinal Cortex Code for the Familiarity of Stimuli 537  
     11.12.6 Cells in the Medial Septum Are Theta Cells 538  
     11.12.7 Summary of Extrahippocampal Place Field Properties 538  
 11.13 Overall Conclusions 538  
 References 540

## ◆ Chapter 12

- Functional Role of the Human Hippocampus 549  
 Craig Stark  
 12.1 Overview 549  
 12.2 Patient H.M. 550  
 12.3 Methods for Studying Human Hippocampal Function 552  
     12.3.1 Behavioral Tasks and Terms 552  
     12.3.2 Behavioral Measures 553  
     12.3.3 Anoxia and Bilateral Hippocampal Lesions 554  
     12.3.4 Depth Electrode Recordings 556  
     12.3.5 Neuroimaging 557  
     12.3.6 Technical Challenge: Alignment of MTL Regions Across Participants 559  
 12.4 Dissociating Hippocampal Function 561  
     12.4.1 Explicit Versus Implicit 561  
     12.4.2 Encoding Versus Retrieval 564  
     12.4.3 Time-limited Role in Declarative Memory 565  
     12.4.4 Spatial Memory 567  
     12.4.5 Associations, Recollections, Episodes, or Sources 569  
 12.5 Conclusions 573  
 References 575

## ◆ Chapter 13

- Theories of Hippocampal Function 581  
 Richard Morris  
 13.1 Overview 581  
 13.2 Cognitive and Behavioral Neuroscience, Interventional Techniques, and the Hippocampus 582  
     13.2.1 Value of Interventional Studies to Identify Function 582  
     13.2.2 Lesions, Functional Hypotheses, and Behavioral Tasks 583  
     13.2.3 Contemporary Lesion Techniques: Pharmacological and Genetic Interventions 585  
     13.2.4 Biological Continuity of Hippocampal Function 588  
 13.3 Declarative Memory Theory 591  
     13.3.1 Outline of the Theory 591  
     13.3.2 Development of a Primate Model of Amnesia 596  
     13.3.3 Domains of Preserved Learning Following Medial Temporal Lobe Lesions in Primates 601  
     13.3.4 Selective Lesions of Distinct Components of the Medial-temporal Lobe Reveal Heterogeneity of Function 602  
     13.3.5 Remote Memory, Retrograde Amnesia, and the Time Course of Memory Consolidation in Primates 606  
     13.3.6 Critique 608

# The Hippocampal Formation

## 1.1 Overview

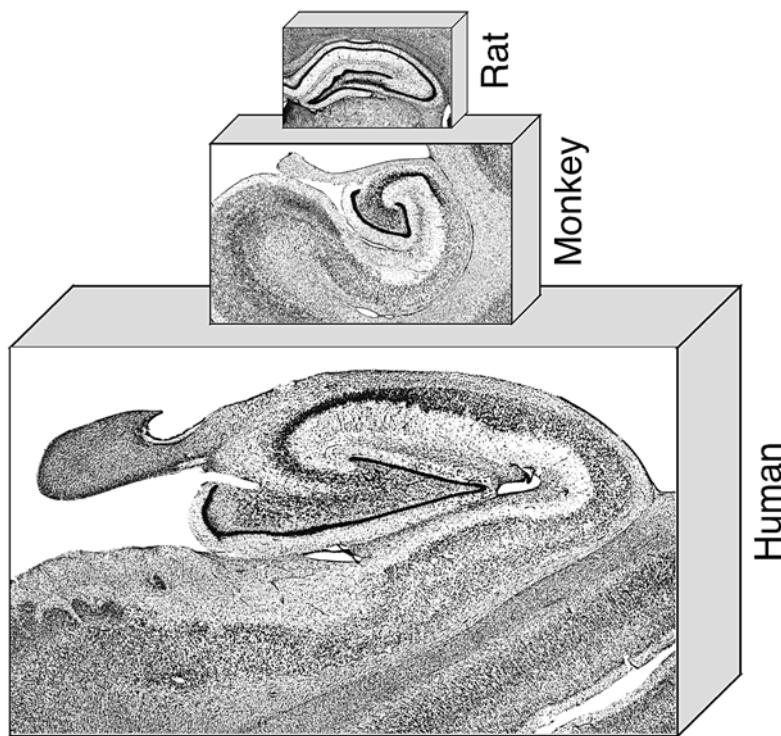

Buried deep within the medial temporal lobe of the human brain lies a group of many millions of neurons organized into a network quite different from that found anywhere else in the nervous system. It is a structure whose bulb-like shape, protruding into the lateral ventricles, has captivated anatomists since the first dissections took place in classical Egypt. The hippocampal formation is a group of brain areas consisting of the dentate gyrus, hippocampus, subiculum, presubiculum, parasubiculum, and entorhinal cortex. The basic layout of cells and fiber pathways of the hippocampal formation is much the same in all mammals (Fig. 1–1).

There are several reasons the hippocampus has attracted the interest of scientists in the many disciplines that now characterize modern neuroscience—the hippocampus has something for everyone. Whether you are a psychologist interested in memory, a synaptic physiologist investigating neuronal and synaptic plasticity, or a computational neuroscientist wanting to build a neural network model, the hippocampus and its associated structures are an attractive set of brain structures on which to work. In parallel, clinicians concerned with the basis of neurological conditions such as epilepsy or Alzheimer's disease had their attention drawn to the hippocampal formation because of the pathological processes observed to occur there and the opportunities that scientific study of this area of the brain offers for novel therapeutics. The hippocampus has been a neural Rosetta Stone. The striking discovery, 50 years ago, that patient H.M. had a relatively pure memory deficit after surgical excision of the medial temporal lobe for the relief of epilepsy had a profound effect on the study of memory and, through that, on our understanding of the functions of the hippocampus itself.

During the last 30 years, the pyramid-shaped cells of the hippocampus have become the most intensively studied neu-

rons in the brain. As a result, we now know a great deal about their development, synaptogenesis, neurotransmitter receptors and ion channels, micro-circuitry, and cell biological machinery. No less impressive has been the molecular analysis of neurotransmission in hippocampal cells; what has been learned from this has revealed general properties that seem to apply in other areas of the central nervous system. We also know something about why and when these cells are activated in the living brain. Recordings from freely moving animals as they navigate around a space with which they have become familiar have shown that individual hippocampal pyramidal cells fire in particular locations. This finding led to the development of new behavioral tools to study the neural mechanisms of memory in animals. Along the extensive dendritic arborizations of these pyramidal cells, there can be many thousands of miniature dendritic spines. These are the sites where most of the excitatory synapses are to be found. An important finding is that the efficiency with which these excitatory synapses transmit messages can vary as a function of neural activity. The circumstances bringing about this synaptic plasticity are now well understood, and we are beginning to understand some of the underlying biochemical mechanisms. Many suspect that synaptic plasticity is a key mechanism of memory. Another exciting feature of the hippocampal formation is that the dentate granule cell is one of the rare types of nerve cell that multiplies throughout life. Adult neurogenesis is likely to yield important lessons about neuronal growth and survival. This is an area of obvious potential importance for neuronal repair and therapeutic intervention.

These observations have emerged from the widespread fascination with this beautiful cortical structure that so attracted the early anatomists. As we shall see, certain structural principles that are characteristic of the hippocampal formation have greatly facilitated structural, physiological, and behavioral analyses.

**Figure 1-1.** Nissl-stained coronal sections through the rat, monkey, and human hippocampal formation. Although there are obvious differences in certain regions, the most striking feature is the general similarity of this brain region across phylogeny.

## 1.2 Why Study the Hippocampal Formation on Its Own?

Can one profitably focus on one group of brain structures and appear to ignore the rest of the brain? The brain is so heavily interconnected that it is misleading to think about the function of one small part of it in isolation. What it does and how it does it might be understood better by comparing it with other brain areas and by thinking about how it works in conjunction with them to realize the seamless fabric of normal brain function. We have much sympathy with this view, not least because the general significance of the many exciting discoveries that have been made about the hippocampus can only become clear with a more inclusive approach in which it and other parts of the brain are considered together. We believe, nonetheless, that there is still value in our focused approach. There are two primary reasons for singling out the hippocampal formation as a brain area worthy of a book in its own right. They have to do with trying to understand its function(s) within the brain and the way in which work on hippocampal tissue has revealed general principles in neuroscience.

First, contemporary research points strongly to the hippocampus having a highly specific role in memory. There has been a great deal of debate about how that role should be characterized; and after the explosive period of research during the last quarter century, a consensus is beginning to emerge. It is now generally recognized that there are multiple types of memory and that the hippocampus plays a part in

only some of them. There is also general agreement that some types of learning and memory are propositional—that is, they relate to memories that can be described as a series of propositional statements—whereas other types, such as the process of acquiring motor skills, are not. The hippocampus is engaged in remembering information that can be described in a propositional or declarative manner. That much is clear. Beyond that, there remain many areas of disagreement and debate that continue to fuel imaginative new research in behavioral and cognitive neuroscience. A striking feature of this strand of research has been the constructive convergence of both “top-down” and “bottom-up” approaches to the study of brain function. Work on the function of the hippocampal formation, arguably more than any other brain area, has led to the development of current concepts about the organization of memory systems in the brain.

Some traditionalists still hold that the various subjects that make up the biomedical sciences—such as psychology, physiology, biochemistry—each has a self-contained level of analysis that is logically independent of other levels of analysis. With this view, a psychological problem requires an answer in strictly psychological terms and a physiological problem a physiological approach. The emerging view at the start of the twenty-first century, however, is that many years of a strictly psychological analysis of learning and memory—beginning with the discovery of Pavlovian conditioning, the ensuing dark phase of behaviorism, and the subsequent enlightenment of the cognitive revolution—failed to unravel the existence of multiple memory systems. It was not until a different “brain-systems” approach was taken during the last part of the twen-

tient century, an approach that emerged from studies of the memory problems faced by patient H.M. and other amnesic patients, that the major breakthroughs in our understanding of the cerebral organization of memory came about. Such thinking led to research that married brain and behavior in single-unit recording and lesion studies in awake primates and freely moving rodents, as well as the development of new behavioral tests of learning and memory. There is a lesson here that we believe is generally applicable to other branches of functional neuroscience. Specifically, the brain-systems approach is one in which there is analytical value in juxtaposing the biomedical sciences with psychology and, in particular, in thinking carefully about what bits of the brain do what.

The second justification for writing this book is that the hippocampus has preeminently been the structure in which many of the general principles of modern neuroscience have been studied and established. Thirty years ago, the most widely studied cell in the nervous system was the alpha motoneuron of the ventral horn of the spinal cord. Today it is the pyramidal cell of the hippocampus. One reason for this development has been the peculiar anatomy of the hippocampus, with all principal cells in a single layer and synaptic inputs to well defined dendritic lamina. This simplified architecture facilitated the recording of both synaptic signals and population discharges. Field potential recording became possible because the well defined somatic and dendritic laminae allowed identification of current sources and sinks in extracellular recordings made *in vivo*. It was through these studies that the basic principle of unidirectional excitatory transmission was first described and the phenomenon of long-term potentiation was discovered. Of particular importance for the study of synaptic function in the context of learning and memory was the fact that field-potential recording of synaptic responses could be made as easily in the freely moving animal as in the hippocampal slice. The pyramidal cell also became a popular cell to study because of the analytical potential of the *in vitro* brain slice. The first brain slices were made from neocortex and piriform cortex with limited synaptic activation. With its better identification of cells and input fibers, the development of the transverse hippocampal slice revolutionized neurophysiology and neuropharmacology. Of course, many fundamental concepts had been worked out beforehand—in the axon of the giant squid, spinal cord, and cerebellum—but the hippocampal slice rendered analytical extra- and intracellular studies of mammalian cells and identified synapses feasible on an unprecedented scale. Work in the hippocampus has been a major contributor to our understanding of the actions and mechanisms of various types of synapse and the various classes of receptors for excitatory and inhibitory amino acids, the many transmitter uptake mechanisms, activity-dependent synaptic plasticity, and the deleterious consequences of excitotoxicity for brain cells. It is the two- or three-layered architecture of the hippocampus and its capacity to survive *in vitro* for long periods of time coupled with a strict layering of synapses in the dendritic tree that has rendered the design and analysis of electrophysiological and

other experiments tractable in a manner that remains difficult in other brain areas and would be wholly impracticable *in vivo*.

Beyond its key role in the development of *in vitro* techniques, the hippocampus has also been the area of choice for many other types of brain research. It is involved in a number of disparate neurological disorders, including epilepsy, Alzheimer's disease, and cerebrovascular disease. Thus, the abnormal electrical activity that is at the root of seizures in epileptic patients is often easily detected in the hippocampus. Moreover, a hallmark feature of the neuropathology of temporal lobe epilepsy is loss of neurons in several hippocampal fields. For example, the characteristic pathological changes of Alzheimer's disease manifest initially in the entorhinal cortex—one of the components of the hippocampal formation—and the disease spreads from there to involve the hippocampus proper and ultimately the entire cerebral cortex. Such findings have led to the development of model systems in which pathophysiological events such as these may be studied and, hopefully, alleviated by treatment.

These two main reasons for writing the book therefore provide us with two intersecting themes that run through many of its chapters. One perspective is functional, the other heuristic.

- What does the hippocampus do?
- What can we learn about general principles of neuroscience from studying the hippocampus?

To achieve these twin aims, we have broken up our task into chapters that are largely organized along conventional disciplinary lines but where, when appropriate, both strands of thought are intertwined.

### 1.3 Defining the Contemporary Era

Our starting point when preparing this book was to define the contemporary era of research as beginning in the 1960s and to regard discoveries made before that as “modern” and those made afterward as “contemporary.” Any division of this kind is arbitrary, but the period of the 1960s and 1970s was a watershed for both functional and mechanistic studies of the hippocampus. That decade saw the first intracellular analysis of synaptic, antidromic, and epileptiform activities of hippocampal neurons; the characterization and interpretation of field potentials signaling excitation and inhibition; and electron micrographs of synapse types and their distribution along the cell bodies and their extensions. It was also at this time that several of the new tract-tracing techniques became available to anatomists, replacing the classic degeneration techniques hitherto used to identify regional connectivity. These advances made it possible to map the extrinsic connections of the hippocampal formation at a previously unachievable level of sensitivity and detail. During the same decade, hippocampal place cells were discovered and the phenomenon

of long-term potentiation was first described in detail. Methodological developments of the 1970s included the hippocampal slice, new tests of recognition memory for primates, and the open-field watermaze, a behavioral technique to study learning in rodents that has since been used extensively to analyze the role of the hippocampus in spatial navigation. Mathematicians also started thinking about the hippocampus as a neural network and so set in motion a theoretical neuroscience that has attracted increasing attention.

## 1.4 Organization and Content of the Book

During the discussions about when the contemporary era actually started, we recognized the enormous contributions made beforehand and upon which so much of modern research rests. Accordingly, we have devoted Chapter 2 to a historical discussion of the key discoveries and concepts of hippocampal neurobiology of the modern era up to about the 1970s. In it, we also identify some of the key figures whose work helped to usher in the contemporary era. In addition, we highlight key concepts in neurobiology that were first established through work on the hippocampal formation.

In Chapter 3, we outline the anatomy of the hippocampal formation, beginning with issues of nomenclature and definition. Here we present the three-dimensional organization of the rodent, monkey, and human hippocampal formation, the detailed architecture of each of its component structures, and the patterns of cellular interconnectivity. Straightaway, we found that we disagreed about certain conceptual issues, such as the status of the “lamella hypothesis” that was proposed nearly 30 years ago on the basis of electrophysiological data. Modern neuroanatomical tract-tracing studies are thought not to support this concept in its original form, although the electrophysiological data remain on the table. After long debate, we arrived at a description of the extent to which connectivity is primarily in the transverse plane and the extent to which longitudinal and other more diffuse projections are a characteristic feature of hippocampal anatomy. Similarly, although recognizing that the original concept of the “trisynaptic circuit” may be too narrow, we continue to stress the sense in which unidirectional connectivity is a distinctive feature of the hippocampus compared to the neocortex, including the parallel connections made from the entorhinal cortex to the dentate gyrus, and to areas CA3 and CA1 of the hippocampus proper.

Chapter 4 considers how this intricate structure develops both from the perspective of overall organization and from that of individual cells. Here the interplay moves from pure anatomy to genes and molecular biology. Modern studies of the development of the hippocampus are characterized by molecular studies in which the temporal expression of the genes responsible for migration, neuronal specification, and axonal guidance—and for major cellular constituents such as receptor subunits—are being mapped out.

Chapter 5 takes us forward to a detailed analysis of individual cells in which we present, side by side, both anatomical and physiological ideas. To understand the principal cell types of the hippocampal formation—pyramidal and granule cells—and the several types of interneuron, one must know what these cells look like, know about their inputs and outputs, and grapple with the biophysical principles that govern how current injected into the cell at a dendritic synapse contributes to cell firing. It is necessary to understand how synapses at various dendritic locations differ in their synaptic effects and how these individual effects sum to control the cell discharge pattern. The large group of after-hyperpolarizing responses is essential for cellular behavior. The important modulatory effects of a set of controlling systems comprise a major topic.

The intricacies of neurotransmission are considered in Chapters 6 and 7 from physiological, pharmacological, and molecular biological perspectives. Chapter 6 considers how the release of glutamate from presynaptic terminals in the hippocampus and its action on various glutamatergic receptors mediate excitatory synaptic transmission. It also discusses the essential role of inhibitory synaptic transmission at GABAergic synapses. Because the hippocampus is one of the few regions where it is possible to have experimental control over a large set of converging inputs to an individual cortical cell, most of our ideas on cellular integration are derived from studies on hippocampal tissue. This chapter describes the intricate molecular machinery responsible for the mobilization of glutamate-containing vesicles, the exocytotic release machinery for glutamate, and its postsynaptic actions. It also outlines the various ligand-binding and modulatory sites on these receptors, the insights coming from the relatively new work on receptor subunits afforded by molecular biology and the mechanisms responsible for transmitter uptake. In many of these studies, genetically altered animals have been essential tools. The chapter touches on the important and developing topic of neuromodulatory transmitters in the hippocampus, such as acetylcholine, norepinephrine, 5-hydroxytryptamine, dopamine, and peptides such as dynorphin and somatostatin. The transmitters influence hippocampal excitability and second-messenger effector mechanisms in an orchestrated cascade of formidable complexity. Chapter 6 also discusses how the many neuromodulatory systems influence the traditional synaptic processes and the mechanisms by which they are mediated. These studies often are models for the general neuronal activity seen in other parts of the nervous system. Chapter 7 discusses the molecular biology of hippocampal cells with particular emphasis on synaptic function. Here, much of the pioneering work on glutamate receptor categorization was made in the spinal cord, whereas the important discovery of the voltage-dependent magnesium block of the *N*-methyl-D-aspartate (NMDA) receptor channel was discovered in hippocampal tissue. Notably, the hippocampal slice has been of critical importance for developing the modern understanding of ionotropic and metabotropic glutamate receptors.

Having described the three-dimensional organization of the hippocampus, its cells, synapses, and their transmitters and receptors, we need next to consider the local circuits that these structures produce and the possible types of neuronal processing they make possible. Chapter 8 takes on this task and endeavors to explain how an impressive multitude of inhibitory interneurons shape the number and pattern of the participating cells in a near-physiological situation. These interactions between principal cells and interneurons are particularly evident during periods of rhythmical theta and gamma activity.

The chapter on local circuits also provides an introduction to Chapters 9 and 10, where we confront activity-dependent neuronal and synaptic plasticity. One of the more extraordinary discoveries of recent times has been that new neurons can be formed in the adult brain. This is contrary to established dogma but, interestingly, the dogma that had been challenged in hippocampal studies nearly 30 years ago but was unappreciated at the time. The dentate gyrus is one of two major sites of adult neurogenesis. In Chapter 9, we discuss the extent to which new cells and connections can be made, a field of acute interest for basic and practical neurobiology. Chapter 10 focuses on processes to explain the fact that, once formed, hippocampal circuits are not immutable, as synapses throughout the various components of the hippocampal formation show both short-term and long-term changes. The latter includes the intensively studied phenomenon of long-term potentiation (LTP). Research on this form of synaptic plasticity has revealed a range of properties that are highly suggestive of a potential cellular memory mechanism. The effort to understand LTP mechanistically led to passionate debates that have stimulated a host of ingenious experiments. Research on synaptic plasticity, perhaps more than any other area of hippocampal neurobiology, spans the twin themes of the book. What is the purpose of LTP? Are its underlying neural mechanisms applicable to other areas of cortex? Research on the induction of this phenomenon has helped unravel one of the most satisfactorily elegant biophysical mechanisms in the nervous system: the role of the NMDA receptor as a coincidence detector. Having detected the conjunction of presynaptic activity and postsynaptic depolarization, this receptor signals the conjunction by an influx of the divalent cation calcium ( $\text{Ca}^{2+}$ ), which then sets in train a cascade of biochemical effects. The discussion of the NMDA receptor complements the earlier description of its molecular basis in Chapter 7. It activates signaling proteins associated with the receptor itself and calcium-dependent kinases. It may also help trigger the release of calcium from intracellular stores, thereby sustaining the synaptically evoked  $\text{Ca}^{2+}$  transient beyond the period that the NMDA receptor-associated ion channel remains open. The resulting biochemical cascade eventually results in an increase in synaptic strength. It should also be recognized that activity-dependent synaptic plasticity is not restricted to increases in synaptic efficacy—decreases can also be induced. This bidirectional feature of synaptic plasticity—that “what goes up must come down”—adds computational flexibility

and power. However, the extent to which bidirectional changes can be seen in the hippocampus in freely moving adult animals remains unclear. Chapter 10 also takes on the task of explaining the various behavioral studies that have attempted to identify the role LTP might play in learning, memory, or other cognitive processes. We outline studies that have examined correlations between the physiological properties of synaptic plasticity and behavioral learning and the effects of blocking it, saturating it, and erasing it. We offer no definitive answer to the question of the purpose of these various types of plasticity, but the tenor of our account is sympathetic to a role in the encoding and storage of certain kinds of memory.

Chapter 11 continues the behavioral theme with a survey of studies in which electrical activity in structures of the hippocampal formation has been recorded during various kinds of behavior. The pioneering work of this kind was conducted in rats and was heralded by the discovery of place cells noted earlier (neurons that fire when rats occupy particular positions in space). The further discovery of a different group of cells that fired during certain kinds of movement and in phase with slow-wave electroencephalographic activity was also important, as were findings of cells that code for the direction in which an animal's head is pointing or show grid-like patterns as an animal traverses a familiar space. These categories of cell are found in distinct areas of the hippocampal formation and in different cell classes within a single area. Work in nonhuman primates has also identified a class of cells that are responsive to the animal's view. The properties of these cells, their role in mapping space, and, according to some, other cognitive functions as well are gradually being unraveled. The process of discovery has been accompanied by the development of a new single-cell methodology that permits simultaneous recording from large numbers of neurons. This tetrode-recording technique enables the properties of several individual neurons in a population to be mapped simultaneously and has applications that extend well beyond hippocampal neurobiology.

Chapter 12 begins with the discovery, almost 50 years ago, that surgical damage to the hippocampal formation and related structures on both sides of the brain causes a profound, lasting global amnesia. Once this unexpected consequence had been observed, neurosurgeons took care not to perform bilateral medial temporal lobectomies. Such memory-impaired patients are therefore rare, but their very existence spurred the development of animal models through which, it is hoped, the role of the hippocampus in memory can be worked out. Modern functional imaging techniques are also providing new insights into the differential activation of various brain areas for different types of memory and different stages of memory processing. Such work has led to new concepts, such as the extent to which neuronal activation in a memory-related area reflects the effort devoted to encoding or retrieval or to the success of achieving either. Such conceptual dissociations are almost impossible to draw on the basis of lesion studies alone.

Chapter 13 takes up the theme set by these human studies to lay out a number of prominent theories of hippocampal function that have been developed from work on animals. One theory concerns the role of the hippocampus in remembering facts and events that can be consciously recalled, and another has to do with its role in mapping and navigating through space. Other theories have been developed to help address some of the issues and problems that have arisen in connection with these two ideas, particularly in situations of predictable ambiguity. We also outline current interest in the idea that the hippocampus plays a critical role in contextual encoding and retrieval, including episodic memory. This section attempts to link behavioral studies on rapidly learned forms of associative memory to the neurobiological observations on circuitry and synaptic plasticity outlined earlier in the book. Although one of the authors of this book is an architect of the second theory discussed, we attempt to present as objective an account of the state of the field as possible.

Chapter 14 takes us to computational models of hippocampal function. Some models focus on its global function, but even when they work they often involve assumptions that seem far removed from real neurobiology. These models are the artificial intelligence and idealized neural network models that can solve interesting cognitive problems—including navigation around the world or remembering associations in memory—but using processing units and learning algorithms that may not exist among real hippocampal cells. Other models incorporate more realistic assumptions about the hippocampal network and its neuronal components, the different classes of cells, and their phase relationships; but their processing tends to be more limited. Ultimately, the value of these models is to provide a predictive framework for understanding the mass of detail we have covered in other chapters of this book. To date, no model incorporates information realistically at each of the levels of the anatomical circuit, cellular architecture, and synaptic transmission. However, the pieces

and patches that will eventually enable a comprehensive neural network account of hippocampal function to be woven together are beginning to become apparent.

Last come Chapters 15 and 16. The first of these chapters picks up from a set of intriguing observations suggesting that the hippocampus, together with the amygdala and prefrontal cortex, play a role in regulating the hypothalamic-pituitary-adrenal axis, which is responsible for the release of stress hormones. The hippocampus contains a particularly high density of corticosteroid receptors of two major types, and this neuroendocrine detection of mild or severe stress has a dramatic impact on hippocampal physiology and memory function, including effects on LTP. Glucocorticoid receptors act as transcription factors, and it has long been thought that the primary expression mechanism was an intracellular regulation of genes. However, it is now becoming clear that there are a variety of more rapid effects of corticosteroid action in the hippocampus. Chapter 16 considers hippocampal pathologies. This is, of course, a large subject in its own right, and we cannot here do justice to a vast field of clinical research. To exclude it, however, would be wrong because all of us have an interest in alleviating the impact of human neurological disease. The importance of these conditions is underscored by the prevalence of disease: Alzheimer's disease alone affects around 20 million people worldwide. Substantial advances have been made in understanding the involvement of various components of the hippocampal formation in epilepsy and Alzheimer's disease, on which we focus; and this information has underpinned improvements in diagnosis and treatment.

This book is our tribute to the thousands of scientists who have contributed to our understanding of this beautiful and enigmatic part of the brain. We hope that it will help design new, revealing experiments and thereby increase our insight into its cellular, molecular, physiological, and behavioral processes. Should it also facilitate clinical studies, our satisfaction will be so much the greater.

## Historical Perspective: Proposed Functions, Biological Characteristics, and Neurobiological Models of the Hippocampus

### 2.1 Overview

This chapter has two major sections. In the first, we provide a selective overview of some of the historically important proposals concerning the function of the hippocampus. The current view, that the hippocampus plays a prominent role in memory, is dealt with in detail in Chapters 12 and 13. In the second major section, we highlight the historically significant advances in neurobiology that have been made by using the unique structure of the hippocampus for studies ranging from defining the morphology of excitatory and inhibitory synapses to developing computational models of memory. This second section is itself divided into subsections that emphasize first the biological characteristics of the hippocampus and then the advantages of the hippocampus as a model system for neurobiological research. Many of the most recent advances are dealt with in appropriate chapters, as we intend this chapter to be primarily a historical overview.

### 2.2 The Dawn of Hippocampal Studies

From the very start of brain investigations, the hippocampus has played a central role. No doubt this is due to the striking appearance of the large, bulging structure impressing itself into the lateral ventricle and visible even to the ancient anatomists. Members of the Alexandrian school of medicine were impressed by the elegant, curved structure, which when seen with its contralateral half strongly resembles the coiled horns of a ram. Hence, the ancient scholars named the hippocampus cornu ammonis, Latin for horn of the ram. This terminology survives in the acronyms for the hippocampal subfields CA1 (cornu ammonis), CA2, and CA3. Over the centuries, this part of the brain has been proposed as the seat of

many functions, ranging from olfaction to motor function and even reason, stubbornness, and inventiveness. The Bolognese anatomist Giulio Cesare Aranzi (circa 1564) was the first to coin the name “hippocampus,” undoubtedly because of its similarity to the tropical fish (Fig. 2–1).

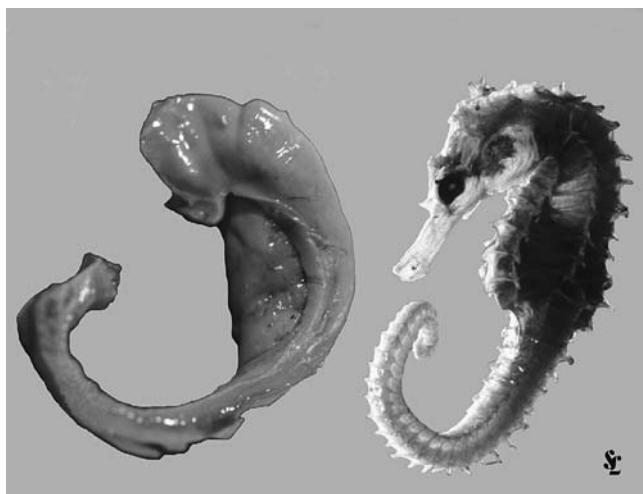

After the advent of microscopy, the hippocampus was perhaps even more impressive, with its characteristic, neatly regimented cellular arrangement. Although the hippocampal formation is organized in a very different way from other cortical areas, it has still played an important role in unraveling some of the basic principles of cortical organization.

Its stunning structure, with cell populations apparently condensed into single layers, has attracted the attention of many investigators of the central nervous system. A striking example is Camillo Golgi's picture from 1886, where he used his revolutionary new technique to illustrate the unique organization of the hippocampus, here reproduced from Golgi et al. (2001) (Fig. 2–2).

As noted in Chapter 1, the two themes of this book—the overall functions of the hippocampus and how its study has shed light on a range of general principles in neuroscience—can be highlighted by reference to the history of research on the hippocampus. Early work inevitably focused on anatomical issues, whereas later research successively brought in physiological, behavioral, and other technologies in an effort to fathom the function of the hippocampus and through it the workings of the brain.

#### 2.2.1 A Famous Dispute About the Significance of the Hippocampus

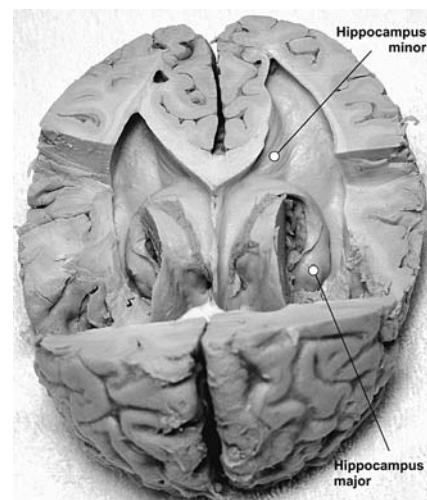

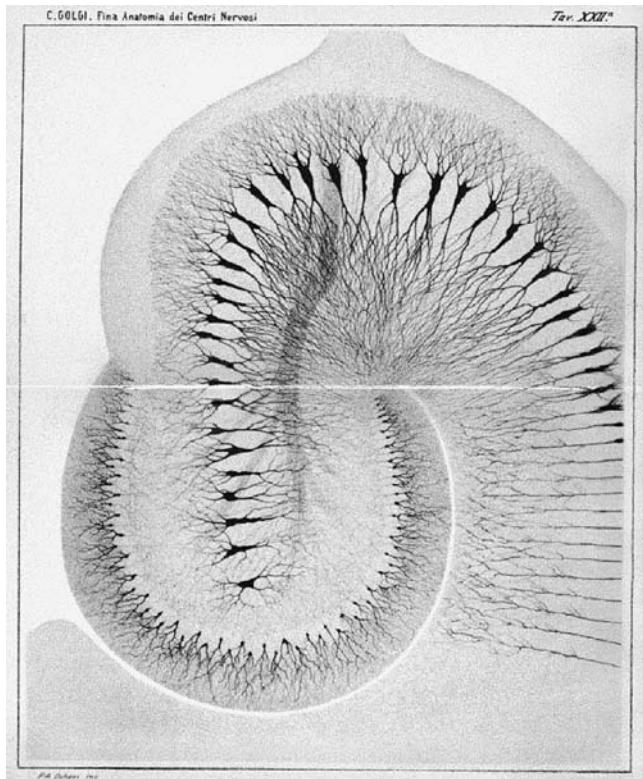

Interest in the hippocampus was particularly high during the eighteenth and nineteenth centuries, a notable example being its curious role in the famous debate between Richard Owen and Thomas Huxley at the British Association in Oxford in June 1860 following the publication of Charles Darwin's book *On the Origin of Species* in 1859 (Gross, 1993). The superin-

**Figure 2-1.** Human hippocampus dissected free (left) and compared to a specimen of *Hippocampus leria* (right). (Source: Courtesy of Professor Laszlo Seress, University of Pecs.)

tendent of the natural history collections of the British Museum, Richard Owen, claimed that only human brains contain a structure he called hippocampus minor, this being one essential distinguishing feature between Man and Apes. This structure is a relatively small bulge on the medial wall of the posterior horn of the lateral ventricle (Fig. 2-3). Huxley

**Figure 2-2.** Section of a rabbit hippocampus stained with the original Golgi method (1886). (Source: Golgi et al., 2001).

**Figure 2-3.** Hippocampus major and minor as seen in a human brain after the dorsal cortex and corpus callosum have been removed.

objected strongly, not least because of his own dissection results. Today, it is difficult to see how this particular bulge could have any bearing on the question of human evolution. The name hippocampus minor is really a misnomer because it has nothing to do with the hippocampal formation per se but is a fold of white matter around the calcarine fissure, in other words a visual cortical structure.

## 2.3 Early Ideas About Hippocampal Function

### 2.3.1 The Hippocampal Formation and Olfactory Function

Although the hippocampus had been casually implicated in a number of functions during the nineteenth and early twentieth centuries, until the 1930s the hippocampal formation was considered by neuroanatomists to be part of the olfactory system. Perhaps this was because macroscopic investigations left the impression that the hippocampus is especially large in macrosmatic animals (with large olfactory mucosa and bulbs) such as nocturnal insectivores and rodents. However, in these macrosmatic animals, the absolute sizes of the olfactory parts of the brain are quite small. In fact, it was claimed that the ratio of the volume of the hippocampus to the olfactory bulb is largest in humans (Rose, 1935). Indeed, as observed by Brodal (1947):

From a functional point of view it is worth emphasizing that the development not only of the fornix, but also of the mammillary body, the mammillo-thalamic tract, the anterior (more particularly the antero-ventral) nucleus of the thalamus and the cingular gyrus runs roughly parallel with the degree of develop-

ment of the hippocampus. All these structures reach their peak of development in man.

A possible basis for the idea of an olfactory function for the hippocampus (an idea that was repeated in numerous textbooks during the first half of the twentieth century) is the appearance of a few early behavioral and clinical observations. For example, David Ferrier (1876) observed “movements of the lip and nostrils on stimulation of the hippocampal lobe in monkeys.” John Hughlings Jackson and Charles Beevor (1890) reported a patient who had subjective olfactory sensations during seizures that originated in the olfactory cortex of the periamygdaloid gyrus. Later, Wilder Penfield and Theodore Erickson (1941) reported a patient who had “olfactory sensations as part of his epileptic seizure and where it seems to be the hippocampus which must be the site of the discharge” (p. 56).

In a scholarly and comprehensive review, Alf Brodal (1947) summarized the evidence for and against such a role for the hippocampal formation. He noted that phylogenetic and comparative neuroanatomical studies suggested that the hippocampus develops in parallel with the olfactory portions of the brain and that it is particularly prominent in macrosmatic mammals such as rodents and insectivores. Moreover, even in the gross brain or in normal histological preparations, fibers from the lateral olfactory tract can easily be traced to brain regions surrounding the hippocampal formation. Even so, Brodal raised a number of arguments against an olfactory role for the hippocampus, suggesting that the association of the hippocampal formation with olfactory function was largely based on circumstantial evidence.

Central to his thesis was the claim that fibers arising in the olfactory bulb did not, in fact, directly innervate any portion of the hippocampus. In particular, although he agreed that some olfactory fibers innervated the anterior portions of the parahippocampal gyrus, they did not extend back into the caudal portion of this gyrus where the entorhinal cortex resides. He did not entirely dismiss an olfactory role for the hippocampal formation and suggested that the entorhinal cortex “should be considered as concerned mainly with the association and integration of olfactory impulses . . . with other cortical influences” (p. 206). Among other negative evidence, Brodal cited several studies that attested to the fact that the hippocampal formation was present in anosmatic and microsmatic animals such as dolphins and whales (Ries and Langworthy, 1937) and that there was substantial regional differentiation in microsmatic humans. Furthermore, he cited the data of William F. Allen (1940) in which lesions of the temporal lobe had no effect on the ability of dogs to perform olfactory discrimination tasks. Brodal (1947) concluded, “No decisive evidence that the hippocampus is concerned in olfaction appears to have been brought forward” (p. 180).

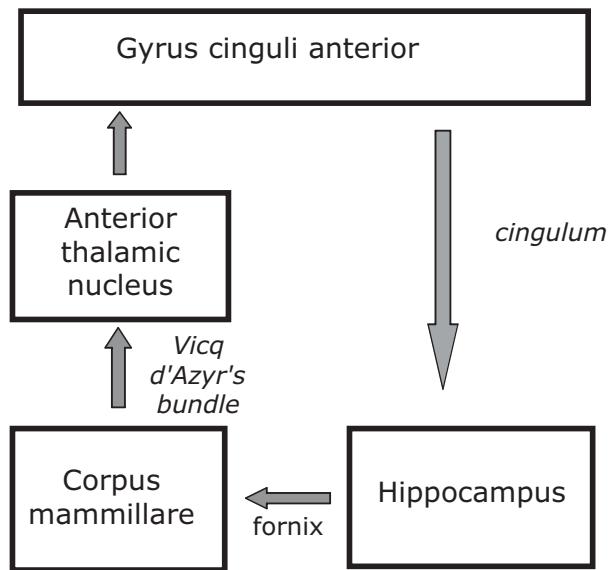

Brodal’s review was highly influential in raising doubts concerning the role of the hippocampus in olfaction. However, at least one of the pieces of evidence cited by Brodal—that there are no olfactory projections to the hip-

pocampal formation—has subsequently proven incorrect. More sensitive anatomical techniques have shown that in the rodent the entorhinal cortex receives a massive direct projection from the olfactory bulb as well as secondary olfactory inputs from the piriform and periamygdaloid cortices (Shipley and Adamek, 1984). Even in the monkey, the anterior portion of the entorhinal cortex is directly innervated by the lateral olfactory tract (Amaral et al., 1987). Thus, the olfactory system retains a privileged position in relation to the entorhinal cortex as none of the other sensory channels from which it receives information originates in primary or even higher order unimodal sensory cortices; rather, it comes from polysensory association cortices. Thus, although Brodal’s review was a milestone in the evaluation of hippocampal function and is partially responsible for the currently held view that the hippocampal formation is not a major component of the olfactory system, olfactory information certainly must contribute to the functions in which the hippocampus is engaged. Interestingly, olfactory learning and memory tasks are now widely used in studies of hippocampal function in rodents.

### 2.3.2 The Hippocampal Formation and Emotion

Another influential neuroanatomical hypothesis was proposed by James W. Papez (1937), who suggested that the hippocampus was part of a circuit that provides the anatomical substrate of emotion. He was influenced by the work of Walter B. Cannon (1929) and Philip Bard (1934), which indicated that the hypothalamus was essential for evocation of the autonomic and visceral aspects of emotional behavior. He accepted the view of Cannon and Bard that emotion has two component processes: emotional behavior and the cognitive appreciation of emotion. In an attempt to explain certain aspects of emotion, he proposed a circuit that interconnected cortical and subcortical structures (Fig. 2–4). In this now famous circuit, which bears his name (Papez circuit), he viewed the hippocampus as a collector of sensory information; this information, in turn, would develop an emotive “state” that would be transferred to the mammillary nuclei. In addition to mediating the appropriate behavioral response to this emotive state, the mammillary nuclei would also relay information to the anterior cingulate cortex via the anterior thalamic nuclei where conscious appreciation of the emotion would be achieved.

The central emotive process of cortical origin may then be conceived as being built up in the hippocampal formation and as being transferred to the mammillary body and thence through the anterior thalamic nuclei to the cortex of the gyrus cinguli. The cortex of the cingular gyrus may be looked on as the receptive region for the experiencing of emotion as the result of impulses coming from the hypothalamic region, in the same way as the area striata is considered the receptive cortex for photic excitations coming from the retina. (Papez, 1937, pp. 725–743)

**Figure 2–4.** Original Papez circuit. Later versions included the amygdala, hypothalamus, prefrontal cortex, and some association cortices.

Again, a comment from Brodal (1981) is skeptical. After having scrutinized the anatomical literature, he stated: “There is no sound biological basis for selecting a few brain regions as being involved in these complex functions (emotions), and today the theory of Papez is of historical interest only” (p. 672).

However, we may conclude that the Papez circuit was important historically because it shifted emphasis away from the idea of olfactory functions of the hippocampus. Moreover, it was one of the early ideas about how the brain might have more autonomy from the environment than suggested by the then current stimulus-response behaviorism. As we shall see, there is only moderate evidence to support the specific idea that the hippocampus is involved in emotion, although the idea has occasionally been championed, most notably in recent years by Jeffrey Gray (1982, 2001).

Papez’s speculations about the role of the hippocampus in emotion appeared to receive support from the experiments of Heinrich Klüver and Paul Bucy, which were carried out at the same time (1937). Klüver was a psychologist interested in the neural locus of action of psychotropic drugs such as mescaline. Together with Bucy, a neurologist, he searched for the locus of action by removing brain tissue from monkeys and looking for changes in their behavioral response to drugs. The changes that followed temporal lobe removal were interesting enough to warrant extensive description, and the constellation of changes is now known as the Klüver-Bucy syndrome. There are two important aspects to the syndrome: changes in visually guided behavior and changes in emotional expression. The lesioned monkeys appeared to have visual agnosia but would compulsively follow stimuli brought into their visual field; they continually placed all objects encountered in their mouths, perhaps owing to their failure to recognize the

objects by sight. In the emotional sphere, they were sexually aberrant and apparently without fear of stimuli that usually are frightening to them. It was this latter observation that appeared to confirm the role of the hippocampus in emotion predicted by Papez. However, it was subsequently shown that the loss of fear and other behavioral alterations could be attributed to damage to the amygdala and its connections with the visual regions of the inferotemporal cortex (Mishkin, 1954; Schreiner and Kling, 1956; Weiskrantz, 1956; Aggleton, 1993; Hayman et al., 1998). The hippocampus was again in search of a function.

Unbeknown to Papez, and probably also to Klüver and Bucy, a report appearing nearly a half century earlier by Sanger Brown and Hans Schäfer (1888) described the results of a large bilateral temporal lobe lesion on a “fine, large, active rhaesus” monkey. In addition to describing virtually all of the behavioral and emotional alterations of the Klüver-Bucy syndrome, they also reported disturbances in memory. They commented on the apparent forgetfulness of the monkey in the following way: “And even after having examined an object in this way with the utmost care and deliberation, he will, on again coming across the same object accidentally, even a few minutes afterwards, go through exactly the same process, as if he had entirely forgotten his previous experience” (p. 262). This little known observation of Brown and Schäfer presaged what has become the most enduring notion of hippocampal function—that it plays an essential role in memory.

### 2.3.3 The Hippocampal Formation and Attention Control

As early as 1938, Richard Jung and Alois Kornmüller had noted that desynchronization of the neocortical electroencephalogram (EEG) was temporally linked to a large-amplitude, sinusoidal wave pattern in the rabbit hippocampus at between 4 and 7 Hz, which they named “theta” activity. Later work suggested that this particular activity was related to enhanced attention (Green and Arduini, 1954). John Green and W. Ross Adey (1956) found that arousal caused an inverse relation between the electrocortical waves of the hippocampus and neocortex. Endre Grastyán and colleagues (1959) proposed that theta activity could be coupled to specific learning states (Fig. 2–13). Both hippocampal and entorhinal theta waves showed distinct changes during the acquisition of conditioned response (Holmes and Adey, 1960).

Other signs pointing to a role for the hippocampus in the control of attention came from electrical stimulation of the anterior part of the temporal lobe, including the hippocampus, which led to widespread and long-lasting desynchronization of the EEG in both anesthetized and awake cats (Kaada et al., 1949; Sloan and Jasper, 1950). Such responses were taken as evidence of a general activation of attention. Stimulation of the hippocampus in awake cats produced a peculiar reaction with pupillary dilatation and slow turning of the head and neck to the contralateral side, as if the animal experienced a weird sensory stimulus in the contralateral visual field (Kaada

et al., 1953). The reaction was associated with enhanced respiration and blood pressure. Similar reactions were elicited from the anterior cingulate gyrus, later to be associated with higher analysis of emotional signals. Modern imaging methods have revealed that this latter area is deeply engaged in the analysis of emotional aspects of sensory stimuli, suggesting that it is a device for estimating potential conflicts between old and new experiences (Bush et al., 2000; Botvinick et al., 2001; Bishop et al., 2004; Kerns et al., 2004).

In summary, this evidence suggests that together with the anterior cingulate cortex some portion of the hippocampus takes part in a certain form of general attention control.

### 2.3.4 The Hippocampal Formation and Memory

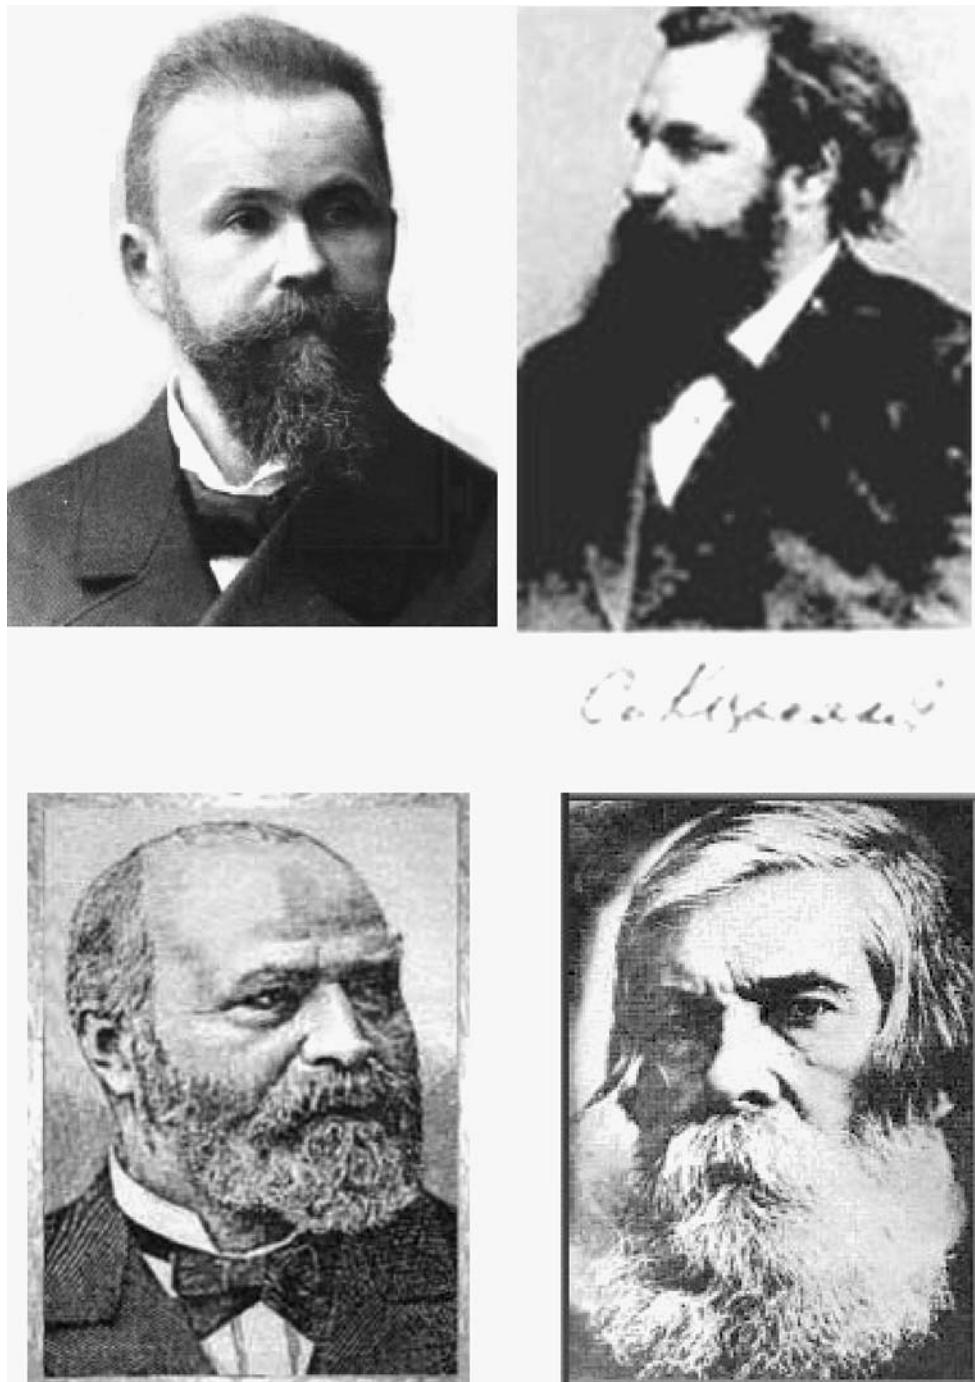

An early effort to analyze memory functions was that by Théodule-Armand Ribot, a French philosopher and psychologist. He proposed that memory loss was a symptom of progressive brain disease. His *Les Maladies de la Mémoire* [Diseases of Memory] (1881) constitutes an influential early attempt to analyze abnormalities of memory in physiological terms. He even proposed that a plausible memory mechanism could be an alteration in the activity of engaged cells in the cortex. This seems to be the first hypothesis to suggest a direct role of nerve cells for memory functions. Strongly influenced by Paul Broca's reports on language localization (Broca, 1861a,b), Ribot's views on localization of function in general were further supported by the clinical evidence of John Hughlings Jackson (1865), which showed memory loss in selected lesions, and by the experimental evidence from David Ferrier (1876), who reported on lip and nostril movements upon stimulation of the hippocampal lobes in monkeys. Richard Semon, much influenced by Ribot but working in Berlin (1908), was responsible for coining the term "engram" to signify a memory "trace" in the form of a physical change in the participating nerve cells.

Remembering that the hippocampal efferent impulses influence many hypothalamic nuclei, including the mammillary bodies, the first link between memory functions and part of the hippocampal system was made by three scientists during the 1880s who sequentially and semi-independently described an affliction causing amnesia. This condition was commonly associated with heavy drinking of alcohol and was later to be named Wernicke-Korsakoff psychosis. Subsequently, this disorder was associated with thiamine deficiency, which is often a correlate of dietary lack in the presence of alcoholism. In 1881, Carl Wernicke first described three patients whose illnesses were characterized by paralysis of eye movements, ataxia, and mental confusion. All three patients, two men with alcoholism and a woman with persistent vomiting following sulfuric acid ingestion, developed coma and died. In all three patients at autopsy, Wernicke detected punctate hemorrhages affecting the gray matter around the third and fourth ventricles and near the aqueduct of Sylvius. He believed them to be inflammatory and therefore named the disease polioencephalitis hemorrhagica superioris (Fig. 2–5).

Independently, Sergei S. Korsakoff (1889, 1890), a Russian psychiatrist, described a similar clinical picture he called psychosis polyneuritica and emphasized that the main symptoms were memory deficits. Finally, Johann Bernhard Alois von Gudden (1896) associated the condition with pathology of the mammillary bodies and the mediodorsal nucleus of the thalamus, both important target stations for hippocampal efferent pathways (see Chapter 3). After the first description of the Wernicke-Korsakoff syndrome, a similar condition with an emphasis on memory impairment was described by another Russian neurologist, Vladimir Bekhterev (1900). He reported two patients with a prominent memory deficit who were later found at autopsy to have softening of the hippocampus and neighboring cortical areas on both sides. This study appears to be the first hint of a hippocampal localization for memory.

### 2.3.5 More Direct Evidence for Hippocampal Involvement in Memory

The idea that the hippocampal formation is intimately associated with memory is due to observations made on brain-damaged patients by William Scoville and Brenda Milner in 1957. Scoville removed the mesial aspects of the temporal lobes from several patients in an attempt to relieve a variety of neurological and psychiatric conditions. The most famous of these, H.M., was a severely epileptic patient whose seizures were resistant to antiepileptic drug treatment. Following surgery, his seizures were reduced, but he was left with a profound global amnesia that has persisted to this day. H.M.'s memory deficit is observable as an inability to remember material or episodes experienced after the operation (anterograde amnesia); it also includes an inability to recall information experienced for some period of time prior to the operation (retrograde amnesia). H.M. can remember items for brief periods, provided he is allowed to rehearse and is not distracted. Upon distraction, however, H.M. rapidly forgets. Thus, he never remembers for any length of time the doctors who test him, his way around the hospital, or the story he has been reading. He reports his conscious existence as that of "constantly waking from a dream" and everything looking unfamiliar (see Chapter 12). The temporal characteristics of H.M.'s retrograde amnesia continue to be controversial. Originally it was thought by Milner to extend up to 2 years prior to the operation, with memories for events earlier than that remaining relatively intact. This duration of retrograde amnesia was later extended to 11 years (Sagar et al., 1985), with the recollection of more distant events preserved. The interpretation of the extent of retrograde amnesia is complicated by the fact that this length of time was approximately equivalent to the period of the preoperative epileptic condition. We shall return to a more detailed discussion of the subsequent work on H.M. and other amnesic patients in Chapter 12. Suffice it to say here that his memory disabilities are due to the removal of a large part of the hippocampal formation and surrounding cortical regions (Fig. 2–7).

The global amnesia reported in H.M. spurred efforts to find an animal model of amnesia. Early studies by Jack Orbach, Brenda Milner, and Theodore Rasmussen (1960) and by R.E. Correll and William Scoville (1967) looked at the effects, in primates, of various temporal lobe lesions on memory tasks such as delayed alternation and delayed response. Deficits were seen with combined lesions of the amygdala and hippocampal formation in the delayed alternation task (where animals are required to alternate their response from one trial

to the next) but not the delayed response task (where animals choose a well learned response after a delay period). Even lengthening the delay failed to reveal a deficit in the delayed response task. Thus, these early attempts in the primate were viewed as falling short of developing an animal model of medial temporal lobe amnesia.

Work on rats also failed to find a convincing memory deficit following hippocampal damage. Lesioned rats had no difficulties learning simple sensory discriminations: to press

**Figure 2–6.** Drawings of the brain of patient H.M., made on the basis of an MRI examination performed 40 years after bilateral resection of the medial temporal lobe. Drawings are of transverse MRI sections from various anterior-posterior levels: A through the amygdala; D at the posterior tail of the hippocampus. (*Source:* Corkin et al., 1997.) The lesion was bilateral, but its right side is here left intact to show structures that were resected.

levers in a Skinner box or to run down alleys to obtain food or avoid punishment. What emerged, however, was a loose constellation of deficits, including changes in exploration and habituation to novelty. For example, hippocampus-lesioned rats placed in novel environments were hyperactive (i.e., they moved around more than control rats and failed to reduce their activity progressively over time). They also failed to alternate choices on two successive runs in a simple T-maze when no rewards were available (spontaneous alternation). Both changes in behavior were attributed to deficits in inhibitory processes; and consequently a role for the hippocampus in response inhibition or Pavlovian inhibition was postulated by Robert Isaacson and his colleagues Robert Douglas and Daniel Kimble (e.g., Kimble, 1963, 1968; Douglas and Isaacson 1964; Isaacson and Kimble, 1972). Another change was a striking deficit in the ability to withhold a prepotent behavioral response, a finding taken as support for the response inhibition hypothesis. Hippocampectomized rats learned to run down an alley or press a lever for food as quickly as normals but were deficient in changing this behavior when the circumstances altered (e.g., when food was withdrawn or when an alternate response was rewarded). Interestingly, they were consistently better at learning one particular type of avoidance task: two-way active avoidance. In this task, the animal must learn to run back and forth between two compartments of a shuttle box to escape punishment. This improved learning seemed particularly anomalous in light of the presumed role of the hippocampus in memory. A third deficit lay in complex maze learning. Whereas they had no trouble learning to make a turn in a simple T- or Y-maze, they failed miserably at more complex multichoice configurations (Kaada et al., 1961; Kimble, 1963; Kveim et al., 1964).

**Figure 2–7.** Brenda Milner (left) pioneered the analysis of the role of the medial temporal lobes in memory. Donald Hebb (right) influenced a generation of neuroscientists with his theories on memory mechanisms. (*Source:* Courtesy Brenda Milner and [www.williamcalvin.com/](http://www.williamcalvin.com/).)

This confused state of affairs remained until around 1970 when several developments took place that together changed the approach to the hippocampal theory. The changes, which have continued to be influential, involved alterations in concepts about memory, the development of new tests for assessing memory, and the application of single-cell recording techniques to behaving animals.

Around this time, it was realized that there might be more than one type of memory, only one of which involved the hippocampus (Gaffan, 1974a; Hirsh, 1974; Nadel and O'Keefe, 1974; Olton et al., 1978). Two related ways of classifying human memory proved particularly influential. The first was Endel Tulving's contrast between memories for episodes set in a spatiotemporal context as distinguished from those for semantic items such as facts and other context-independent material (Tulving, 1972). The second was the related but different distinction between declarative and procedural memories, which was originally introduced by Terry Winograd (1975) in the field of artificial intelligence, subsequently applied to studies of amnesia by Cohen and Squire (1980), and extensively promulgated by Larry Squire and his colleagues (Squire, 1988, 2004). The former include both episodic and semantic memory, and the latter refers to skills and other stimulus-response habits. Both memory schemes have influenced research on amnesic patients and animal models of amnesia (see Chapters 12 and 13).

The second important development around 1970 flowed from the realization that the behavioral tests for animal memory available at that time were not optimal for testing hippocampal function. David Gaffan (1974b) introduced unique object recognition tasks. Mortimer Mishkin and Jean Delacour (1975) developed a version of this task that has become the standard test for recognition memory in the monkey (see Chapter 13). Following the introduction of these more powerful testing paradigms, efforts to establish memory systems became increasingly more fruitful.

### 2.3.6 The Hippocampus as a Cognitive Map

An important development in the analysis of hippocampal function was the use of implanted microelectrodes to monitor single-neuron activity in the hippocampus of the awake intact animal (Hirano et al., 1970; Vinogradova et al., 1970; O'Keefe and Dostrovsky, 1971; Ranck, 1973). These experimenters described the relations between cellular activity and a variety of sensory and behavioral parameters (Fig. 2–8). One correlate—that of the animal's location in the environment—gave rise to the cognitive map theory, which has fostered research into the spatial functions of the hippocampus (O'Keefe and Dostrovsky, 1971, see Chapters 11 and 13). This theory suggested that the hippocampus in animals was dedicated to spatial memory and allowed the animal to navigate in familiar environments. Extension of this theory to humans envisaged the addition of a temporal signal, allowing the hippocampus to act as a spatiotemporal context-dependent (episodic) memory. Lynn Nadel, John O'Keefe, and Abe Black (1975) proceeded to look carefully at the problems that rats with hippocampal

**Figure 2–8.** Olga Vinogradova was among the first who recorded single units from the hippocampus of awake animals (rabbits) while testing their behavioral responses to natural stimuli. She interpreted her recordings to mean that the hippocampus served as a novelty detector. (Source: Courtesy of Richard Morris.)

lesions had with avoidance learning. They concluded that deficits were found only when the animals had to learn to avoid places, not when they were given a clear prominent object or cue to avoid. Selective tests for the spatial functions of the hippocampus, including the Olton radial arm maze and the Morris watermaze, were subsequently developed (see Chapter 13).

### 2.3.7 Conclusions

We have provided a brief overview of some of the historical perspectives concerning the function of the hippocampal formation. Although there is widespread acceptance of the view that the hippocampal formation is involved in some aspects of memory, there may still be some surprises as to other potential functions of the hippocampal formation. As an important example, the hippocampus has been implicated in the modulation of stress responses through inhibitory projections to the hypothalamus. As described in Chapter 15, this putative role of the hippocampus has been implicated in a variety of normal and abnormal stress responses such as post-traumatic stress disorder.

## 2.4 Special Features of Hippocampal Anatomy and Neurobiology

We now turn to an overview of some of the early research on the hippocampal formation and the important historical

figures associated with it. The outcome of some of this research led to general principles of neuroscience (e.g., the neuron doctrine), whereas others have established the existence of unique features of the hippocampal system (e.g., the largely unidirectional nature of the intrinsic excitatory connections). In some cases, the motivation for studying the hippocampal formation was not so much to understand its function but to capitalize on some unique aspect of its anatomical and physiological organization to carry out an experiment of more general interest more easily.

A number of features have attracted scientists to the hippocampus for studies of general neuronal and systems properties. A short list of the useful anatomical and neurobiological features of the hippocampus includes the following.

- A single cell layer and strictly laminated inputs
- Predominantly unidirectional connections between a series of cortical regions
- Extrinsic and intrinsic fibers making numerous *en passage* contacts with target neuronal dendrites, running orthogonal to the main dendritic axis
- Synapses that are highly plastic
- Tissue that can be used in transplantation studies
- Neurons that can be successfully grown in culture
- Acute or cultured slices surviving for prolonged periods *in vitro*

The most striking difference between hippocampal and neocortical cortices is the aggregation of the principal cells in a single layer. Another major difference between the two cortical types is the direction of the afferent fibers. In contrast to the input to neocortical areas where most afferent fibers are radially oriented, the extrinsic and intrinsic afferent nerve fibers of the hippocampal formation run in a horizontal direction (parallel to the pial surface) and orthogonal to the apical dendritic axis.

Hippocampal studies were important during the nineteenth century controversy between the *neuron doctrine* and the *reticular theory*. The neuron doctrine proposed that each neuron was an individual cell that contacted but did not merge with other target neurons. The reticular theory, on the other hand, posited that nerve cells form a syncytium where one cell emits a protrusion, or fibril, that continues into other cells, thus creating an interconnected network of fibers from a large number of neurons. This controversy continued for some time because microscopes at the time were not able to resolve the neuronal membranes and the spaces (e.g., the synaptic clefts) that separated individual neurons.

Camillo Golgi, who strongly supported the reticular theory, used observations of the hippocampal formation to bolster his arguments. Employing the *reazione nera* (black reaction), as he called the staining technique, later to be called the Golgi method, he repeatedly pointed to the convergence of fine axonal branches from a large number of dentate granule cells to form a dense bundle in the hilus of the dentate gyrus (vertical bundle in Fig. 2–2). Here, he believed filaments from various axons made a large intertwined feltwork, thus sup-

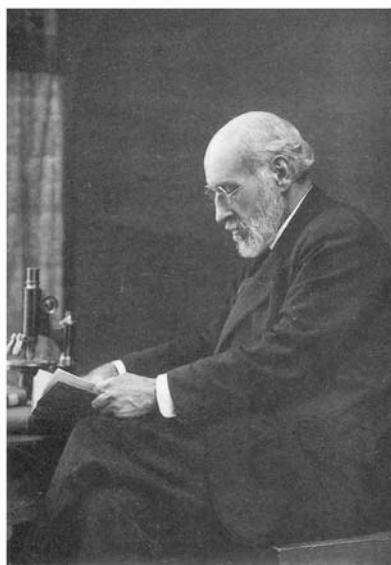

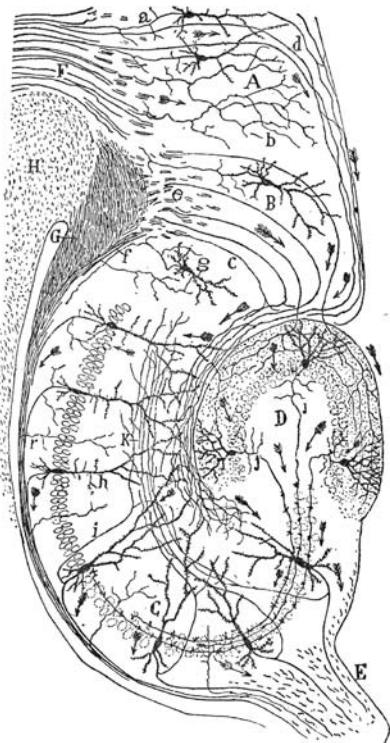

porting the reticular theory. He also pictured the dendrites of granule cells as being continuous with blood vessels that occupied the hippocampal fissure. Camillo Golgi's most outspoken adversary in the conflict over the neuron doctrine versus the reticular theory was Ramon y Cajal, whose support of the neuron doctrine came, ironically, from preparations made with Golgi's method. Although he also had many examples from the hippocampal formation, particularly in newborn rodents, his favorite preparation was the cerebellum. After examining thousands of preparations, he became convinced that individual neurons did not form a syncytial network. One particularly important piece of evidence was that he observed individual neurons that were in the process of dying. Neurons adjacent to these cells were entirely healthy. This was convincing evidence to Ramon y Cajal that neurons were individuals, not just members of interdependent groups. The debate lasted a number of years with a large number of participants, and was notable for the vigorous exchanges between the two factions.

The final resolution of this classic debate did not occur until the advent of electron microscopy, which conclusively supported the neuron doctrine by showing the neurons as individual entities with no connecting intercellular fibrils (Shepherd, 1972).

#### **2.4.1 Early Neuroanatomical Studies of the Hippocampus**

Hippocampal neuroanatomy benefited from the pioneering investigations of Camillo Golgi (1886), Luigi Sala (1891), and Karl Schaffer (1892). Santiago Ramon y Cajal (1893) described the stratification of the various afferent systems and drew a distinction between cells with long and short axons (Fig. 2–9). This observation made it clear that a hippocampal neuron could influence a large number of target cells and areas. Even before the formal definition of synapses by Charles Sherrington in 1897, Ramon y Cajal saw the functional implication of lamination. He suggested that there was a convergence of afferent input onto a single neuron, a notion that we take for granted today. His monumental effort, including an analysis of all portions of the hippocampal formation in a number of animal species, allowed him to propose a functional circuit diagram of this region. Following his principle of dynamic polarization—input to the dendrites, output through the axon—he placed arrows indicating his view of the direction of impulse flow through the hippocampal formation; many of these circuit characteristics have stood the test of time. He emphasized the size and variability of the various dendritic trees and gave a detailed description of dendritic spines and their distribution (structures that were dismissed by Golgi as artifacts of his staining method).

Simultaneous with Ramon y Cajal's first studies, the Hungarian anatomist Karl Schaffer, who gave his name (Schaffer collaterals) to the axons from CA3 cells that terminate in CA1 (1892), found by meticulous charting of well impregnated Golgi material not only that axons had short

branches but that some axons could be very long, connecting neurons in neighboring cortical fields. Nearly 40 years later Rafael Lorente de Nó (1934), building upon the work of his compatriot Ramon y Cajal, greatly extended the analysis of the many hippocampal cell types and their axonal and dendritic patterns. He described many detailed networks of interconnected neurons (Fig. 2–10). On the basis of their dendritic tree and connections, he divided the hippocampal formation into a set of clearly defined divisions and coined the well known terms CA1 to CA4.

The pioneering neuroanatomists came impressively close to modern-day thinking in their proposed schemata for functional connectivity in the hippocampus. More often than not, the diagrams of Ramon y Cajal (1893, 1911) indicated the correct direction of information flow. Likewise, the detailed drawings of various neurons by Lorente de Nó (1934)—in which he used the number of dendritic spines to estimate the relative efficiency of afferents terminating at various positions on the dendrites—allowed him to formulate a general rule about summation. Even so, to understand the operational rules of the hippocampus, specific details beyond the major sources and trajectories of the main afferent and efferent pathways were needed.

#### 2.4.2 New Fiber Tracing Methods

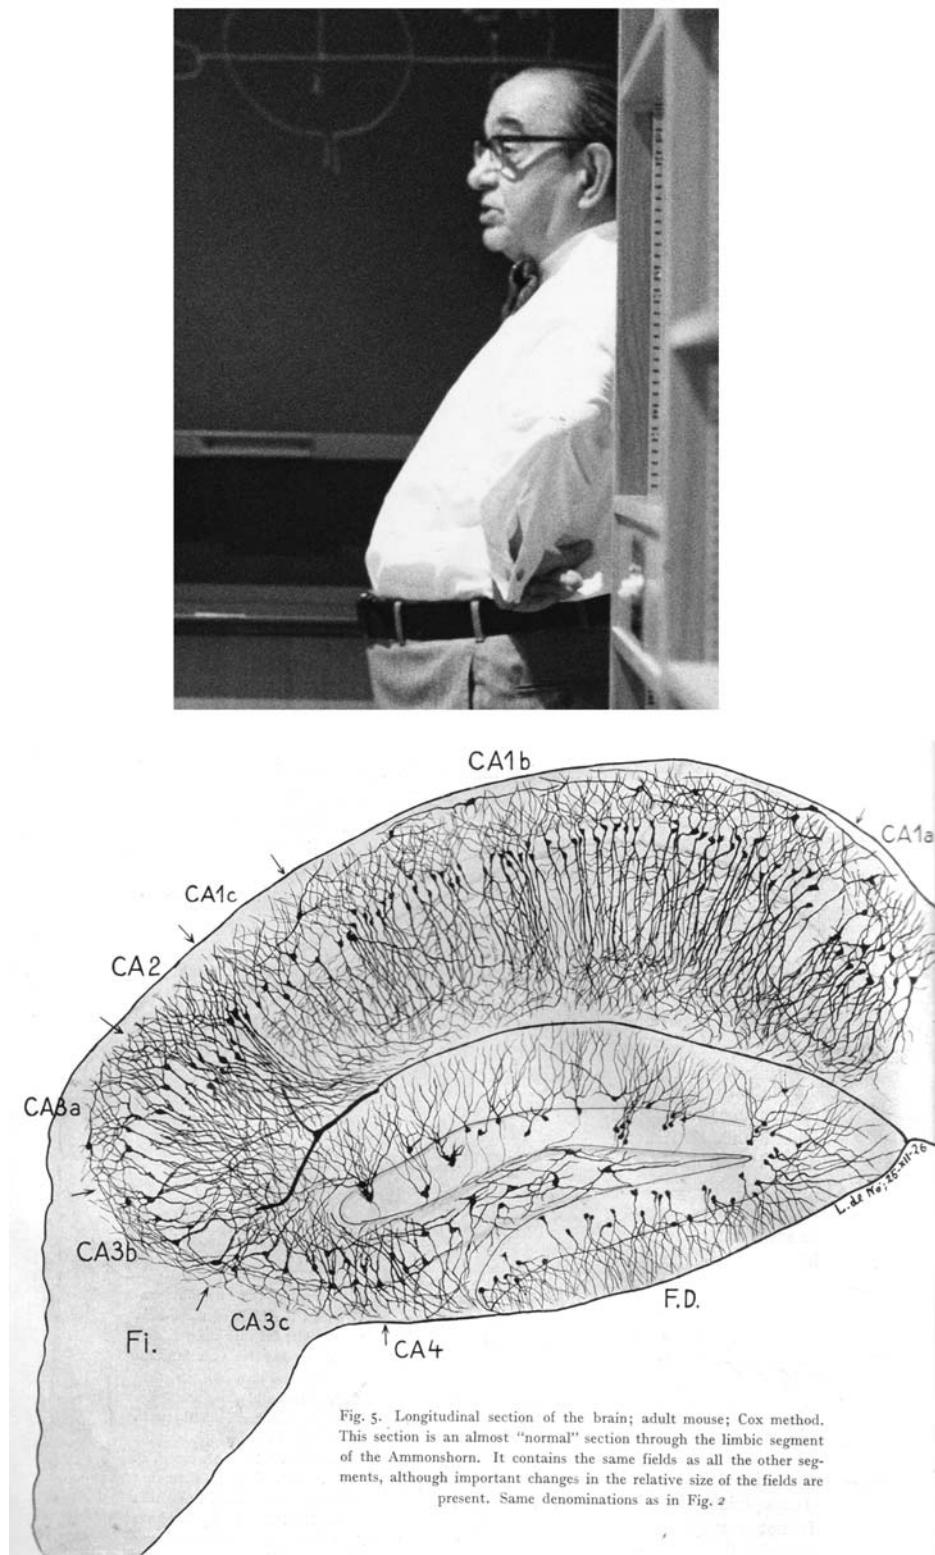

In parallel with the classic neuroanatomical studies with the Golgi method just described, much work was carried out to trace major afferent and efferent fiber systems in the central nervous system. The early studies exploited the fact that

degenerating fibers could be stained better than intact fibers. Temporal myelinization gradients were also useful. Unfortunately, these methods initially met with limited success in the hippocampus. Although the hippocampus contains several fiber systems with moderately thick myelinated fibers, most of its axons are much thinner than in other parts of the central nervous system (Shepherd et al., 2002). These features are probably one reason why the first available methods for experimentally establishing pathways by degenerating fibers did not give satisfactory results. For example, even after appropriate lesions, Vittorio Marchi's original method (Marchi and Algeri, 1886) stains only a small number of degenerating fibers in the alveus and fimbria. In addition, the stained fibers are exclusively among the thicker of those present.

#### 2.4.3 New Anatomical Techniques that Revolutionized Connectivity Studies

The situation improved greatly when certain variants of silver impregnation were applied to lesioned hippocampal pathways. Admittedly, the first silver degeneration method developed by Paul Glees (1946), was disappointing in the hippocampus despite the success it had in pathways of the brain stem. However, Nauta's 1950 method, soon followed by the Nauta and Gygax variant (1954) and Fink and Heimer's method (1967), were all remarkably effective.

Although similar in principle to other methods, Walle Nauta's methods turned out to be highly useful in hippocampal tissue. By employing the first variant of Nauta's tech-

**Figure 2-10.** Top: a rare picture of the pioneer Lorente de Nò, who had every reason to be proud of his 1934 drawings shown below, signed along the margin. The diagram shows the cell types and divisions and the terminology in general use today: fascia or gyrus dentata, CA1 to 4, subiculum, pre- and parasubiculum and the entorhinal area. niques, Theodor Blackstad (1956, 1958) (Fig. 2–11) showed how commissural and ipsilateral afferents to several parts of the hippocampus terminated in laminae oriented parallel to the cell layers (Fig. 2–11). These data not only verified the general principles established by Ramon y Cajal on stratification of afferent fibers but in addition showed astonishing density of presynaptic boutons in the innervated zone.

#### **2.4.4 Predominantly Unidirectional Connectivity Between Cortical Strips**

A key aspect of hippocampal connectivity was to emerge from these analyses: unidirectionality. Because the Golgi technique stains a relatively small proportion of the total number of neurons, this picture needed to be complemented by methods giving more quantitative data. Systematic study of each region of the hippocampal formation with suitable silver degeneration techniques, later supplemented by electron microscopic and anterograde and retrograde tracing methods, led to the realization that each component of the hippocampal formation projects to its neighboring region but generally does not receive a return pathway from this target (Hjorth-Simonsen, 1973). This was in good accord with previous physiological studies in which activation of the perforant path led to sequential activation of CA3 followed by CA1. A cut of CA3-to-CA1 fibers removed activity caudal to the section in CA1 and subiculum. On the other hand, stimulation in CA1 did not give synaptic activation in the CA3 region. These findings

**Figure 2-11.** Theodor Blackstad, often called the father of modern hippocampal histology because of his ground-breaking studies of its external and internal connectivity, with charting of degenerating fibers through silver staining and electron microscopy. (*Source:* Courtesy of Jon Storm-Mathisen.)

were the basis for the so-called trisynaptic circuit (Andersen et al., 1966). With this unidirectionality, the hippocampal system differs fundamentally from the reciprocal connectivity of nearly all neocortical areas. This principle of hippocampal neuroanatomy is discussed in detail in Chapter 3.

When a small fiber bundle of the Schaffer collaterals was stimulated, the amplitude of the synaptic potentials showed a characteristic distribution over the CA1 region. Signals were detected in the whole transverse extension of CA1. However, within the borders to CA3 and the subiculum, the largest potentials were detected along a strip oriented nearly transversely to the longitudinal axis of the hippocampus, with gradually reducing amplitudes on either side, the range spanning nearly half the length of the hippocampus. With stronger stimulation, the synaptic potentials generated a population spike (see Section 2.3), which had the same main orientation but with more restricted longitudinal distribution (Andersen et al., 1971b). This general arrangement was found for all four pathways studied—perforant path, mossy fibers, Schaffer collaterals, CA1 axons in the alveus—and the same orientation was found with orthodromic as with antidromic testing. This arrangement, which was named the lamellar organization, has received considerable opposition, mostly on anatomical grounds (see Chapter 3), probably because the name lamella invited visualizing a set of thin slices with sharp borders, like a loaf of bread. Instead, the lamella should be seen as the main orientation of a set of overlapping fan-shaped fiber regions (Li et al., 1994), with most branches and their synaptic effect along the major orientation and gradually less influence on either side. The efficiency of the transverse slice is an illustration of this organization, although the spread of fiber orientation allows signals to be elicited in slices cut at a less than optimal angle.

#### **2.4.5 New Tracing Studies Using Axonal Transport**

In addition to the connectivity of single cells, it was necessary to determine how aggregations of neurons were connected so early researchers could gain insight into how larger systems could operate in concert. New anatomical techniques exploited intra-axonal transport. Maxwell Cowan (Fig. 2–12) and his colleagues introduced a new technique for fiber tracing based on the anterograde transport of injected radioactive amino acids (Cowan et al., 1972) (Fig. 2–12). Here, they exploited earlier information showing that radioactive proteins could be transported inside axons in both anterograde and retrograde directions (Grafstein, 1971; Lasek, 1975). Cowan had an impressive lineage: His doctoral (PhD) studies were carried out under the mentorship of Thomas Powell of Oxford University (Fig. 2–12). Powell, Cowan, and Geoffrey Raisman were responsible for many of the classic studies of hippocampal and fornix connections (Raisman et al., 1965, 1966). Max Cowan's laboratory, in turn, spawned a number of hippocampal researchers, including Larry Swanson, Brent Stanfield, and David Amaral, who among them conducted a

**Figure 2-12.** Thomas (Tom) Powell (*top left*) and W. Maxwell (Max) Cowan (*top right*), the former born in Britain and the latter in South Africa. They both had illustrious careers in neuroscience, starting their work by tracing fiber systems in the hippocampal formation. (*Source:* Courtesy of Geoffrey Raisman.)

substantial portion of the modern studies on hippocampal connectivity. The autoradiographic method had the merit of allowing extremely small and discrete injections to be placed, with the  $^3\text{H}$ -amino acids being taken up and transported by cells of origin, not fibers of passage. One important result of this study was that it became clear that direct hypothalamic projections of the hippocampal formation arose not from the hippocampus proper but from subiculum regions (Swanson and Cowan, 1977). However, the hippocampal formation can influence a multitude of hypothalamic nuclei through multi-synaptic pathways.

In addition to the autoradiographic method, new methods that depended on axonal transport of various proteins or plant lectins were developed (Kristensson and Olsson, 1971; Gerfen and Sawchenko, 1984).

Fibers containing monoamines were also found to innervate the hippocampus. The first reports described noradrenaline (norepinephrine)-containing axons from the locus coeruleus (Segal and Bloom, 1974a,b).

#### 2.4.6 Electron Microscopy Offers New Opportunities

The first steps toward analysis of the number and types of synapses in the central nervous system also profited from work on the hippocampus. Following the pioneering work of Sanford Palay and George Palade in other brain regions (Palay and Palade, 1955), Lionel Hamlyn (1963) carried out the first electron microscopic analysis of the hippocampus. He provided the first comprehensive description of all synapses contacting the various portions of the dendritic tree in both CA3 and CA1 pyramidal cells. The introduction of electron

microscopy gave an unprecedented view of the details of individual cells and the contacts of neural circuits of the hippocampus and its main target nuclei (Raisman, 1969).

Moreover, the electron microscope also provided a new method for fiber tracing. When a fiber system was lesioned, the subsequent degeneration of both fibers and their associated boutons darkened within 1 to 2 days, a process that could be used for both synapse identification and connectivity studies (Alksne et al., 1966).

#### 2.4.7 Hippocampal Synapses Are Highly Plastic: Early Studies of Sprouting

The term *plasticity* is used to indicate several types of change. In addition to the well known activity-dependent alterations of synaptic efficiency (e.g., long-term potentiation, described in Chapter 10) there are numerous examples of anatomical changes in cell dimensions and number and in axonal length, branching and connections, and biochemical content in response to various stimuli or injury (see Chapter 9). The hippocampal formation was the first brain region in which axonal sprouting and reactive synaptogenesis were unequivocally demonstrated. Convincing experimental evidence of adult synaptic reorganization was described by Geoffrey Raisman (1969). He studied two sets of afferent fibers—one from the hypothalamus and the other from the hippocampus—that converged on cells of the septal nuclei. After long-term lesions of the fimbria, there was an increased number of multiple synapses (boutons in contact with several dendritic spines), interpreted as being the result of residual axons sprouting. Conversely, following removal of hypothalamic afferents, fimbrial fibers were found to contact somata of sep-

tal cells, which they rarely do normally. In another report, Raisman and Pauline Field (1973) exploited the fact that fimbria fibers innervate a segment of the lateral septal nucleus on both sides of the midline. A unilateral fimbrial lesion gave rise to remarkable sprouting from the contralateral fiber system such that the total number of fimbrioseptal synapses remained unchanged. Further work by the same group using transplantation of embryonic tissue for reinnervation of denervated hippocampal areas (Raisman and Field, 1990) sparked interest in the plasticity of hippocampal afferent and efferent fiber systems. However, the authors also warned that the reorganization was not necessarily adaptive or functionally important. A special case was the crossed entorhinal-dentate pathway, allowing a set of control experiments to determine factors of importance for reinnervation (Steward et al., 1974).

Nearly simultaneously, sprouting of hippocampal fiber systems was demonstrated with another approach by Gary Lynch and Carl Cotman and their associates (Lynch et al., 1972; Mosko et al., 1973; Matthews et al., 1976; Cotman et al., 1977; Goldwitz and Cotman, 1978). This group first showed that the acetylcholinesterase-containing septohippocampal fibers innervating the dentate gyrus increased in intensity and distribution if the perforant path fibers to the same region were removed. Electron microscopy confirmed that there was an early postlesion loss of synapses followed by a partial recovery. The remarkably efficient and fast regeneration is an impressive example of the plastic properties of hippocampal neurons. After lesions to the perforant path, for example, the maximal reduction of associated boutons in the molecular layer of the dentate gyrus was seen after about 5 days. However, after 2 weeks there was substantial recovery, and after 3 weeks the tissue had regained normal bouton density (Matthews et al., 1976).

#### **2.4.8 Hippocampal Neurons: Transplantable with Retention of Many Basic Properties**

Another remarkable example of neuronal plasticity is the ability of transplanted neuronal cells to emit axonal branches that grow and connect to existing neuronal target cells. The hippocampal formation was the testing ground for analysis of incorporation of embryonic transplants. After the work by Raisman's group, described above, Anders Björklund's group (Björklund et al., 1975, 1976) independently investigated the regenerative ability of transplanted monoaminergic tissue to reinnervate normal hippocampal tissue. They showed that transplanted tissue containing catecholamine- or acetylcholine-synthesizing neurons could extend axons and reinnervate the hippocampus in a normal fashion. When a graft of norepinephrine-containing neurons, whether from a peripheral source such as the sympathetic superior cervical gland or from a central location such as the locus coeruleus, was allowed to grow into a noradrenergic denervated hippocampus, grafted cells were observed to send out axons that entered the hippocampal formation but only if the cholinergic septo-hippocampal fibers were cut (Björklund and Stenevi,

1981, 1984). Lesions of the commissural or perforant path fibers did not induce such effects. The grafted sympathetic axons respected the lamination borders and formed typical norepinephrine-containing boutons with target neurons.

Similar results were obtained when cholinergically deafferented hippocampi received implants of acetylcholine-containing cells placed in a cavity formed after the original septal region had been removed. Again, both peripherally and centrally located donor neurons were effective, and the reinnervation by transplanted cholinergic fibers displayed homotypic localization. Particularly impressive was the functional recovery of spatial learning ability and the partial restitution of hippocampal place cell activity (Shapiro et al., 1989), which paralleled the regrowth of cholinergic fibers (Dunnett et al., 1982).

Following these encouraging initial observations, transplantation research in the hippocampal formation flourished. Subsequent efforts were directed at determining if cerebellar neurons would survive when transplanted into the hippocampus and if hippocampal tissue might be electrophysiologically active when grafted into the cerebellum and vice versa. In the latter situations, the transplanted hippocampal tissue assumed its original cellular appearance and synaptic lamination, and the cells showed electrophysiological properties typical of hippocampal neurons (Hounsgaard and Yarom, 1985).

#### **2.4.9 Hippocampal Cells Grow Well in Culture**

The hippocampus has become a favorite source of neurons in several forms of tissue culture. Early successes at defining the parameters for successful survival and maturation of hippocampal neurons came from the work of Gary Banker in the laboratory of Max Cowan (Banker and Cowan, 1977; Banker and Goslin, 1991). In such cultures both neurons and glial cells are readily identifiable and may be manipulated or recorded as individual elements. A disadvantage, however, is that the original cytoarchitecture disappears, including such characteristic hippocampal features as the laminated input with synaptic segregation. This problem led to the development of the organotypic slice by Beat Gähwiler and colleagues (Gähwiler, 1981, 1988; Gähwiler and Brown, 1985). With this technique, thin slices of hippocampal tissue can be grown for several weeks with an impressive capacity for neuronal growth and differentiation (Zimmer and Gähwiler, 1984). With care, most neuronal phenomena seen *in vivo* or in acute slices can be demonstrated. In addition, the longevity of the preparation makes possible a number of experiments, including rehabilitation after injury and analysis of the long-lasting effects of growth factors.

#### **2.4.10 Development of Hippocampal Slices: From Seahorse to Workhorse**

A major technological advance for hippocampal research, and indeed for the field of neurobiology, was the development of the *in vitro* hippocampal slice preparation. The pioneer in this

effort was the neurochemist Henry McIlwain. He set out to develop a reliable and functional *in vitro* preparation to investigate how various stimuli and compounds influenced the biochemistry of central nervous tissue (Li and McIlwain, 1957). He used a variety of preparations from the central nervous system. Despite considerable success, most of the horizontally cut neocortical slices did not allow a physiologically realistic afferent impulse pattern. More physiologically relevant data came when he employed slices from the piriform cortex. Here, stimulation of the lateral olfactory tract elicited synaptic and cell activity in neurons of the piriform cortex (Yamamoto and McIlwain, 1966a,b; Richards and McIlwain, 1967; McIlwain and Snyder, 1970). Tim Bliss and Chris Richards (1971) showed that field potentials similar to those found in the intact animal could be elicited in slices of the dentate gyrus cut along the septal-temporal axis of the hippocampus. With some technical modifications of the McIlwain procedure, Per Andersen, Knut Skrede, and Rolf Westgaard started to use transversally sectioned hippocampal slices from guinea pigs and demonstrated that intrinsic pathways could be successfully activated (Skrede and Westgaard, 1971). Single-cell activity could be recorded and showed short-term synaptic plasticity similar to that in intact, anesthetized preparations (Andersen et al., 1972). Rat and mouse hippocampal slices were useful as well, with the same type of signals as are seen in intact preparations. A distinct advantage was the great stability of the isolated slice preparation, which allowed long-lasting high-quality intracellular recordings to be made (Schwartzkroin, 1975). Important also was the precision with which electrodes could be placed and lesions created. The virtual lack of a blood-brain barrier is an experimenter's dream. A new opportunity arose when intracellular recording could be combined with iontophoretic delivery of transmitter candidates or blockers from multiple pipettes arranged to hit various parts of the dendritic tree (Schwartzkroin and Andersen, 1975). Fortunately, acute slices also supported well developed long-term potentiation (Schwartzkroin and Wester, 1975), a prerequisite for the wealth of analytical studies of this phenomenon (see Chapter 10).

## 2.5 Several Neurophysiological Principles Have Been Discovered in Hippocampal Studies

Although at first glance the hippocampal formation appears to be a special part of the brain with many features not seen elsewhere, it shares enough general features with other cortical regions to make it remarkably useful for studies of a general nature. Neurobiological principles that have been discovered from work on hippocampal preparations include:

- Identification of excitatory and inhibitory synapses and their localization, transmitters, and receptors
- Discovery of long-term potentiation and long-term depression

- Role of oscillations in neuronal networks
- Underlying mechanisms of epileptogenesis

### 2.5.1 Identification of Excitatory and Inhibitory Synapses

George Gray (1959) found that synapses in visual and frontal cortex could be divided into two distinct structural types, which he called type 1 and 2. Type 1 synapses were more heavily stained, and the synaptic specialization was asymmetrical in that the presynaptic density was less intensely stained than the postsynaptic density. Type 1 synapses were usually associated with dendritic spines. Type 2 synapses had pre- and postsynaptic densities with the same moderate staining intensity, and they were found mainly in association with dendritic shafts and neuronal somata. As to possible functional consequences of these differences, Gray (1959) concluded that, "At present there is no evidence to suggest that type 1 and type 2 synapses are functionally different" (p. 252).

When Gray's colleague Lionel Hamlyn (1963) studied the hippocampus, he found the same two synapse types and a similar distribution on dendritic spines and shafts. All synapses involving spines were of type 1, whereas synapses formed on the soma and thicker dendritic trunks or smooth branches were always type 2. A simultaneous report by Theodor Blackstad and Per Flood (1963) corroborated these data. It was comforting that the hippocampal cortex showed the same synaptic structures as those in neocortical areas. Conversely, this similarity made it possible that findings in hippocampal tissue also could be generalized to other cortical areas. What was needed for such a purpose was a correlation of functional and structural data from the same tissue. Such an opportunity arose with the advent of intracellular recordings from hippocampal neurons.

### 2.5.2 Gray Type 2 Synapses are Inhibitory and are Located on the Soma of Pyramidal and Granule Cells

In an influential intracellular study, Eric Kandel, W. Alden Spencer, and Floyd Brinley, Jr. (1961) reported on the ubiquitous and long-lasting inhibitory postsynaptic potentials (IPSPs) following both orthodromic and antidromic activation of cat CA2-CA3 pyramidal cells. Per Andersen, John Eccles, and Yngve Lønning (1964a) used a combination of intracellular recording of IPSPs and laminar analysis of the associated field potentials elicited by the same two activation modes. They showed that the initial phase of the IPSP in both CA1 and CA3 pyramidal cells and in dentate granule cells was associated with an extracellular positive field potential with a sharp maximum at the cell body layer, indicating a synaptic current leaving the somata of many principal neurons. This observation could be explained if the basket cell synapses, which terminate at the soma and initial axon, caused activated hyperpolarizing chloride conductances, and were in fact inhibitory interneurons. The basket cell synapses were exclu-

sively Gray type 2 (Hamlyn, 1963). Andersen, Eccles, and Løyning (1964b) looked for cells that were not antidromically invaded from the alvear fibers and thus were not pyramidal cells. They discovered a subset of such neurons that discharged repetitively with a time course corresponding to the rise time of synaptically activated IPSPs found in pyramidal and dentate granule cells, respectively. The location of such cells corresponded to the basket cells described by Ramon y Cajal (1911) and Lorente de Nó (1934). Hippocampal IPSPs were found to be bicucculine-sensitive by David Curtis, John Felix, and Hugh McLennan (1970) and therefore were mediated by  $\gamma$ -aminobutyric acid ionotropic receptor type A (GABA<sub>A</sub>) receptors.

Thus, the dentate and hippocampal basket cells were the first interneurons for which both the functional role and the identity of the effective synapses were revealed. Subsequently, findings from the hippocampal formation served as a template for similar searches in the cerebellum, thalamus, and other parts of the central nervous system.

However, the basket cell inhibition was far from exclusive. Later work in the cerebellum, hippocampus, and neocortex showed that many more types of inhibitory interneurons and synapses were present (Eccles et al., 1966).

### **2.5.3 Gray Type 1 Synapses are Excitatory and are Located on Dendritic Spines**

Identification of the morphological and functional characteristics of excitatory synapses was also first carried out in the hippocampus. Kandel et al. (1961) saw examples of excitatory postsynaptic potentials (EPSPs) in cat CA3 and CA2 pyramidal cells in response to subiculum or fimbria stimulation, but they were surprised how relatively rare such responses were compared to the ubiquitous IPSPs. This relative rarity made them difficult to analyze in detail. In rabbits and rats, field potential recording allowed better identification of synaptically activated cells.

Identification of excitatory synapses and their localization were the result of a combination of extra- and intracellular responses to various excitatory afferent pathways and a new method for marking synapses. In the perforant path-to-dentate granule cells, the first association between a field EPSP (fEPSP) and an intracellular EPSP was made by Per Andersen, Birgitta Holmqvist, and Paul Voorhoeve (1966b), proving that the fEPSPs used were monosynaptic events and that the synapses in question were excitatory.

With a similar approach, several other excitatory synapses were identified including perforant path fibers activating dentate granule cells, mossy fibers activating CA3 cells, and commissural and local intrinsic fibers in the stratum oriens activating CA1 pyramidal cells. Using intracellular recordings of monosynaptic EPSPs in rabbits and cats, in response to stimulation of four independent afferent fiber systems to CA1 and the dentate granule cells, the activated synapses were identified as excitatory. In each system, synaptic activation

gave rise to a localized fEPSP carrying a population spike, proving the excitatory nature of the connection. Following specific surgical lesions to each of these monosynaptic excitatory pathways, the method of Alksne et al. (1966) showed that boutons belonging to all four pathways were electron-dense, closely associated with dendritic spines, and Gray type 1 (Andersen et al., 1966a). Thus, the widely accepted idea that cortical (and many other) excitatory synapses are Gray type 1 and are usually located on dendritic spines emerged from these studies of the hippocampal formation.

In conclusion, within a few years during the 1960s, both inhibitory and excitatory synapses of the hippocampus were identified with respect to location, anatomical type, and function. These findings turned out to be applicable to many, albeit not all, parts of the central nervous system.

### **2.5.4 Long-lasting Alterations of Synaptic Efficiency After Physiological Stimulation**

Since the discovery of long term potentiation (LTP), hippocampal synapses have been the most studied exemplars of synaptic plasticity. These investigations are dealt with in detail in Chapter 10. Prior to the discovery of LTP, many other processes had been studied as potential models for learning. In particular, post-tetanic potentiation (PTP) was a common candidate for a number of years. Originally described by Martin Larrabee and Detlev Bronk in the sympathetic ganglia (1939), PTP appeared as enhanced synaptic responses following a period of high frequency tetanization of afferent fibers. The main weakness of PTP as an adequate mechanism for behavioral learning was its limited duration; in the spinal cord, PTP lasted only up to 7 minutes (Lloyd, 1949). The duration was increased to 30 minutes by Alden Spencer (Spencer et al., 1966) using long-lasting tetanization of polysynaptic spinal reflexes.

Limited duration was also an obstacle in the usefulness of the early studies of synaptic plasticity in the hippocampus. Several investigators had noted the remarkable growth of synaptic potentials during a period of high frequency stimulation (Cragg and Hamlyn, 1955; Kandel and Spencer, 1961b; Gloor et al., 1964). The critical question was: Would the enhanced excitability last for a significant period following cessation of the tetanic stimulation? Andersen (1960) noted that a period of enhanced synaptic response of commissural responses of CA3 and CA1 cells did indeed follow a short period of 10- to 20-Hz stimulation, but the duration was only up to 8 minutes and was initially regarded as an example of a special form of PTP. It soon became clear, however, that longer-lasting enhancement could be achieved when higher stimulation frequencies and, above all, repeated tetani were applied, as was first reported by Lømo (1966). This important discovery led the way to a description of truly long-term synaptic plasticity (hours and weeks), which is the basis for studies of LTP to this day (Bliss and Lomo, 1970, 1973). For a

full description of the processes and mechanisms underlying LTP, see Chapter 10.

### 2.5.5 Hippocampal Systems: Exhibiting Several Types of Oscillatory Behavior

A few years after Hans Berger (1929) described the human EEG, Alois Kornmüller in Berlin began a search for possible electrical equivalents to the cytoarchitectonic parcellation of the cerebral cortex pioneered by Korbinian Brodmann (1909), as mentioned in Section 2.1.3.

Working with rats, Case Vanderwolf (1969) discovered that theta activity occurred each time the animal initiated a “voluntary” movement, in contrast to movements initiated more automatically or in a reflex-like manner. He also identified two types of theta activity—atropine-sensitive and atropine-insensitive—the former related to attention and the latter to movements (Kramis et al., 1975). Atropine is an alkaloid that blocks muscarinic cholinergic receptors. In elegant analytical studies, Abe Black obtained evidence that the higher-frequency hippocampal theta activity was related to motor activity rather than to learning as such (Dalton and Black, 1968; Black, 1972; Black and Young, 1972) (see also Chapter 11).

Theta activity is also of interest as a means of identifying hippocampal interneurons and their relation to behavior (see Chapters 8 and 11). In addition, other types of oscillation at different frequencies, including beta and gamma

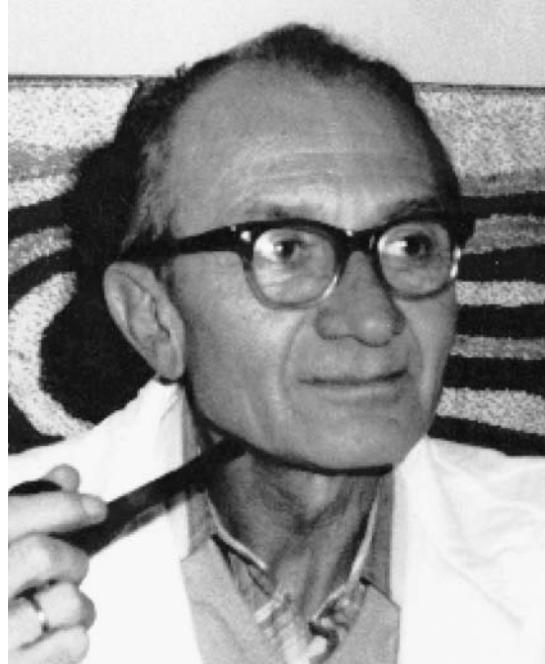

ranges, have been studied in hippocampal preparations (see Chapter 8).

### 2.5.6 Studies of Epileptiform Behavior

Richard Jung (1949) reported that electrical polarization (by long-lasting direct current) of the hippocampal formation readily gave rise to electrical after-discharges similar to those seen during epileptic seizures. By measuring the stimulus currents necessary to elicit such seizures in various tissues, he concluded that compared to other cortical areas the hippocampal formation needed considerably less current to elicit epileptiform seizures. This observation was in good accord with clinical experience gained from the EEG techniques introduced during the mid-1930s, suggesting that many epileptic conditions originated in medial temporal structures (Fig. 2-13).

Further progression of an electrographic seizure is often characterized by a set of depolarizing burst responses in which the extracellular responses are typically seen as a large local negative wave carrying a number of high frequency spikes of decreasing amplitude on its back, the so-called burst response (Ajmone-Marsan, 1961) at the onset of epileptiform discharges (von Euler et al., 1958; Kandel and Spencer, 1961b; Gloor et al., 1964). After a period with spontaneous high amplitude burst responses, the electrographic records diminish and all cells cease firing because of a depolarization block. Both *in vivo* and *in vitro* hippocampal preparations have been

and named theta waves, measured the low hippocampal threshold for epileptic seizures, and gave the first descriptions of visual cortical neuronal responses to contours, contrasts, and colors. (Source: Courtesy of Volker Dietz.)

**Figure 2-13.** Endre Grastyan (*left*), a Hungarian neuroscientist, was among the first to investigate the role of the hippocampus in conditioned learning. (*Source:* Courtesy of Gyorgyi Buzsaki.) Richard Jung (*right*) had a number of discoveries to his credit. He discovered

favorite tools in the search for cellular and network properties underlying the generation and spread of epileptiform activity (see Chapter 16). Among these preparations are the epileptiform activity provoked by kainic acid injections in CA3, GABA blockade by benzyl penicillin, and the effect of ouabain intoxication. An important model for epileptiform activity is the kindling phenomenon, described by Graham Goddard, D.C. McIntyre, and C.K. Leech (1969), who elicited seizures by repeated low-strength stimulation of the amygdala. Despite the ease with which electrographic seizures may be recorded from the hippocampus or the entorhinal area, these areas do not usually develop the kindling phenomenon. The role of the hippocampal formation in experimental and clinical epilepsy is discussed in Chapter 16.

## 2.6 Development of Methodological Procedures for General Use

The hippocampal cortex has served as a test bench for the development of a variety of general neuroscientific methodologies. In many instances this has led to the realization that the apparently special features of hippocampal tissue is also found in other central nervous structures. For example, the physiological properties of CA1 hippocampal pyramidal cells have much in common with those of neocortical pyramidal cells.

Below are listed some areas where hippocampal neurobiology has been instructive for neuroscience in general.

- First use of microelectrodes for extracellular neuronal studies
- Development of tetrodes for unit recording from behaving animals
- Interpretation of field synaptic potentials and population spikes as tools for analysis of extracellular signals
- Pioneering use of intracellular recording for central nervous system neurons
- Isolated slices of cortical tissue for neuroscience studies
- Development of histochemical methods for localization of neurotransmitters and receptor types
- Transplantation studies
- Pharmacological studies of central neurons and synapses
- Molecular biological analysis of synaptic function
- Formulation of computational models to explain ways in which neural networks can implement learning and memory

### 2.6.1 Hippocampus as a Test Bed for Microelectrode Work

Many of the standard methods used in neurobiology were developed in the peripheral or autonomous nervous systems or in muscular tissue. Recording from single nerve fibers was pioneered by Edgar Adrian and Yngve Zotterman work-

ing on the chorda tympani and lingual nerves (1926). Microelectrodes were developed during studies in cardiac and skeletal muscle by Ralph Gerard's group in Chicago (Ling and Gerard, 1949). In the spinal cord, Chandler McC. Brooks and John Eccles (1947) used microelectrodes to detect what they called a focal potential, a field potential generated by monosynaptic activation of motoneurons by volleys in muscle afferent fibers.

The first use of microelectrodes in the brain for extracellular recording of single nerve cell discharges was in the hippocampus by Birdsie Renshaw, Alexander Forbes and, Robert Morison (Renshaw et al., 1940). The researchers had greater success detecting activity of single nerve cells in the hippocampus than in neocortex, possibly because the latter tissue was more depressed at the levels of pentobarbital anesthesia used. In the hippocampus, these researchers recorded spontaneous and evoked discharges of what they called "axon-like spikes." Their description stated: "what is evidently the discharge of the same unit - they recur repeatedly with the same waveform" (p. 90). When describing the individual elements with a constant amplitude and predominantly negative polarity, they used what later became the classic criteria for identifying individual nerve cell discharges. Renshaw et al. localized such discharges to elements in the pyramidal layer and concluded that the "axon-like spikes" were discharges of individual pyramidal cells.

### 2.6.2 Pioneers of Intracellular Recording

The same experimental advantages that facilitated the analysis of extracellular unit recording potentials also paved the way for using the hippocampus for intracellular recording. The first to succeed in this technically demanding enterprise were Denise Albe-Fessard and Pierre Buser in 1952. They were surprised by the fact that nearly all penetrated cells showed a large, long depolarizing signal. Both its large amplitude and long duration made interpretation difficult. Initially, they took the response to be an EPSP. Later, it turned out to be an artifact recording of a large IPSP, which due to an electrode-induced chloride infusion went in the depolarizing direction. They did not record EPSPs with their technique, however.

The first satisfactory intracellular recordings from cortical neurons were made by Charles Phillips in 1956. He recorded from Betz' cells in the precentral gyrus of cats and characterized their response to both antidromic and orthodromic activation. This too proved a technically difficult task, not least because of the difficulty of finding monosynaptic afferent fibers to stimulate. Fortunately, the situation turned out to be easier in hippocampal preparations. As described in Section 2.3, Kandel, Spencer, and Brinley (1961) carried out the first comprehensive intracellular study of hippocampal pyramidal cells. In addition to their analysis of EPSPs and IPSPs (see above), they reported on prepotentials, which were short depolarizing deflections at the very start of the full action potential, interpreted as a sign of dendritically generated action potentials. They also recorded major features associ-

ated with the transition from normal behavior to epileptiform behavior in the form of slow depolarization waves and the occurrence of giant depolarizations with superimposed burst discharges (burst responses) (Kandel and Spencer, 1961a,b). This was an essential step in epilepsy research.

In contrast to the wealth of inhibitory synaptic data, there was a surprising paucity of excitatory synaptic signals. This may be related to the barbiturate anesthesia with its facilitating effect on IPSPs, an effect also discovered in the hippocampus by Roger Nicoll and Eccles (Nicoll et al., 1975). As mentioned above in the discussion of IPSP and EPSP identification (see Section 2.3.1), intracellular recording from hippocampal neurons was essential for the identification and localization of inhibitory synapses to the soma and of excitatory synapses to dendritic spines.

### 2.6.3 Tetrode Development

Following the recording of single-cell activity in awake, behaving animals (O'Keefe and Dostrovsky, 1971; Ranck, 1973) it became clear that hippocampal cells signaled differently from, say, visual cortical cells. The latter could be classified as sensitive to contrast or color and with specific and repeatable patterns to a standardized stimulus delivered to a restricted part of the visual field—the cell's receptive field. In contrast, hippocampal cells showed a much lower rate of discharge, more variability from one trial to the next, and a receptive field related to the aberrant concept of space (see Chapter 11). Subsequently, it became clear that hippocampal neurons operated in ensembles and deciphering the full code might receive simultaneous recording from a number of neighboring cells. This led to the development of recording techniques with double electrodes, or stereotrodes (McNaughton et al., 1983), and finally quadruple electrodes, or tetrodes (O'Keefe and Recce, 1993; Wilson and McNaughton, 1993). Such electrode assemblies allow simultaneous recording of a large number of cells in the freely moving and behaving animal by taking into account the constant shape and form of the potential generated by discharges of each of the active cells as seen by each of the four electrodes. The tetrode technique has revolutionized the study of hippocampal neuronal activity and spatial behavior. For a further account of this field, see Chapter 11.

### 2.6.4 Field Potential Analysis

After the pioneering use of microelectrodes during the 1940s, several years passed before further progress was made in studies of the hippocampal region using cell discharge recordings. During the mid-1950s, however, several groups started to use field potentials to understand the pattern of activation or inhibition of hippocampal systems.

In an early study of field potentials, Lorente de Nó (1947) studied the signal sequence when a nerve volley traveled antidromically into the hypoglossus motor nucleus. He offered the first theoretical explanation for the generation of such field potentials.

In the hippocampal formation, the histological arrangement is highly favorable for field potential studies of both orthodromic and antidromic activation (see Box 2–1). The dense packing of the cell bodies, the roughly parallel position of the apical dendrites of hippocampal neurons, and the ease with which they can be synchronously activated are three main reasons for the striking appearance of hippocampal field potentials.

The main advantage of using field potentials is that an extracellular potential recording may give an accurate index of synaptic activity with regard to amplitude, time, and polarity. First, the parallel orientation of a large number of principal cells may generate a field potential of considerable magnitude. The fEPSP has maximum negativity in the region with the highest concentration of activated excitatory synapses. Neighboring activated synapses add their effect largely linearly, justifying the use of the fEPSP amplitude as a measure of synaptic strength. Conversely, synchronous and local activation of inhibitory fibers also gives rise to large currents, but in the opposite direction. The usefulness of the recording procedure coupled with its simplicity lies at the heart of the popularity of field potential studies.

Brian Cragg and Lionel Hamlyn (1955) were the first to record significant elements of the hippocampal field potentials. However, because they placed their stimulation electrode very close to the recording site, the axonal conduction distance was very short. Consequently, their records of the synaptic component of the field potentials were brief and difficult to isolate from the rest of the compound signal ("action potential" in their nomenclature). Nevertheless, they were able to report the first evidence of conduction along the apical dendrites and found that the minimal latency was associated with the dendritic position of the activating synapses. With a commissural input, the shape and conduction of these action potentials were similar to those found with close-range stimulation (Cragg and Hamlyn, 1957).

The large compound action potential that followed stimulation at close range, later called the "population spike," was first noted by Cragg and Hamlyn (1955, 1957). Although claims to dendritic conduction had been made on the basis of neocortical surface stimulation, the specialized hippocampal histological arrangement made interpretation of the records much more convincing. Today, a new and much more detailed view on dendritic conduction has emerged, largely owing to whole cell patch recordings from dendrites. Again, much of the evidence for dendritic properties has been obtained from hippocampal preparations (Spruston et al., 1995; Johnston et al., 1996; Stuart et al., 1997) (see details in Chapter 5).

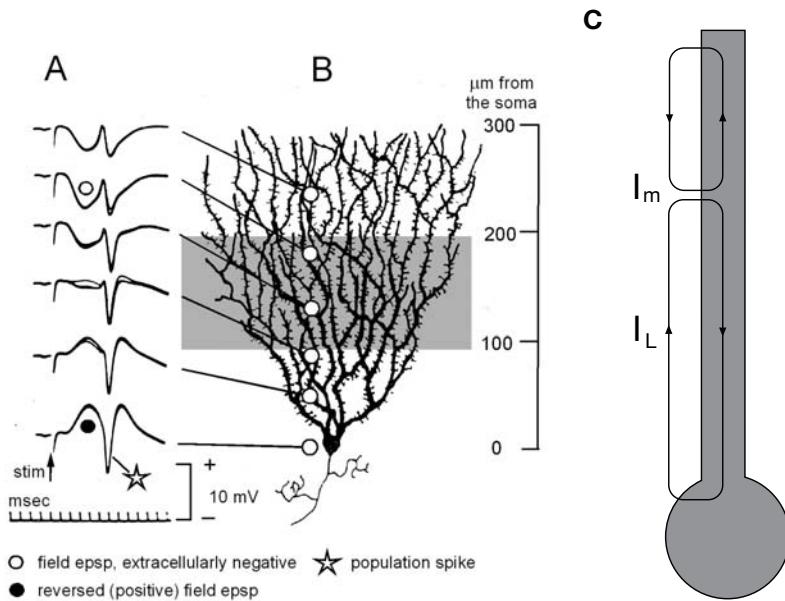

Several other groups exploited the laminated synaptic arrangement to identify the field potentials associated with restricted dendritic synapses. To make the hippocampus a useful preparation for studying synaptic activation, it was necessary to ascribe a standard extracellular signal to a standardized input. Recording from various dendritic positions, Andersen (1960) described how commissural fibers to CA1

**Box 2-1****Field potentials and current source density analysis**

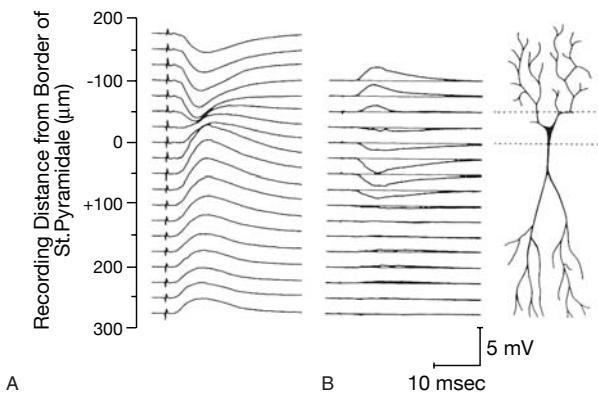

Field potentials are extracellular potentials recorded from groups of nerve cells in response to synaptic or antidromic stimulation. In laminated structures such as the hippocampus, field potentials provide surprisingly detailed information on cellular activity.

A field potential is generated by extracellular current flowing across the tissue resistance between the recording electrode and, in general, the ground electrode. Although measurable extracellular voltages are generated by action potentials in a single neuron, and form the basis of single unit recording, synaptic currents generated by single neurons are generally too small to be detected. In the hippocampus, and other highly laminated structures such as the olfactory cortex, the synchronous and localized currents generated by synaptic activation of a population of pyramidal or granule cells gives rise to a characteristic and easily measured response called a population or field EPSP (fEPSP); with weak stimulation, the synaptic response is below threshold for the generation of action potentials in the target cells, and a pure fEPSP is generated. With stronger stimulation, the cells discharge synchronously, giving rise to a population spike which is superimposed on the rising phase of the fEPSP. Unlike the all-or-none action potential generated by a single neuron, the population spike is a graded response; as stimulus intensity increases, the number of neurons discharged becomes greater, and the population spike becomes correspondingly larger.

In Box Fig. 2-1 stimulation of medial perforant path fibers activates synapses in the middle third of the molecular layer of the dentate gyrus (shaded gray). The field responses recorded at various positions along the soma and dendritic tree are shown on the left. Synaptically generated current flows into the dendrites in the activated region; inside the cells, current flows proximally and distally away from the synaptic region, exiting where membrane area is greatest, notably in the region of the soma. The current loop is completed extracellularly, with current flowing radially from distal and proximal sources towards the sink in the synaptically active region. With a distal ground electrode, these synchronous extracellular currents give rise to field EPSPs that are negative in the region of current sinks and positive in regions of strong current sources. Note that the current sink generated by synaptic activation is in the molecular layer, while the passive source is in the cell body region and in distal dendrites; the converse situation obtains for the population spike; here, the active sink is in the cell body region while the passive source is in the dendrites. The polarity of the fEPSP and the population spike are, as a result, spatially out of phase.

**Box Fig. 2-1.** Field potentials. A. Field potentials generated by dentate granule cells in response to stimulation of the medial perforant path. Activated synapses are located in the middle third of the dendritic tree (gray band in B). In this region the field potential (fEPSP) is negative, reversing to a positive polarity near the cell body layer. The population spike (star) is negative in the cell body layer, and positive in the dendritic region. (Source: Andersen et al., 1966a). C. The direction of intracellular, extracellular and transmembrane current flow generated by synaptic activation in an activated neuron.

**Box Fig. 2-2.** Current source density analysis. A. Field potentials evoked by weak activation of fibers projecting to stratum oriens in area CA1, evoking a pure synaptic response without a superimposed population spike. B. CSD analysis reveals a sink (positive) in stratum oriens and a source (negative) in the cell body layer and proximal dendrites. Arbitrary units. (Source: Richardson et al., 1987).

A further refinement called current source density (CSD) analysis allows the precise regions of inward and outward current to be plotted. Box Fig 2-2A displays the fEPSPs recorded at different locations in area CA1 *in vitro* following weak synaptic activation. For a given latency, a depth profile can be generated, showing how the amplitude and polarity of the response changes with location.. By Ohm's law, the current flowing in the longitudinal direction, parallel to the dendrites, is proportional to the rate of change of voltage in that direction:

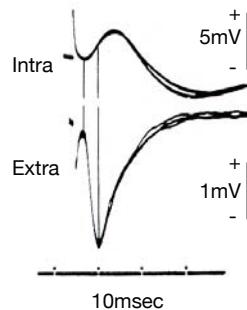

$$I_L = k \cdot \partial V / \partial L$$

where  $I_L$  is the longitudinal current density at a given point  $L$  along the longitudinal axis of the cell,  $V$  is the potential at point  $L$ , and  $k$  is the conductivity of the extracellular space. Thus the first spatial derivative of the depth profile yields a plot of the longitudinal current as a function of location at the selected latency. Current flowing through the membrane at any point must be equal to the rate at which longitudinal current changes at that point, i.e.

$$I_M = -\partial I_L / \partial L = -k \cdot \partial^2 V / \partial L^2$$

The second spatial derivative of the depth profile is thus proportional to the amplitude of the membrane current density,  $I_m$ . By repeating this analysis at a succession of latencies, the time course of current sinks and sources at each location can be calculated. A full CSD analysis, computed from the sequence of fEPSPs evoked at different locations along the dendritic tree by weak stimulation of Schaffer commissural fibers projecting to the basal dendrites of pyramidal cells in area CA1 is shown in Box Fig. 2-2B. The voltage responses are on the left, and the current source density analysis, revealing the development of sources and sinks over time, are plotted on the right.

Field EPSPs have the same time course as the synaptic current that generates them, and are therefore phase advanced with respect to intracellular EPSPs which are delayed by the time required for the membrane current to charge membrane capacitance (Box Fig 2-3). Further discussion of field potential theory can be found in Stevens (1966), Rall and Shepherd (1968), Nicholson and Freeman (1975) and Johnston and Wu (1994).

**Box Fig. 2-3.** The extracellular field EPSP reflects intracellular events, but is phase advanced with respect to the intracellular EPSP. Recordings were made from the dentate gyrus *in vivo* (Source: Lømo, 1971).

and CA3 gave a local negative field potential in exactly the same strata where Theodor Blackstad (1956) had found that the relevant fibers terminated. Such negative field potentials were taken as a sign of excitatory synaptic activity and was called a field excitatory postsynaptic potential (fEPSP). Above a given strength the fEPSP was interrupted by a compound action potential, called the population spike because it was interpreted as the synchronous discharge of a number of pyramidal cells. This interpretation was supported by the observation that most of the synaptically activated unitary cell discharges fell within the time envelope of the population spike (Andersen et al., 1971a).

Thus, the extracellular field potentials can be used as a sensitive, quantitative measure of the intensity of excitatory and inhibitory synaptic effects and the efficacy of postsynaptic activation. Final confirmation of the field potential interpretation given above came with intracellular recording of dentate granule cells (Andersen et al., 1966b; Lømo, 1971) and the use of isolated slices, where intracellularly recorded EPSPs were associated with excitatory field potentials in CA1 pyramidal cells (Schwarzkoenig, 1975; Andersen et al., 1980).

### **2.6.5 Histochemistry: Pioneered in the Hippocampus**

We have become used to the hippocampus as a favorite preparation for histological, electrophysiological, and behavioral studies. Less well known is its essential role in the development of neurochemical methodology and histochemistry. Once again, it was the packing of homogeneous cells into compact cell layers and the striking stratification of afferent fibers and synapses to specific parts of the dendritic tree of principal cells that appealed to the exploring scientist.

Until the middle of the twentieth century, virtually all neurochemical analyses were conducted on homogenized tissue of relatively large samples from various parts of the brain. This procedure was thought to be necessary because of the extreme complexity of central nervous tissue. In an attempt to perform analysis of more discrete CNS elements, Oliver Lowry exploited the synaptic lamination of the hippocampus to perform a detailed neurochemical dissection of cortical tissue. He noted the following:

Ammon's horn is a region of the cerebral cortex which is organized in such a manner as to invite quantitative histochemical study.

Enzyme concentrations and lipid type and concentration were measured for individual strata of the hippocampal cortex. In a pioneering series of papers (Lowry et al. 1954a,b,c; 1964), Lowry and his colleagues made several fundamental advances. First, they introduced a number of methodological improvements. By dissecting freeze-dried tissue from thin slices of hippocampus under a microscope, they were able to reduce the sample size to 5 to 10 µg of tissue. Second, the accuracy of the enzymatic measurements greatly improved. The enzymes of interest spanned a large range from acid and alkaline phosphatases through adenosine triphosphatase,

cholinesterases, and aldolase to lactic, malic, and glutamic dehydrogenases. Lowry's group also determined the lipid content and type as related to cortical layers. Third, it was the first instance when a neurochemist explicitly exploited a special histological arrangement for localizing biochemical elements, initially in the hippocampus and then in the cerebellum. His group reported impressive homogeneity in a single stratum and often a considerable variation among various strata. In particular, he noted the much higher ATP concentration in the dendritic areas than in the cell body layer.

Using a microdissection method, Storm-Mathisen and Fonnum (1972) were able to attain quantitative data for GABA and glutamate concentrations in various hippocampal strata. The amount of GABA was particularly high in the pyramidal layer, in accord with the concentration of inhibitory boutons here. However, the high amount of GABA even in the stratum lacunosum-moleculare pointed to new challenges.

Peter Lewis and Charles Shute (1967) extended the chemical dissection by performing the histochemical analysis directly on sections from the hippocampus. They showed that the distribution of acetylcholinesterase was concentrated in certain lamina, an approach that heralded a new approach to chemical analysis of the CNS. This histochemical approach also provided the groundwork for many of the studies on synaptic sprouting that followed during the 1970s (see Chapter 9).

The later development of histochemical and immunohistochemical studies have largely concentrated on microscopic sections. For this approach, hippocampal tissue has also been a favorite choice. Among these developments, the electron microscopic identification of bouton contents with antibodies raised against an aggregate of amino acids and bovine globulin marked an entirely new, powerful approach (Storm-Mathisen et al., 1983). Thus, the hippocampus has played an important role in the development of histochemical techniques for both fresh and fixed tissue.

### **2.6.6 Pharmacological Analysis of Cellular Properties**

The hippocampus has also been important for the development of ideas in the neuropharmacology of synaptic transmission in the CNS. Following the demonstration of glutamate sensitivity of spinal cord cells by David Curtis and Jeff Watkins (1960), Tim Biscoe and Donald Straughan (1966) found that hippocampal pyramidal cells were sensitive to iontophoretic application of glutamate. Together, these studies suggested the radical (at the time) possibility that glutamate was an excitatory neurotransmitter in the CNS. Support came from an ingenious study on hippocampal slices in which Nadler et al. (1976) measured  $\text{Ca}^{2+}$ -dependent release of aspartate and glutamate. Because the release of both compounds was grossly reduced after lesions of commissural or entorhinal fibers, the release is likely to have come from boutons of the two fiber systems, thus supporting the idea that aspartate or glutamate could be excitatory transmitters.

Postsynaptic inhibition produced by Purkinje cells in the lateral vestibular, and deep cerebellar nuclei was first shown to be mediated by GABA by Obaka and colleagues (1967). As mentioned above for hippocampal inhibition, David Curtis, John Felix, and Hugh McLellan (1970) showed that the large, ubiquitous IPSPs in all principal cells of the hippocampus could be blocked by localized application of bicuculline methochloride, establishing that these IPSPs were therefore mediated by GABA<sub>A</sub> receptors. Thus, the studies of Curtis and his colleagues extended the Obata et al. results to cortical inhibitory pathways.

### **2.6.7 Development of Computational Models of Neural Networks**

In a remarkable set of three papers, David Marr (1969, 1970, 1971) developed a theoretical proposal for the mode of operation of three major components of the CNS. Arguably, the triad inaugurated modern computational neuroscience. Further description of this development is found in Chapter 14.

Marr started with the cerebellum, for which he proposed the main operation to be a comparison between an initial state of the motor system and the state after an elemental movement had taken place (Marr, 1969). The next article dealt with the neocortex and how the cortical matrix behaved during perception and attention (Marr, 1970). The third paper contained a description of the mode of operation of the archicortex (Marr, 1971), meaning the hippocampal formation. Basing his proposal on what was then known about its neural cytoarchitecture, he hypothesized that the hippocampus performed a simple memory function which allowed the animal to make use of previous experience to adapt its behavior. In the process, he described how elemental neurophysiological processes could perform certain basic mathematical procedures. For example, inhibition exerted at a dendritic level would cause relatively little enhancement of the resting membrane potential of the neuron, a procedure equivalent to subtraction. In contrast, inhibition at the soma level, produced by basket cells, would represent a much stronger change of the membrane potential, removing a substantial part of the synaptic drive, equivalent to mathematical division.

He also pointed to the recurrent axon collaterals of CA3 as a possible neural basis for attractor networks in which the excitatory interactions between networks of pyramidal cells could form the basis of content-addressable memories and support retrieval of a complete memory from partial information (see Section 5 in Chapter 14).

### **2.6.8 The Hippocampal Formation: A Test Bed for Several Types of Neural Dysfunction and Neuropathology**

It is a well established clinical observation that epileptic patients exhibit a high frequency of temporal lobe foci, often coupled with the neuropathological finding of hippocampal sclerosis (Sommer, 1890; Gastaut, 1956). As a result, the hip-

pocampus has been a focus of interest in epilepsy research (Schwartzkroin, 1997).

The hippocampal formation has proven to be particularly vulnerable to various traumatic insults. Spielmeyer (1925) noted that Sommer's sector, which corresponds to the CA1 field of the hippocampus, is a brain structure extremely vulnerable to ischemic or hypoxic insults. This may be related to a lower level of mitochondrial oxidative enzymes in CA1 pyramidal dendrites than in other hippocampal subregions (Davolio and Greenamyre, 1995; Kuroiwa et al., 1996). Early neuropathologists also noted that the hippocampal formation is a major target for pathological changes in patients suffering from senile dementia of the Alzheimer's type (Alzheimer, 1909). These issues continue to challenge modern neuroscience, as described in Chapter 16.

# Hippocampal Neuroanatomy

## 3.1 Overview

Where is the hippocampal formation and what does it look like? What types of neurons are located in this group of structures, and what types of connections do they form? What is the difference between the hippocampus and the hippocampal formation? Does the hippocampus look similar in the rat, monkey, and human brains? Are other components of the hippocampal formation similar across species? Are the principles of neuroanatomical connectivity similar or different from those found in other brain regions? These are only some of the neuroanatomical issues that are explored in this chapter. The elegant neuronal architecture of the hippocampal formation and the simplicity and orderliness of its major connections have been seductive features to neuroscientists for decades. Yet, there are pragmatic reasons why a working knowledge of its neuroanatomy is important.

First, it is likely that certain peculiarities of the neural organization of the hippocampus, such as its highly associational intrinsic connections, provide important clues to its function(s). Second, the design of functional, electrophysiological, pharmacological, and behavioral studies require increasingly sophisticated knowledge of its boundaries, cell types, connections, and chemical neuroanatomy. This chapter lays the structural foundations for discussions of the functional organization of the hippocampal formation explored later in the book.

### 3.1.1 Hippocampus: Part of a Functional Brain System Called the Hippocampal Formation

One of the most captivating features of the hippocampus is its neuroanatomy. The relatively simple organization of its principal cell layers coupled with the highly organized laminar distribution of many of its inputs has encouraged its use as a model system for modern neurobiology. Despite more than a

century of neuroanatomical study and literally tens of thousands of research articles on the hippocampus, there is still no consensus concerning certain facets of its nomenclature. Hippocampal researchers tend to follow one of several implicit “views” about what the hippocampus is and what it is not. The view adopted in this book is that the hippocampus is one of several related brain regions that together comprise a functional system called the hippocampal formation.

The hippocampus proper has three subdivisions: CA3, CA2, and CA1. (CA comes from *cornu ammonis*; the derivation of these terms is discussed shortly.) The other regions of the hippocampal formation include the dentate gyrus, subiculum, presubiculum, parasubiculum, and entorhinal cortex. Thus, although the title for this book is *The Hippocampus Book*, a more correct, albeit less melodious, title would have been *The Hippocampal Formation Book*. The rationale for grouping these cytoarchitectonically distinct brain regions under the rubric hippocampal formation is developed throughout this chapter.

### 3.1.2 Similarities and Differences Between the Hippocampal Formation and other Cortical Areas

In some ways, such as the occurrence of large, pyramid-shaped projection neurons and smaller interneurons, the neural organization of some portions of the hippocampal formation resembles other cortical regions. Yet in important ways, such as the largely unidirectional passage of information through intrahippocampal circuits and the highly distributed three-dimensional organization of intrinsic associational connections, the neuroanatomy of the hippocampal formation is unique. It has often been touted as a heuristically simple model of neocortical organization, but this perspective demeans both the hippocampal formation and the neocortex. It is more profitable to highlight and investigate the distinctive neuroanatomical features of the hippocampal formation as

potential clues to its particular function(s) and the mechanisms by which these functions are realized.

Our understanding of hippocampal neuroanatomy leads to the prediction that whatever processes this group of structures carries out they are likely to be quite different from those performed in other cortical regions. The hippocampal formation, for example, is one of only a few brain regions that receive highly processed, multimodal sensory information from a variety of neocortical sources. Moreover, its own system of widely distributed intrinsic neuronal networks is ideally suited for further mixing or comparing this information. This ability to integrate information from all sensory modalities may thus be a unique attribute of the hippocampus conferred by the highly convergent-divergent organization of its connections.

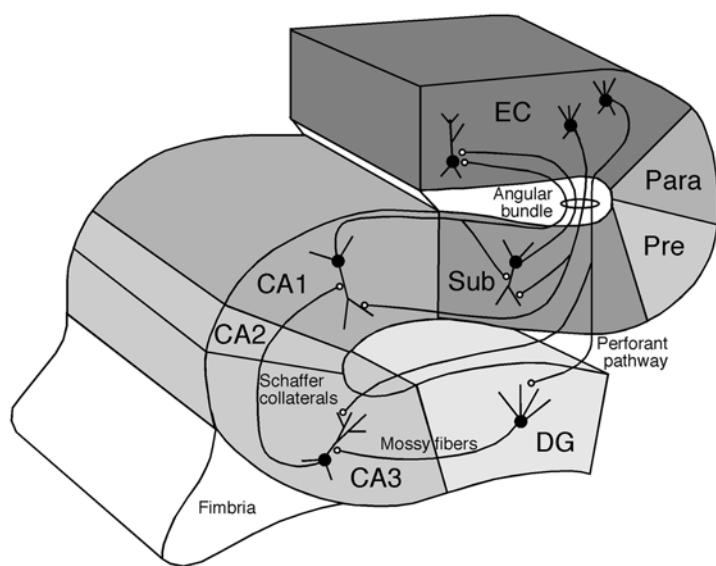

### 3.1.3 Hippocampal Formation: With A Unique Set of Unidirectional, Excitatory Pathways

A common organizational feature of connections between regions of the neocortex is that they are largely reciprocal (Felleman and Van Essen, 1991). If cortical region A projects to cortical region B, region B often sends a return projection

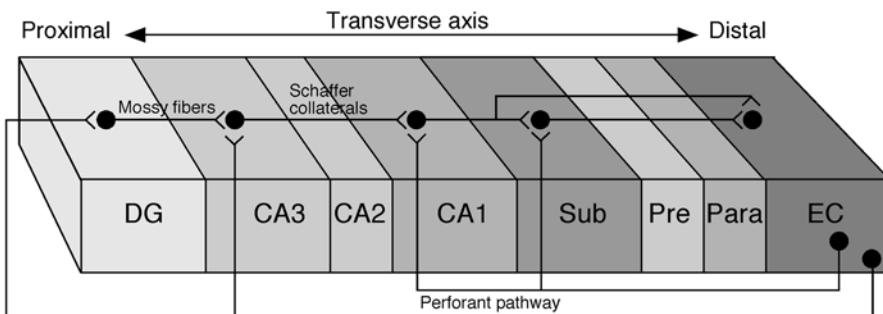

back to region A. As first described by Ramón y Cajal (1893), this is clearly not the case for the connections that link the various parts of the hippocampal formation (Fig. 3–1). The entorhinal cortex can, for convenience, be considered the first step in the intrinsic hippocampal circuit. The logic behind this is developed later in the chapter, but the priority afforded to the entorhinal cortex is based on the fact that much of the neocortical input reaching the hippocampal formation does so through the entorhinal cortex. Cells in the superficial layers of the entorhinal cortex give rise to axons that project, among other destinations, to the dentate gyrus. The projections from the entorhinal cortex to the dentate gyrus form part of the major hippocampal input pathway called the perforant path. Although the entorhinal cortex provides the major input to the dentate gyrus, the dentate gyrus does not project back to the entorhinal cortex. This pathway is therefore nonreciprocal, or unidirectional.

Likewise, the principal cells of the dentate gyrus, the granule cells, give rise to axons called mossy fibers that connect with pyramidal cells of the CA3 field of the hippocampus. The CA3 cells, however, do not project back to the granule cells. The pyramidal cells of CA3, in turn, are the source of the major input to the CA1 hippocampal field (the Schaffer col-

A

B

**Figure 3–1.** The hippocampal formation.

**A.** Neurons in layer II of the entorhinal cortex project to the dentate gyrus and the CA3 field of the hippocampus proper via the perforant pathway. Neurons in layer III of the entorhinal cortex project to the CA1 field of the hippocampus and the subiculum via the perforant and alvear pathways (see text for a detailed description). The granule cells of the dentate gyrus project to the CA3 field of the hippocampus via mossy fiber projections. Pyramidal neurons in the CA3 field of the hippocampus project to CA1 via Schaffer collaterals. Pyramidal cells in CA1 project to the subiculum. Both CA1 and the subiculum project back to the deep layers of the entorhinal cortex. **B.** Projections along the transverse axis of the hippocampal formation; the dentate gyrus is located proximally and the entorhinal cortex distally.

lateral axons). Following the pattern of its predecessors, CA1 does not project back to CA3. The CA1 field of the hippocampus then projects unidirectionally to the subiculum, providing its major excitatory input. Again, the subiculum does not project back to CA1.

Once one reaches CA1 and the subiculum, the pattern of intrinsic connections begins to become somewhat more elaborate. CA1, for example, projects not only to the subiculum but also to the entorhinal cortex. Furthermore, whereas the subiculum does project to the presubiculum and the parasubiculum, its more prominent cortical projection is directed to the entorhinal cortex. Through these connections both CA1 and the subiculum close the hippocampal processing loop that begins in the superficial layers of the entorhinal cortex and ends in its deep layers. Although this cursory survey of the intrinsic connections of the hippocampal formation leaves out many of the facts that make the system somewhat more complex, it does serve to emphasize that the hippocampal formation is organized in a fashion that is distinctly different from most other cortical areas.

### **3.1.4 Hippocampus of Humans and Animals: Same or Different?**

Once one has gained a familiarity with the neuroanatomical appearance of the rat hippocampal formation, it is not difficult to identify each of the major subdivisions in the monkey or human hippocampal formation (Fig. 3–2). Although the volume of the hippocampus is about 10 times larger in monkeys than in rats and 100 times larger in humans than in rats, the basic hippocampal architecture is common to all three species. Yet there are some striking species differences. The compact pyramidal cell layer in the CA1 region of the rat, for example, becomes thicker and more heterogeneous in the monkey and human. Whereas this layer is only about 5 cells thick in the rat, it can be more than 30 cells thick in the human. The other region that demonstrates striking species differences is the entorhinal cortex. In the rat, the entorhinal cortex is typically divided into two main, cytoarchitectonically distinct subdivisions. In the monkey there are seven subdivisions, and in the human brain the classical cytoarchitectonists defined as many as 27 subdivisions (although recent descriptions recognize only 8 subdivisions, similar to what is observed in monkeys). Thus, despite the fact that the hippocampal formation is often portrayed as a phylogenetically primitive brain region, it nonetheless demonstrates substantial species differences.

Although the patterns of connectivity appear to be generally similar in the rodent and primate brains, there are again striking species differences. One example is the organization of the commissural connections of the dentate gyrus. In the rat, there is a massive commissural system that provides nearly one-sixth of the excitatory input to the dentate gyrus (Raisman, 1965; Gottlieb and Cowan, 1973). In the macaque monkey and presumably in humans, however, commissural connections in the dentate gyrus are almost entirely absent

(Amaral et al., 1984). Another example is the more complex organization of the primate entorhinal cortex, which appears to be associated with stronger interconnections with the associational areas of the neocortex, which are more developed in primates. Myriad other subtle species differences (e.g., the chemical neuroanatomy of the hippocampal formation) have been noted in the literature. Certain neuroanatomical differences have even been described in different strains of mice that seem too subtle to be worthy of note yet could be of enormous practical importance given the current interest in the use of transgenic techniques. A major future challenge is to determine whether and how these structural and neurochemical alterations affect the functioning of the hippocampal formation.

Thus, to address the question posed in the title of this section—is the hippocampus of humans and animals same or different—the answer is both.

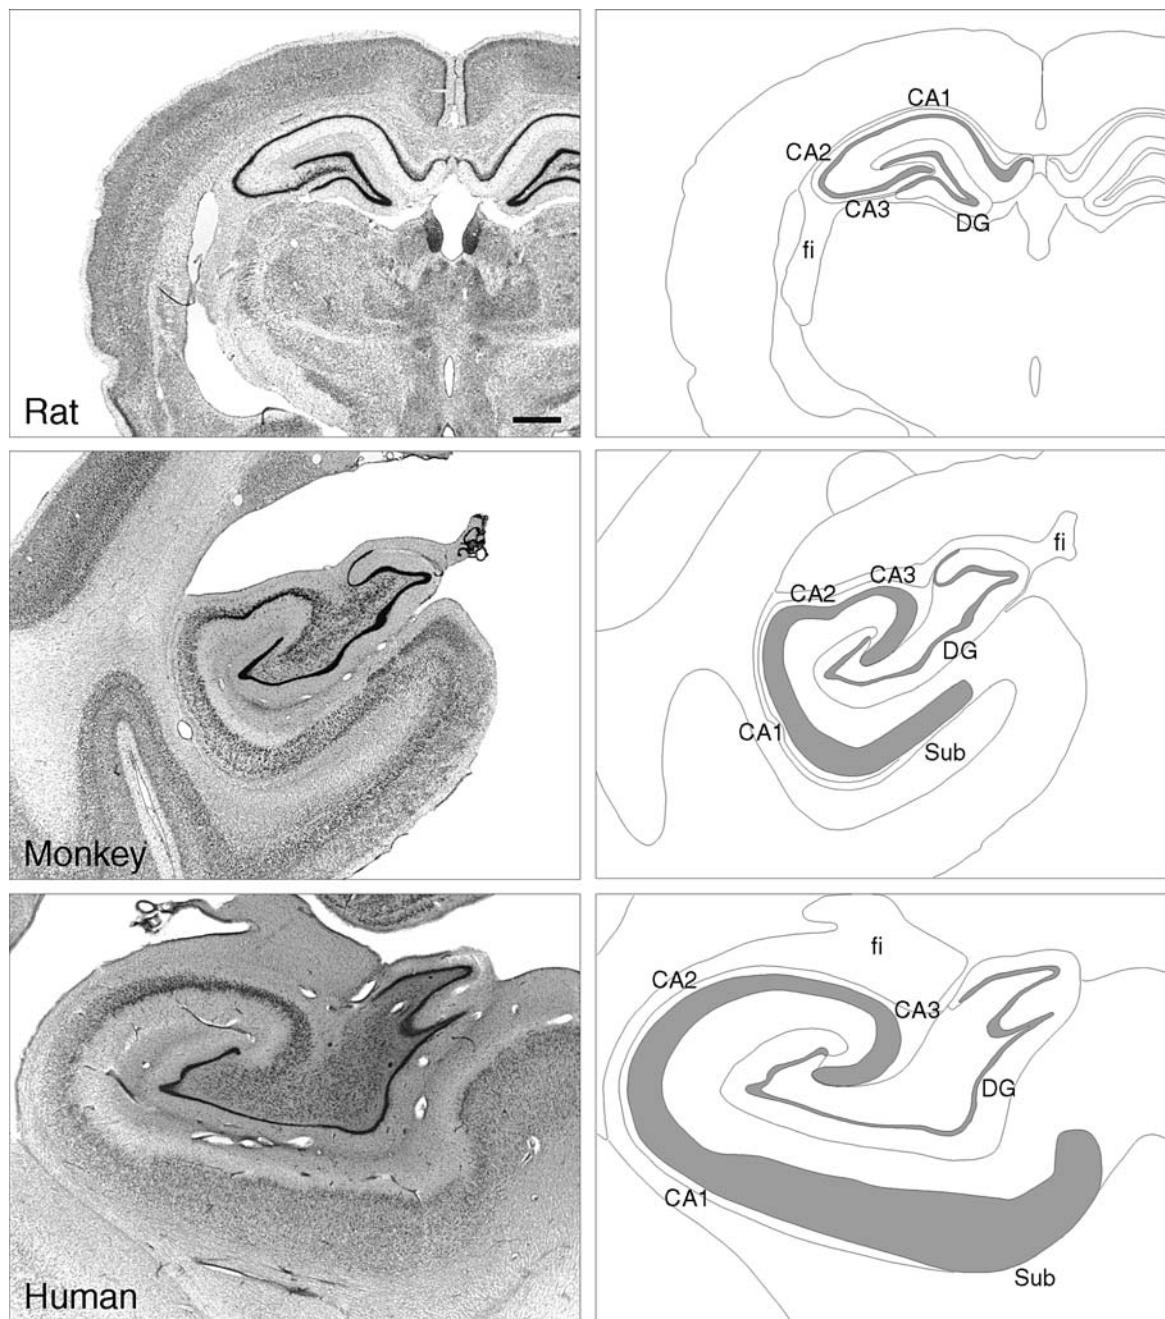

### **3.1.5 Synopsis of the Chapter**

Our rationale for focusing on the rodent (mainly the rat) hippocampal formation in the first half of this chapter is that much of the available neuroanatomical data have been derived from studies carried out in this animal and because of the prominent role the rat plays in current functional analyses of the hippocampal formation. Unfortunately, far less work has been carried out in the mouse, the clear choice for molecular biology studies. It is widely presumed that the neuroanatomy of the mouse hippocampal formation is similar to that of the rat—though some additional confirmation would certainly be welcome. We next compare and contrast the picture of hippocampal anatomy obtained from studies of the rat with that of the monkey. We also describe the extensive cortical connections of the entorhinal cortex in the macaque monkey and the emerging prominence of adjacent related brain regions, such as the perirhinal and parahippocampal cortices. We then move on to compare information on the monkey hippocampal formation with what is known about the human hippocampal formation. The chapter concludes with a summary of the principles of hippocampal intrinsic circuitry and a discussion of how they may govern the flow of information through the hippocampal formation.

### **3.2 Historical Overview of Hippocampal Nomenclature—What's in a Name?**

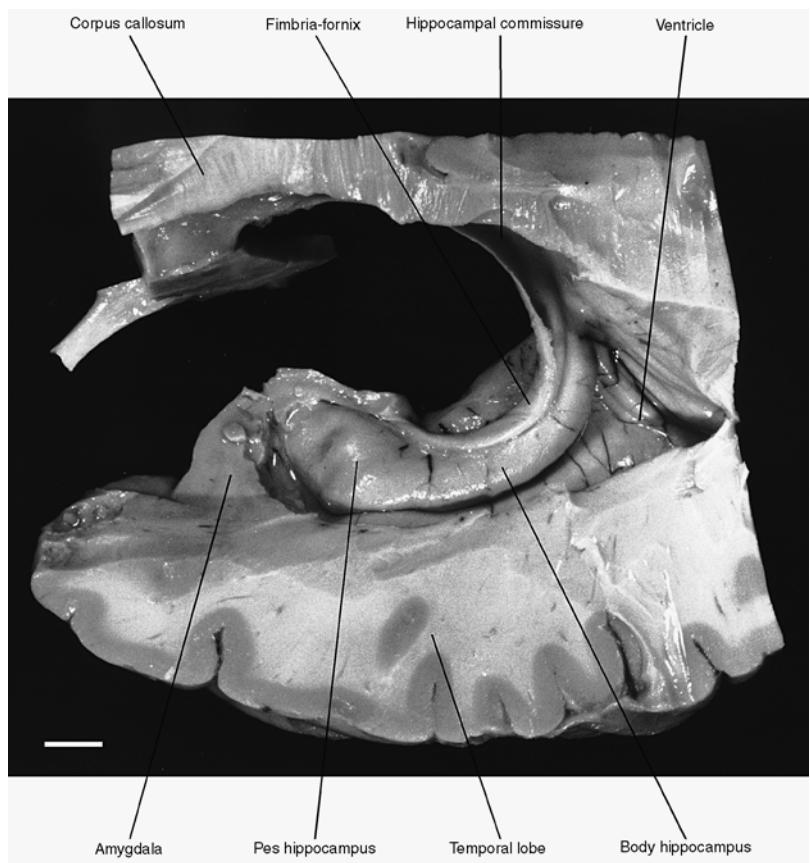

The hippocampal formation has been prodded and sliced and stained by anatomists for nearly 400 years. Like many brain regions, it has fallen victim to the imposition of various and often confusing terminologies to describe its gross anatomical and histological structure. The term hippocampus (derived from the Greek word for sea horse) was first coined during the sixteenth century by the anatomist Arantius (1587), who considered the three-dimensional form of the human hip-

**Figure 3-2.** Nissl-stained sections and line drawings illustrating the general organization and similarities of the subdivisions of the hippocampal formation in the rat, monkey, and human. Note the differences in the relative position of the fimbria in the rat (located lateroventrally) and in the monkey and human (located mediodorsally). Bar in A = 1 mm and applies to all panels.

pocampus, lying in the floor of the inferior horn of the lateral ventricle, to be reminiscent of this sea creature (Fig. 3-3). Arantius also likened the shape of the hippocampus to a silk worm, but his term “*bombycini* or *bombyx*” never caught on. Because Arantius did not take the trouble to stake claim to the hippocampus by illustrating its location and structure, other anatomists felt free to devise their own terms. The main, or intraventricular, portion of the human hippocampus was first illustrated by Duvernoy in 1729, and he continued to assign

both the names sea horse and silk worm to this region. Others likened the arched structure of the hippocampus to a ram’s horn, and De Garengeot (1742) named the hippocampus “*cornu ammonis*” or “Ammon’s horn” after the mythological Egyptian god Amun Kneph, whose symbol was a ram. According to the *Nomina Anatomica*, the term hippocampus is currently acknowledged to be the standard term for the bulge occupying the floor of the lateral ventricle in the human brain. The term Ammon’s horn is now only rarely used,

**Figure 3-3.** Dorsolateral view of the human hippocampus after removing the overlying structures. The lateral ventricle has been opened, exposing the shape of the hippocampus. Bar = 1 cm.

although a curious irony of current terminology is that, although hippocampus has become the standard term, subdivisions of this structure are referred to using abbreviations of cornu ammonis (CA3, CA2, CA1). Some of the terms mentioned above, as well as many others, have found their way into descriptions of the histological structure of the hippocampal formation; hence it is helpful, at the start, to discuss neuroanatomical terms currently associated with the hippocampus.

A few terms are now of only historical interest. The hippocampus was for some time considered to be a prominent part of the rhinencephalon, which, loosely speaking, referred to a group of forebrain structures thought to be related especially to the sense of smell. In a classic article published in 1947, however, Alf Brodal concluded that the hippocampus could not be functioning solely as an olfactory structure because anosmic mammals such as dolphins had a substantial hippocampal formation (Brodal, 1947). It seemed unreasonable to Brodal that the hippocampus would be so robust in a nonsmelling creature if it functioned solely as a component of the olfactory system (see Chapter 2).

During the 1930s, the neurologist James Papez considered the hippocampus to be a central component of a system for emotional expression, and in many textbooks the hippocampus is still claimed to be the central component of the so-called Papez circuit. In Papez's view, the hippocampus was a conduit by which perceptions of emotionally salient situations could be collected and channeled to the hypothalamus where

they could recruit or effect appropriate emotional responses (Papez, 1937). Despite the admirable job done by Papez in marshaling largely circumstantial evidence in support of his view, there has been little modern substantiation of Papez's theory. The role of orchestrator of emotional expression is now more closely linked with another prominent medial temporal lobe structure, the amygdaloid complex.

The hippocampus is also associated with the term "limbic system." The origin of this term stems from the description by the neurologist Broca (1878) of "le grande lobe limbique," which comprised a series of contiguous cortical and subcortical structures located on the medial surface of the brain and surrounding the ventricle at the border (limbus) of the cortical mantle. The limbic lobe was described initially as including such circumventricular structures as the subcallosal, cingulate, and parahippocampal gyri, as well as the underlying hippocampal formation. The number of structures included under the rubric "limbic system" has escalated dramatically since the 1950s, however, and has included such diverse structures as the amygdala, septal nuclei, and midbrain periaqueductal gray matter. The proliferation of brain regions encompassed by the term limbic system has fueled a long-lasting debate about the utility of this term either as a neuroanatomical or functional entity. Suffice it to say that in this book the hippocampal formation is viewed as an independent functional system rather than part of the larger, ill-defined group of structures collectively referred to as the limbic system. That said, the hippocampal formation obviously does

not function in isolation. Even as a functionally defined, independent system, it relies on interconnections with many other brain systems to do its job effectively.

### **3.2.1 Definition of Hippocampal Areas: Definition of Terms**

When a histological section through the hippocampus is prepared and stained for cell bodies by a Nissl method, it is immediately obvious that a number of cytoarchitectonically distinct structures are encompassed in the region grossly defined as the “hippocampus.” A number of terminologies have been applied to some of these regions, and several synonymous terms are still commonly employed. Beyond the problem of different terms being applied to the same region, the borders between several regions of the hippocampal formation have not yet been firmly established. The terms adopted in this book are based, in part, on converging evidence from cytoarchitectonic, histochemical, connectional, and functional data and in part on personal preference.

The term hippocampus has historically been plagued by the fact that it is used as a term both for a gross anatomical region of the brain (the bulge or protuberance in the floor of the human lateral ventricle) and for one of the cytoarchitectonically distinct entities that make up the region. As a result, the meaning of the word hippocampus is context-dependent and may be ambiguous. We reserve the term hippocampus for the region of the hippocampal formation that comprises the CA fields (CA3, CA2, CA1) identified by the neuroanatomist Rafael Lorente de Nó (Lorente de Nó, 1934). The term hippocampal formation, in contrast, is applied to a group of cytoarchitectonically distinct adjoining regions including the dentate gyrus, hippocampus, subiculum, presubiculum, parasubiculum, and entorhinal cortex (Fig. 3–1). The adjective hippocampal, by necessity, remains somewhat vague and context-dependent. In general, it is used to refer to the larger area (as in “hippocampal lesions”) rather than to the cytoarchitectonic region. If this seems confusing, the terminological definitions of the next few paragraphs may provide clarification.

The main justification for including the six regions named above under the rubric hippocampal formation is that they are linked, one to the next, by unique and largely unidirectional (functional) neuronal pathways. The early literature on the hippocampal formation emphasized the first three links in the hippocampal circuitry that were highlighted by applying the term “trisynaptic circuit” to the ensemble of pathways (Andersen et al., 1971).

EC → DG (synapse 1), DG → CA3 (synapse 2),  
CA3 → CA1 (synapse 3)

The definition of this powerful excitatory circuit was produced by a collaboration between early neuroanatomical and electrophysiological studies. It should be borne in mind, however, that the term trisynaptic circuit was coined during an era when it was assumed that the hippocampus proper generated

the main output projections and that these projections were directed subcortically. With the discovery of robust projections from CA1 to the subiculum and entorhinal cortex, and the major projections from the entorhinal cortex to the neocortex, the trisynaptic circuit is now considered to be only a portion of the functional circuitry of the hippocampal formation. As it is now clear that the subiculum is the main source of subcortical projections and the entorhinal cortex is the main source of projections to the neocortex, the concept of the trisynaptic circuit, although of great significance in the history of hippocampal research, is currently less influential on theories of hippocampal function.

The reader who ventures from the relative safety of this book into the primary hippocampal literature should be aware that our usage of the term “hippocampal formation” is widely, though not universally, accepted. Some authors include only the allocortical (a term applied to cortical regions having fewer than six layers) regions as parts of the hippocampal formation. Three-layered cortical regions typically have a single neuronal cell layer with fiber-rich plexiform layers above and below the cell layer. In articles employing this usage, the hippocampal formation comprises the dentate gyrus, hippocampus, and subiculum. The remaining fields—presubiculum, parasubiculum, and entorhinal cortex—are then typically grouped together on the basis of their multilaminar structure under the term retrohippocampal (retro = behind) or parahippocampal (para = alongside or near) cortex. In yet other variants, the terms hippocampus or hippocampal complex are sometimes applied to the combination of the dentate gyrus and hippocampus proper. Clarification of the nomenclature is typically the first sign of maturity for a scientific enterprise, and we scrupulously adhere to the nomenclature in which the hippocampal formation comprises the six structures listed above.

Having outlined the major regions of the hippocampal formation, we now delve more deeply into the subdivisions of each of these regions. Before doing so, however, it is important to note that the terminology we apply to these regions is a hybrid derived from the analyses of classical and modern hippocampal neuroanatomists. The two main contributors to the surviving hippocampal terminologies are Santiago Ramón y Cajal (Ramón y Cajal, 1893) and his student Raphael Lorente de Nó (Lorente de Nó, 1933, 1934). Some of their subdivisions, based solely on the analysis of Golgi-stained material, have not stood the test of time or the introduction of modern neuroanatomical methods. Many revisions of their nomenclature have been made as information has become available concerning the connections and chemical architecture of the hippocampal formation.

### **3.2.2 Subdivisions of Hippocampal Areas**

The dentate gyrus is a trilaminar cortical region with a characteristic V or U shape. The dentate gyrus has a relatively similar structure at all levels of the hippocampal formation and is not typically divided into subregions. When discussing fea-

tures of the dentate gyrus, however, it is often useful to refer to a particular portion of the V- or U-shaped structure. The portion of the granule cell layer that is located between the CA3 field and the CA1 field (separated by the hippocampal fissure) is called the suprapyramidal blade; and the portion opposite this is the infrapyramidal blade. The region bridging the two blades (at the apex of the V or U) is the crest.

The hippocampus, especially in rodents, can easily be divided into two major regions: a large-celled region that abuts the dentate gyrus and a smaller-celled region that follows from it. Ramon y Cajal called these two regions *regio inferior* and *regio superior*, respectively. The terminology of Lorente de Nó has achieved more common usage and is employed here. He divided the hippocampus into three fields: CA3, CA2, and CA1. His CA3 and CA2 fields are equivalent to the large-celled *regio inferior* of Ramon y Cajal, and his CA1 field is equivalent to the *regio superior*. In addition to the greater size of the pyramidal cells in CA3 and CA2 compared to CA1, the inputs and outputs of these areas are also different. The pyramidal cells of CA3, for example, receive the mossy fiber input from the dentate gyrus, whereas the CA1 pyramidal cells do not.

The CA2 field has been the subject of substantial controversy. As originally defined by Lorente de Nó, it is a narrow zone of cells interposed between CA3 and CA1. CA2 has large pyramidal cell bodies similar to those in CA3 but, like CA1, it is not innervated by the mossy fibers from the dentate gyrus. Although the existence of CA2 has often been questioned, the bulk of available evidence indicates that there is indeed a narrow CA2 field that can be distinguished from the other hippocampal fields using a variety of criteria, including neurochemical markers. Lorente de Nó also defined a CA4 field. As originally clarified by Theodor Blackstad (1956) and then by David Amaral (1978), the region that Lorente de Nó called CA4 is actually the deep, or polymorphic, layer of the dentate gyrus.

The subiculum, presubiculum, and parasubiculum are sometimes grouped under the term “subicular complex.” Because each of these regions has distinct neuroanatomical features, they are better thought of as independent cortical areas. The border between CA1 and the subiculum occurs precisely at the point where the Schaffer collateral projection from the CA3 field ends. In the rodent, this occurs approximately where the condensed pyramidal cell layer of CA1 begins to broaden into the thicker layer of the subiculum.

The presubiculum lies adjacent to the subiculum and is typically thought to have more than the three layers that characterize the dentate gyrus, hippocampus, and subiculum. However, the exact delimitation of the deep layers of the presubiculum and the differentiation of cells belonging to the presubiculum from those that belong to the deep layers of the entorhinal cortex has never been clearly established. The most distinctive feature of the presubiculum is the densely packed external cellular layer, which is populated by relatively small, tightly packed pyramidal cells. The parasubiculum is characterized by a wedge-shaped layer II with cells that resemble but

are somewhat larger and less compact than those in the presubiculum.

The entorhinal cortex is the only hippocampal region that unambiguously demonstrates a multilaminar appearance. Based on differences in the organization of these layers and more recently on differences in connectional attributes, the entorhinal cortex has been divided into two or more subregions depending on the species. We shall return to a description of the subdivisions of the entorhinal cortex later in the chapter.

Before moving on to descriptions of the three-dimensional organization of the hippocampal formation in the rat, monkey, and human brains, we must say a few more words concerning nomenclature. We often want to refer to a specific portion of one of the hippocampal regions. Given the complex shape of the hippocampal formation, no reference system is wholly adequate, and any description inevitably involves arbitrary decisions about where to start or finish, which direction is up or down, and so on. We have adopted a reference system in which the dentate gyrus is considered to be the proximal pole of the hippocampal formation and the entorhinal cortex is the distal pole (Fig. 3–1). A portion of any hippocampal field can therefore be defined in relation to this proximo-distal axis. For example, the proximal portion of CA3 is located closer to the dentate gyrus, and the distal portion is located closer to CA2.

We also often need to specify subregions within the thickness of a particular hippocampal region. As in most other cortical areas, this radial dimension is usually described along a superficial-to-deep axis. In six-layer structures, layer I is close to the pial surface, and layer VI is located close to the subcortical white matter. Consistent with this convention, regions closer to the pia or hippocampal fissure are considered superficial and those in the opposite direction—closer to the alveus or ventricle where applicable) are considered deep. The molecular layer of the dentate gyrus, for example, is superficial to the granule cell layer. This superficial–deep nomenclature has the merit of being applicable to all portions of the hippocampal formation and to all of its cytoarchitectonic fields. It has the drawback, however, of being somewhat counterintuitive to neuroscientists, especially electrophysiologists, whose electrodes approach the hippocampus from the alveus in the septal (or dorsal) portion of the hippocampus. As an electrophysiologist advances an electrode from the dorsal surface of the brain toward the hippocampus, it would first hit the alveus and then the pyramidal cell layer. Although the alveus might seem like the “superficial” portion of the hippocampus because it is closer to the surface of the brain, it is actually its deep portion. As the electrode continues its advance toward the hippocampal fissure, it enters the superficial portion of the hippocampus. Crossing the hippocampal fissure, it then enters the superficial portion of the molecular layer of the dentate gyrus, and a further advance would bring it to the deep portion of the molecular layer, the suprapyramidal granule cell layer, the hilus, and finally the infrapyramidal granule cell and molecular layers.

### 3.2.3 Major Fiber Bundles of the Hippocampal Formation

Three major fiber systems are associated with the hippocampal formation (Fig. 3–4, see color insert). The first is the angular bundle, which carries fibers between the entorhinal cortex and the other fields of the hippocampal formation. The second is the fimbria-fornix pathway through which the hippocampal formation is interconnected with the basal forebrain, hypothalamic, and brain stem regions. The third comprises the dorsal and ventral commissures, through which the hippocampal formation of one hemisphere is connected with the hippocampal formation of the contralateral hemisphere. We deal with these in greater detail in Section 3.3.2.

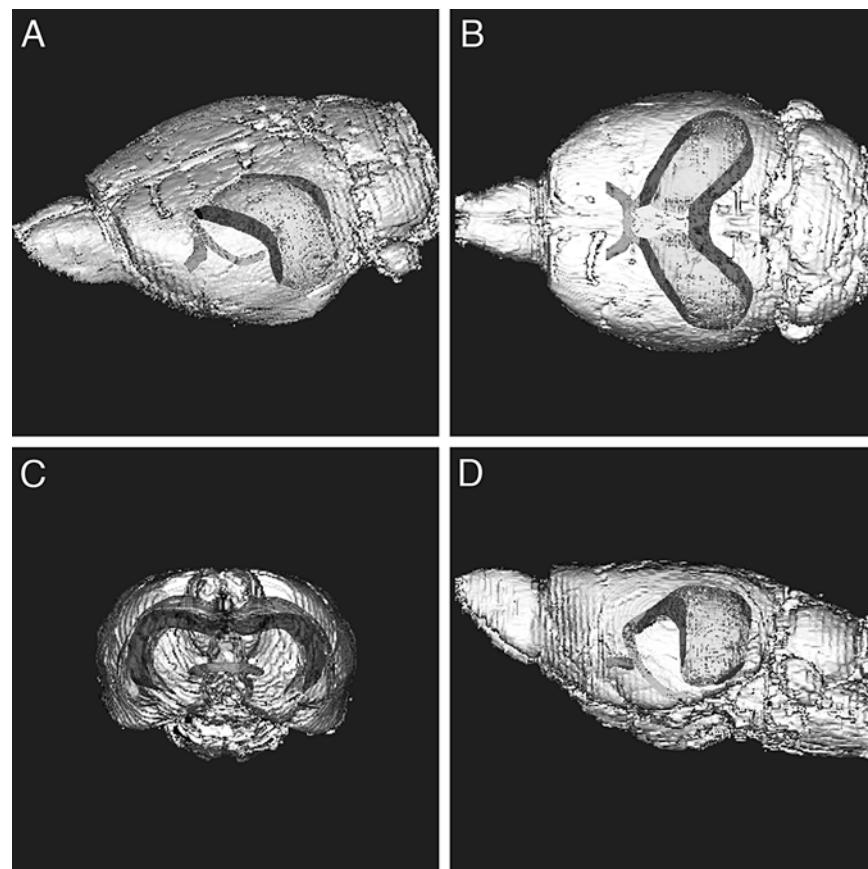

### 3.3 Three-dimensional Organization and Major Fiber Systems of the Hippocampal Formation

The hippocampal formation is positioned quite differently in the rodent and primate brains (Figs. 3–5 through 3–7, see color insert). This is due in part to the more developed cerebral cortex in primates, which tends to “force” the dentate gyrus and hippocampus into the temporal lobe. Whereas

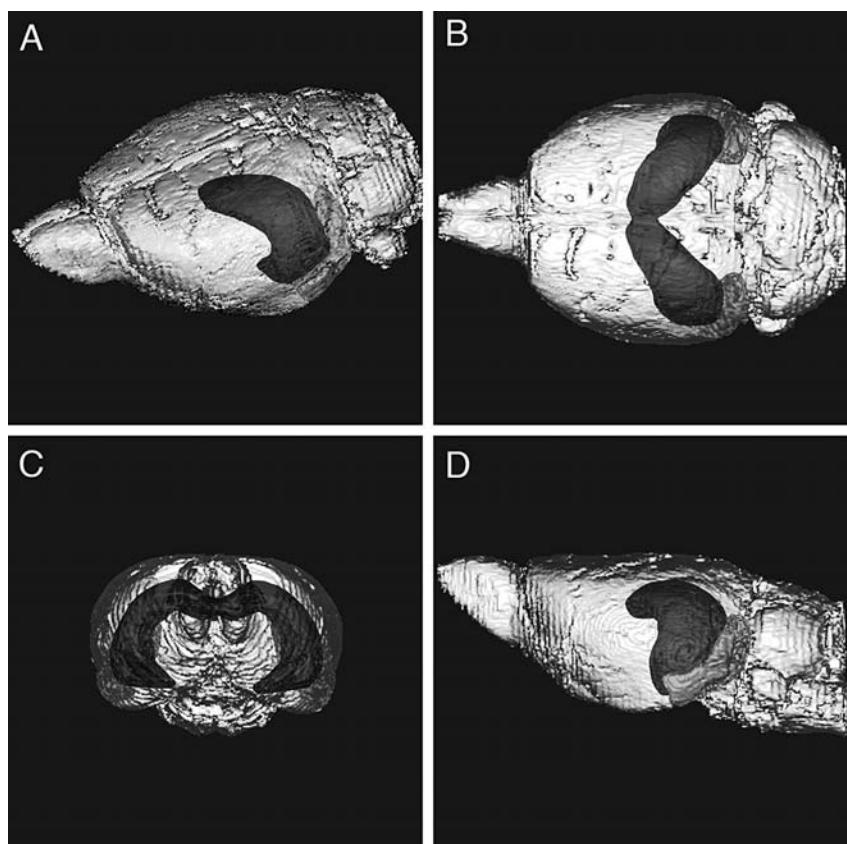

many of the fields of the rodent hippocampal formation are grossly C-shaped and vertically oriented, they tend to be much more linear and horizontally oriented in primates.

#### 3.3.1 Rat Hippocampal Formation

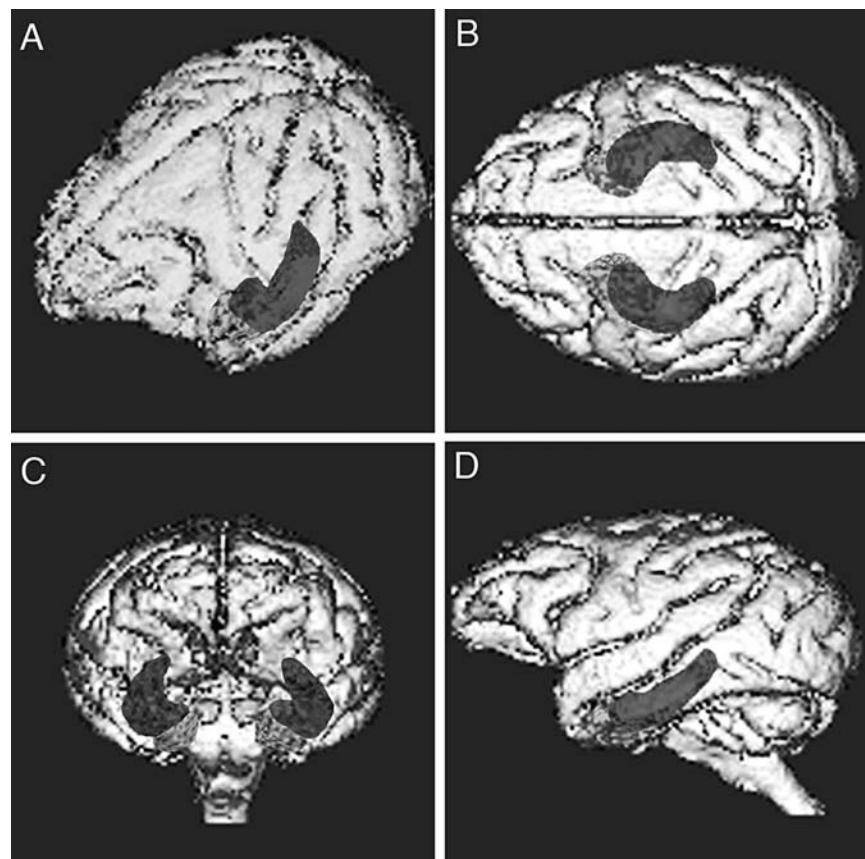

The rat hippocampal formation is an elongated, banana-shaped structure with its long axis extending in a C-shaped manner from the midline of the brain near the septal nuclei (rostrodorsally) over and behind the thalamus into the incipient temporal lobe (caudoventrally). The long axis of the hippocampal formation is referred to as the septotemporal axis and the orthogonal axis as the transverse axis (Fig. 3–8). What is not obvious from a surface view of the hippocampal formation is that different regions make up the structure at different septotemporal levels. At extreme septal levels, for example, only the dentate gyrus and the CA3–CA1 fields of the hippocampus are present. About a third of the way along the septotemporal axis the subiculum first appears, and the presubiculum and parasubiculum are seen at progressively more temporal levels. The entorhinal cortex is located even farther caudally and ventrally. The dorsolateral limit of the entorhinal cortex occurs approximately at the rhinal sulcus, which forms a prominent, rostrocaudally/horizontally oriented indentation on the ventrolateral surface of the rat brain. This sulcus nominally separates the entorhinal cortex ventrally

**Figure 3-8.** Line drawing of the rat brain shows the septotemporal and transverse axes of the hippocampal formation.

from the perirhinal and postrhinal cortices dorsally. At rostral levels, however, the perirhinal cortex extends somewhat ventral to the rhinal sulcus, and at caudal levels the entorhinal cortex extends just slightly dorsal to the rhinal sulcus.

### **3.3.2 Major Fiber Systems of the Rat Hippocampal Formation**

#### **Angular Bundle**

A major fiber pathway associated with the hippocampal formation is the angular bundle, a fiber bundle interposed between the entorhinal cortex and the presubiculum and parasubiculum. The angular bundle is the main route taken by fibers originating from the ventrally situated entorhinal cortex as they travel to all septotemporal levels of the other hippocampal fields, particularly the dentate gyrus, hippocampus, and subiculum. In addition, the angular bundle contains commissural fibers of entorhinal and presubicular origin and fibers to and from a variety of cortical and subcortical structures that are interconnected with the entorhinal cortex.

The perforant path comprises the efferent entorhinal projections that traverse, or perforate, the subiculum on their way to the dentate gyrus and the hippocampus. This is the main route by which neocortical inputs reach the dentate gyrus and the hippocampus. We present a more detailed description of the perforant path in the discussion of the inputs to the dentate gyrus and the connectivity of the entorhinal cortex.

Entorhinal fibers also reach the hippocampus via the alveus, the temporoammonic alvear pathway first described by Cajal. At temporal levels, most of the entorhinal fibers reach the CA1 field of the hippocampus after perforating the subiculum (via the classic perforant pathway). At more septal levels, the number of entorhinal fibers that take the alvear pathway increases (Deller et al., 1996). In fact, in the septal portion of the hippocampal formation, most of the entorhinal fibers to CA1 reach this subfield via the alveus. These fibers make sharp right-angle turns in the alveus, perforate the pyramidal cell layer, and finally terminate in the stratum lacunosum-moleculare. The alveus is therefore also a major route by which entorhinal fibers reach their targets in CA1.

#### **Fimbria-Fornix Pathway**

The fimbria-fornix fiber system provides the major conduit for subcortical afferent and efferent connections (Daitz and Powell, 1954; Powell et al., 1957). It is perhaps easiest to understand the fimbria-fornix system by analogy with the corticospinal fiber system. The corticospinal fibers are given different names at different points on their journey from the motor cortex to the spinal cord. Similarly, the subcortical afferent and efferent fibers of the hippocampal formation are given different names at different points in their trajectory from or toward the forebrain or brain stem. Because of this, and because the exact transition between fimbria and fornix is difficult to define, some hippocampal researchers use the term

fimbria-fornix to emphasize the continuity of fibers in these bundles.

The ventricular, or deep, surface of the hippocampus is covered by a thin sheet of myelinated fibers called the alveus. These fibers form a white sheet overlying the hippocampus that can be clearly seen when the overlying neocortex is aspirated. The alveus is a complex fiber system with both extrinsic afferent and efferent fibers, and fibers forming part of the intrahippocampal network travel within it (i.e., the entorhinal-CA1 alvear pathway, the CA1-subiculum projection, and the CA1-entorhinal projection). Some alvear fibers originate from the pyramidal cells of the hippocampus and subiculum and are en route to subcortical termination sites (Meibach and Siegel, 1975). At temporal levels of the hippocampal formation, the subcortically directed output fibers extend obliquely in the alveus, from medial to lateral, over the surface of the hippocampus and collect in a bundle called the fimbria (from the Latin word for fringe), which becomes progressively thicker as it progresses from the temporal to the septal level (i.e., as axons from more septally located pyramidal cells are added to the bundle). The rat fimbria has a flattened appearance, contains approximately 900,000 axons, and is situated along the lateral and rostral aspects of the hippocampus. The fibers of the fimbria are not randomly distributed but are organized in a topographic fashion (Wyss et al., 1980). Axons located medially in the fimbria (i.e., those closest to the hippocampus) tend to arise from more septal levels, whereas those located laterally arise from more temporal levels. Fibers from the subiculum are situated deeper to those from the hippocampus.

The fornix is the continuation of this bundle of hippocampal output fibers to the subcortical target structures; it forms a flattened bundle located just below the corpus callosum very close to the midline (fornix is the Latin word for arch, which is the shape of this tract over the diencephalon). Both fimbria and fornix carry fibers from the hippocampus and subiculum; the fornix, however, carries fibers primarily from the septal third of these structures. As the fibers of the fimbria leave the hippocampus and descend into the forebrain, they are referred to as the columns of the fornix. The fornix splits around the anterior commissure to form a rostrally directed precommissural fornix, which innervates the septal nuclei and nucleus accumbens, and a caudally directed postcommissural fornix, which extends toward the diencephalon. As the postcommissural fornix begins its course into the diencephalon (ultimately reaching the mammillary nuclei of the posterior hypothalamus), two smaller bundles split off. One, the medial corticohypothalamic tract, innervates a number of anterior hypothalamic areas. The other, called the subiculothalamic tract, carries fibers to the anterior thalamic nuclei (Swanson and Cowan 1975; Canteras and Swanson, 1992).

The fimbria and fornix also carry fibers that are traveling to the hippocampal formation. Many of the subcortical inputs to the hippocampal formation, including those from the septal nuclei (to the septal portion of the hippocampal formation), the locus coeruleus, and the raphe nuclei enter via the

fimbria-fornix pathway. Some subcortical structures have projections that follow other pathways into the hippocampal formation. Fibers from the anterior thalamus, for example, travel through the thalamic radiations and supracallosal stria to innervate the presubiculum. Still other subcortical projections, particularly those from the amygdala, travel to the hippocampal formation via the external capsule.

### Dorsal and Ventral Hippocampal Commissures

A third major fiber system associated with the hippocampal formation is the commissural system (Blackstad, 1956; Raisman et al., 1965; Laatsch and Cowan, 1967; Laurberg, 1979). In the rat, there are both dorsal and ventral commissures. Some 350,000 fibers cross the midline in the ventral hippocampal commissure, which is located just caudal to the septal area and dorsocaudal to the anterior commissure. Many of these fibers are true commissural fibers and are directed to both homotopic and heterotopic fields in the contralateral hippocampal formation. A much smaller number of fibers are directed into the contralateral descending column of the fornix and ultimately innervate the same structures on the contralateral side of the brain that receive the ipsilateral pre- and postcommissural fornix. The dorsal hippocampal commissure crosses the midline just rostral to the splenium (posterior part) of the corpus callosum and carries fibers mainly originating from or projecting to the presubiculum and entorhinal cortex. The dorsal hippocampal commissure is the route by which the presubiculum contributes a major projection to the contralateral entorhinal cortex.

### 3.3.3 Monkey Hippocampal Formation

The first point we address in this section is how the appearance and position of the nonhuman primate hippocampal formation differs from that of the rat. Much of the work on the monkey hippocampal formation has been carried out in Old World monkeys, primarily the macaque monkey. The description we provide here is for the hippocampal formation of typical research monkeys, such as *Macaca fascicularis* and *Macaca mulatta* (cynomolgus and rhesus macaque monkeys, respectively). The hippocampal formation in the macaque monkey is not nearly as C-shaped in its long axis as it is in the rat. It lies almost horizontally in the temporal lobe; and, as in the human, it makes up the major portion of the floor of the temporal horn of the fourth ventricle. The major determinant of the change in position of the primate hippocampal formation is the massive development of the associational cortices of the frontal and temporal lobes. As a result of the caudal and ventral transposition of the temporal lobes that takes place developmentally to accommodate the larger cortical surface, the primate hippocampal formation comes to lie almost entirely within the medial temporal lobe. Because of the ventrostral rotation of the monkey hippocampal formation, the homologue of the temporal pole of the rat hippocampal formation is located rostrally in the monkey brain, and the equivalent of the septal pole of the rat hippocampal formation

is located caudally. Because the term septotemporal is not appropriate for the monkey hippocampal formation (no portion of it approaches the septal area), it is more common to refer to the long axis in the primate as the rostrocaudal axis. The orthogonal axis, however, is still referred to as the transverse axis.

Two additional points should be made about the position of the monkey hippocampal formation. First, at the rostral limit of the lateral ventricle, some fields of the monkey hippocampal formation flex medially and then caudally. This is the monkey homologue of the pes hippocampi that is so prominent in the human brain. At the rostral levels where this flexure occurs, there are two representations of the hippocampal formation in standard coronal views of the brain. It is difficult in this flexed region of the monkey hippocampal formation, when viewed in standard coronal, Nissl-stained sections, to specify the identity and borders of the subdivisions of the hippocampal formation. The most medial and caudal portion of the hippocampal formation (i.e., the part that is bent backward) is the actual "rostral" pole of the monkey hippocampal formation, even though it is physically located somewhat caudal to the rostral extreme of the hippocampal formation. To make reference to different portions of the monkey hippocampal formation, we call the medial portion of the hippocampal formation the uncus region (because it forms much of the medially situated bulge that in the human would be called the uncus). The flexed, rostrally located portion that runs mediolaterally is called the genu; and the laterally situated, main portion of the hippocampus is the body.

The second point to note is that the monkey entorhinal cortex is physically associated with only the rostral portion of the other hippocampal fields. The entorhinal cortex extends caudally just to the level of the lateral geniculate nucleus, whereas the dentate gyrus, hippocampus, and subiculum extend well caudal to this level. It is equally important to point out that the rostral half of the entorhinal cortex extends beyond the rostral limit of the other hippocampal fields, where it is located ventromedial to the amygdaloid complex. Throughout virtually all of its rostrocaudal extent, the lateral border of the entorhinal cortex is at the rhinal sulcus, as in the rat.

The fiber bundles of the monkey hippocampal formation are fundamentally similar to those in the rat, although there are a number of minor differences. First, the fimbria is located dorsomedially in the monkey rather than ventrolaterally as in the rat (Fig. 3-2). Second, the fimbria leaves the substance of the hippocampal formation at a point near the splenium of the corpus callosum. Thus, the compact bundle of fibers that is called the body of the fornix travels rostrally as a pendulous, flattened cable hanging under the corpus callosum. Upon reaching the level of the anterior commissure, the bundle descends as the columns of the fornix and follows the same trajectories outlined for the rat. Third, the ventral and dorsal hippocampal commissures are relatively less prominent in the monkey than in the rat, reflecting the more restricted commissural connections observed in the monkey brain (Amaral et al., 1984; Demeter et al., 1985). The more prominent of the two commissures in the monkey is the dorsal hippocampal

commissure. It carries fibers from the presubiculum and entorhinal cortex to the contralateral side; it also carries fibers originating in the parahippocampal cortex.

The subdivision of the hippocampal formation into various regions is fundamentally the same in rat and monkey brains. There are, however, substantial species differences in certain subregions, especially CA1 and the entorhinal cortex, which are addressed in greater detail later in the chapter.

### 3.3.4 Human Hippocampal Formation

The three-dimensional position of the human hippocampal formation is similar to that in the macaque monkey brain (Figs. 3–6 and 3–7, respectively). However, owing to the larger development of the temporal association cortex, in particular that of the entorhinal and perirhinal cortices, the structure of the ventromedial surface of the brain, including the gyral patterns, is substantially different in the human and monkey brains. After a brief summary of the gross anatomical attributes of the main or intraventricular portions of the human hippocampal formation, we review some of the differences of the associated cortical regions.

The classic gross anatomical image of the human hippocampal formation is of a prominent bulge in the floor of the temporal horn of the lateral ventricle (Fig. 3–3). As in the monkey, this portion of the hippocampal formation is widest at its rostral extent where the structure bends toward the medial surface of the brain. In this area, two to five subtle gyri, or *digitationes hippocampi*, form the *pes hippocampi* (Gertz et al., 1972). The substance of the *pes hippocampi* is formed by several of the hippocampal fields, and the constituents differ at different rostrocaudal levels (see below). Continuing caudally from the *pes hippocampi*, the main body of the hippocampus gets progressively thinner as it bends dorsally toward the splenium of the corpus callosum.

The fimbria is situated on the medial surface of the human hippocampus, as in the monkey (Fig. 3–2). At rostral levels, the fimbria is thin and flat but becomes progressively thicker caudally as fibers are continually added to it. As the fimbria leaves the caudal extent of the hippocampus, it fuses with the ventral surface of the corpus callosum and travels rostrally in the lateral ventricle. The portion of these fimbrial fibers located between the caudal limit of the hippocampal formation and the fusion with the corpus callosum is called the crus of the fornix, whereas the major portion of the rostrally directed fiber bundle is, as in the monkey, called the body of the fornix. At the end of its rostral trajectory, the body of the fornix descends as the columns of the fornix. At about the point where the fimbria fuses with the posterior portion of the corpus callosum, fibers extend across the midline to form the hippocampal commissure. A variety of gross anatomical terms have been applied to this commissure, but the term *psalterium* (alluding to a harp-like stringed instrument) is most common. As noted previously, the primate hippocampal commissural connections are much more limited than in the rodent; and as suggested by stereotaxic depth

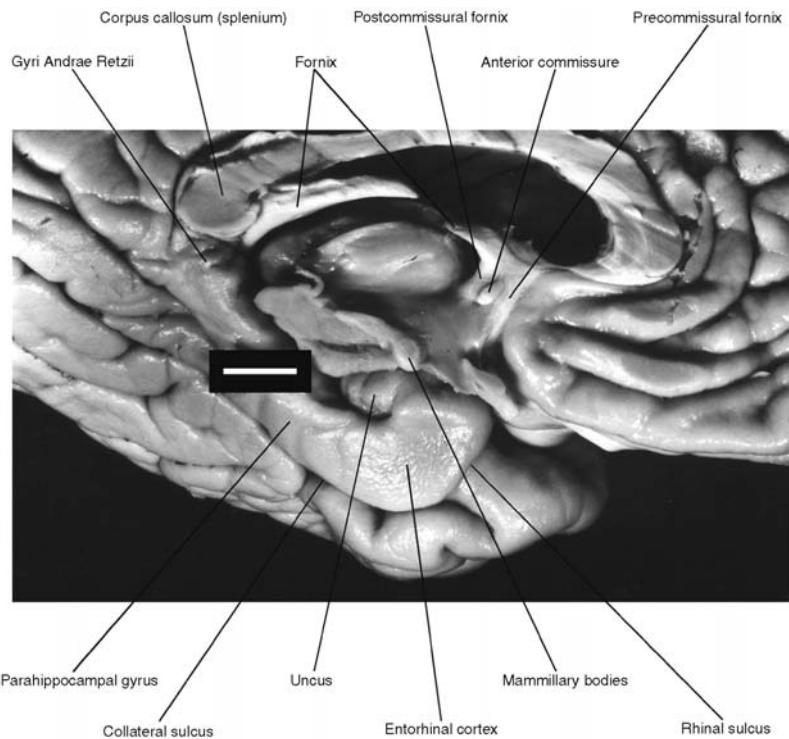

encephalography, there is almost no commissural interaction between the hippocampal formations located on each side of the human brain (Wilson et al., 1987).

The ventral surface of the human temporal lobe is demarcated into mediolateral strips by two prominent rostrocaudally oriented sulci (Figs. 3–9 and 3–10). The more lateral of the two is the occipitotemporal sulcus, which is often broken by small, transverse gyri. The more medial of the sulci, and the one that is more closely associated with the hippocampal formation, is the collateral sulcus. The collateral sulcus is often continuous with the rostrally situated rhinal sulcus. Unlike the situation in the rat and the monkey, however, the rhinal sulcus is relatively insignificant in the human brain and is associated only with the most rostral portion of the entorhinal cortex. It is thus not a useful border for the lateral boundary of the entorhinal cortex.

The collateral sulcus forms most of the lateral border of what has classically been termed the parahippocampal gyrus. The parahippocampal gyrus is a complex region that contains a number of distinct cytoarchitectonic fields and has been defined in different ways by different authors. In recent years, the parahippocampal gyrus has often been broken up into an anterior part, which comprises mainly the entorhinal cortex and associated perirhinal cortex, and a posterior part, which includes the areas TF and TH of Von Economo (1929).

Unlike the situation in the monkey, where the rhinal sulcus forms a reasonably reliable lateral border for the entorhinal cortex, the collateral sulcus does not provide a discrete lateral boundary for the human entorhinal cortex. The entorhinal cortex actually ends approximately midway along the medial bank of the collateral sulcus. The two fields of the perirhinal cortex, areas 35 and 36 of Brodmann (1909), form the remainder of the medial bank, fundus, and a portion of the lateral bank of the collateral sulcus. The perirhinal cortex is massively enlarged in the human brain and may account, in part, for the prominence of the collateral sulcus. The border zone between the entorhinal cortex and the perirhinal cortex was called the trans-entorhinal zone by Braak (1972, 1980). In this region, neuroanatomical markers that label layer II of the entorhinal cortex demonstrate an oblique band of labeled cells, which makes it appear that layer II is diving underneath the layers of the perirhinal cortex. Because the perirhinal cortex terminates at a variable point along the lateral bank of the collateral sulcus, it is extremely difficult to define the borders of the entorhinal and perirhinal cortices using imaging modalities such as magnetic resonance imaging. The only way it is currently possible to define the border of these fields accurately is through histological analysis.

Interestingly, much of the areal extent of the human entorhinal cortex (at least the rostral portions) can be visually identified on the surface of the brain by the conspicuous bumps, named *verrucae* (latin for warts), that mark its pial surface. These bumps mark the islands of cells that constitute layer II of the entorhinal cortex. The dorsomedial aspect of the entorhinal cortex is marked by a conspicuous mound, or secondary gyrus, referred to as the *gyrus ambiens* (Fig. 3–10). The dorsomedial limit of the entorhinal cortex with the amygdala

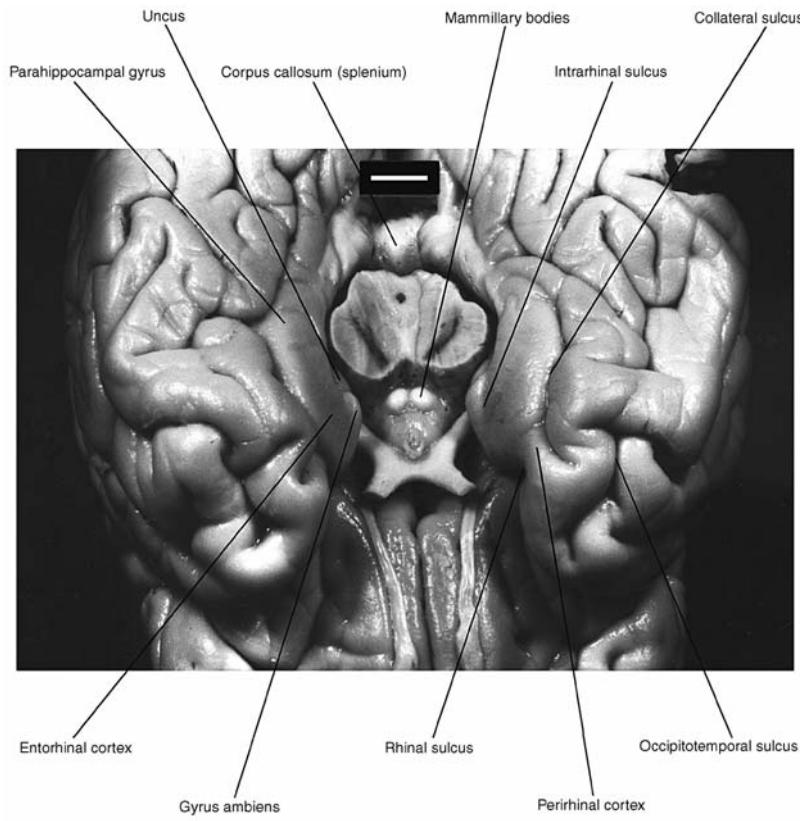

**Figure 3-9.** Ventromedial view of the human temporal lobe. Bar = 1 cm.

daloid complex is marked by the shallow sulcus semiannularis, which is located dorsal to the gyrus ambiens.

There is a series of prominent bulges on the medial surface of the hemisphere just caudal to the dorsomedial portion of the entorhinal cortex; this is generally labeled the uncus

(or hook) in gross anatomical descriptions (Fig. 3-9). The most rostral of the uncal bulges is often separately labeled the gyrus uncinatus. Histological sections through the gyrus uncinatus indicate that it is made up of the amygdalohippocampal region (of the amygdaloid complex) and the

**Figure 3-10.** Ventral surface of the human brain after the brain stem and cerebellum have been removed. Bar = 1 cm.

transition zone between the amygdala and hippocampus. The middle bulge, called the band of Giacomini, is generally composed of the most medial part of the dentate gyrus. The most caudal of the uncal bulges, called the intralimbic gyrus, is composed mainly of a portion of the CA3 field of the hippocampus.

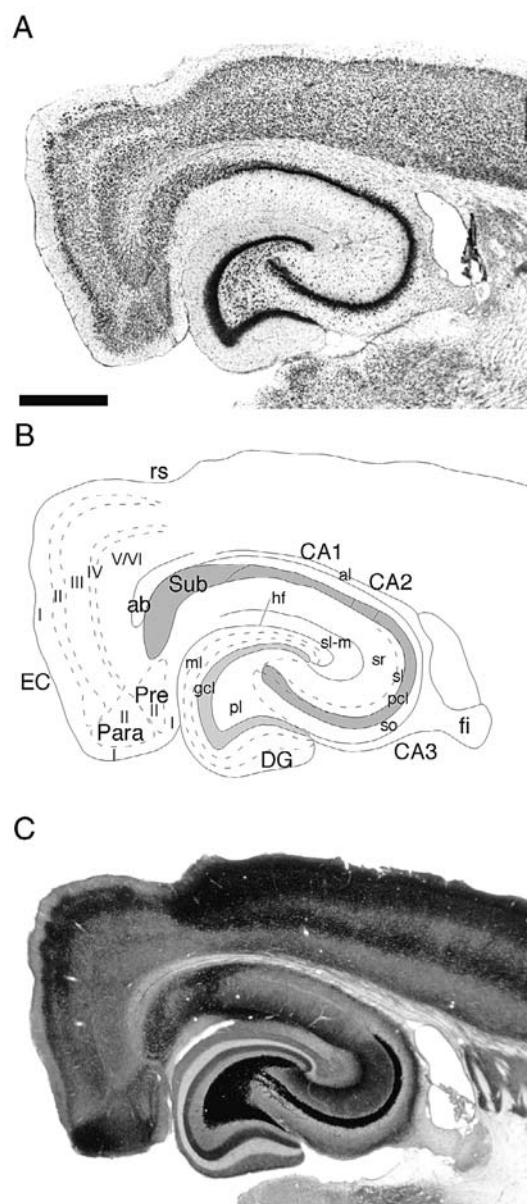

As the parahippocampal gyrus meets the retrosplenial region caudally, a group of small bumps known as the gyri Andreeae Retzii are seen on the medial surface of the brain (Fig. 3–9). This irregular region of human cortex marks the caudal limit of the hippocampal formation and is composed principally of CA1 and the subiculum. Two obliquely oriented small gyri located deep to the gyri Andreeae Retzii are called the fasciola cinerea (which corresponds to the caudalmost part of the dentate gyrus) and the gyrus fasciolaris (which corresponds to the caudal pole of the CA3 field). A thin remnant of the hippocampal formation surrounds the splenium of the corpus callosum and ascends dorsally over the corpus callosum to form the induseum griseum (or supracommissural hippocampal formation), which comprises remnants of the subiculum and other fields of the hippocampal formation.

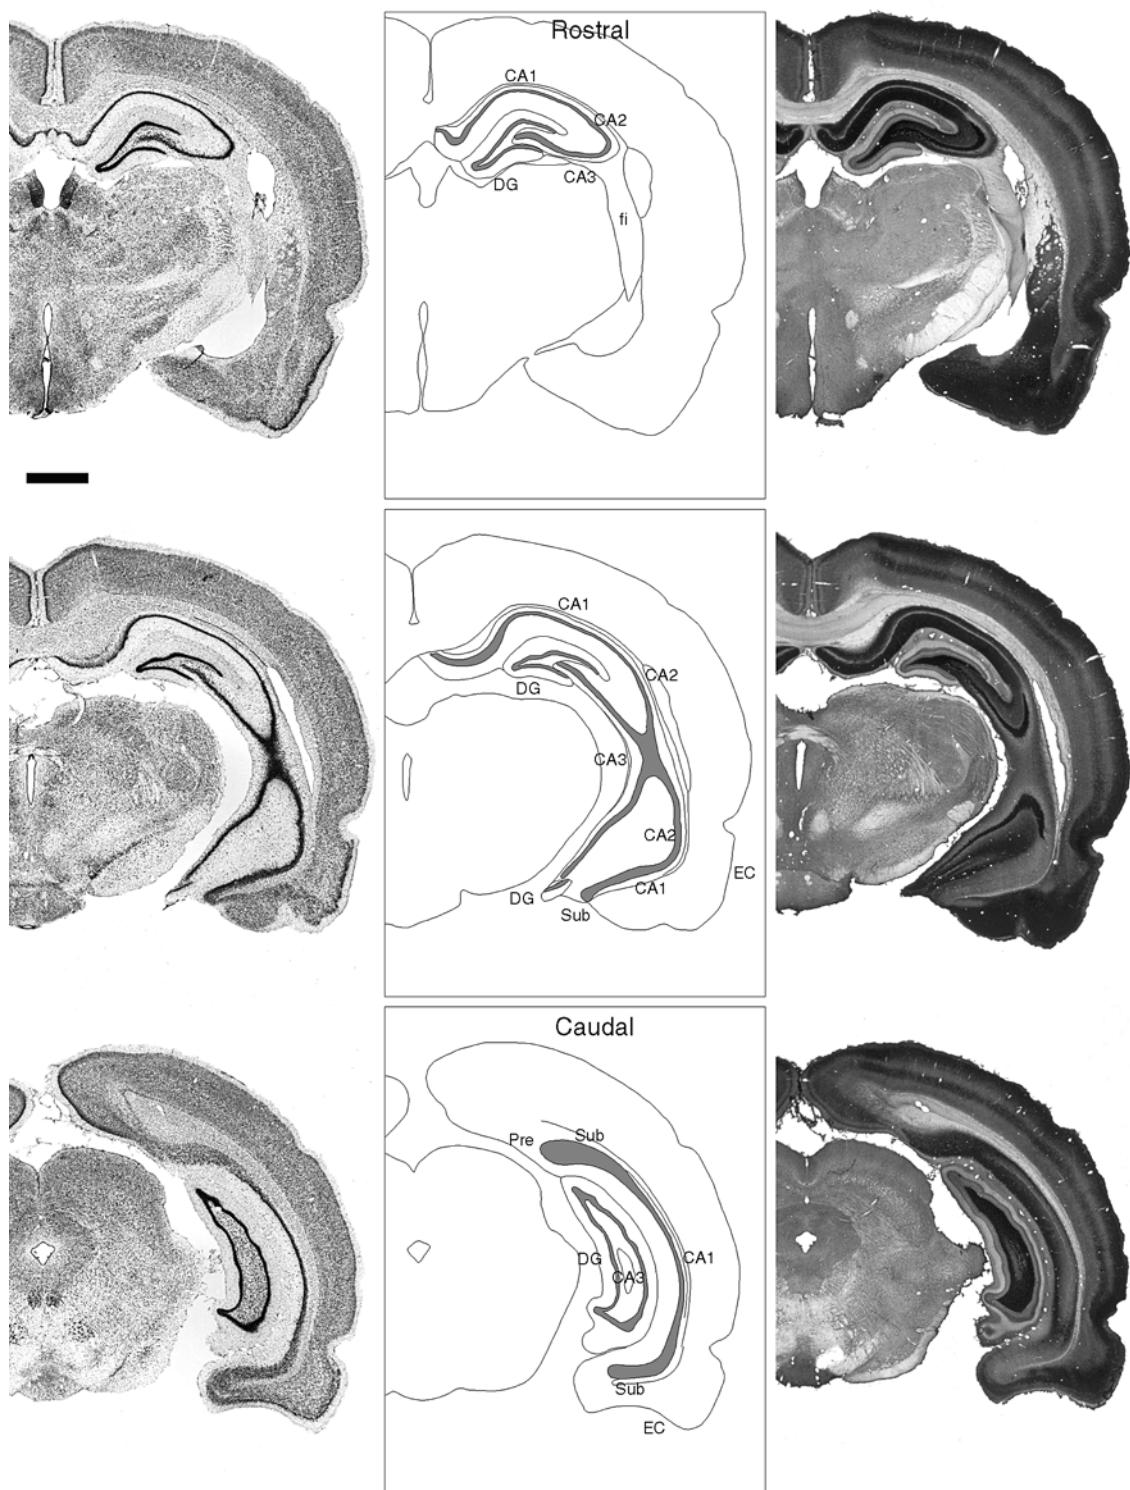

### 3.4 Neuroanatomy of the Rat Hippocampal Formation

We have now concluded our overview of the gross or three-dimensional organization of the rat, monkey, and human hippocampal formations. In the sections that follow, we review the neuroanatomical organization of each of the fields of the hippocampal formation of the rat, beginning with the dentate gyrus and ending with the entorhinal cortex. In each section, we describe the cytoarchitectonic organization followed by a summary of the resident neurons and finally a survey of the pattern of intrinsic and extrinsic connections. The amount of information available for each of the cytoarchitectonic fields of the hippocampal formation varies substantially. The most detailed anatomical information is available for the dentate gyrus, perhaps because it is the simplest of the hippocampal fields. For this reason and because the dentate gyrus is the first structure to receive direct entorhinal input and does not project outside the hippocampal formation, we begin our description here. We then progress through the hippocampus and other hippocampal fields.

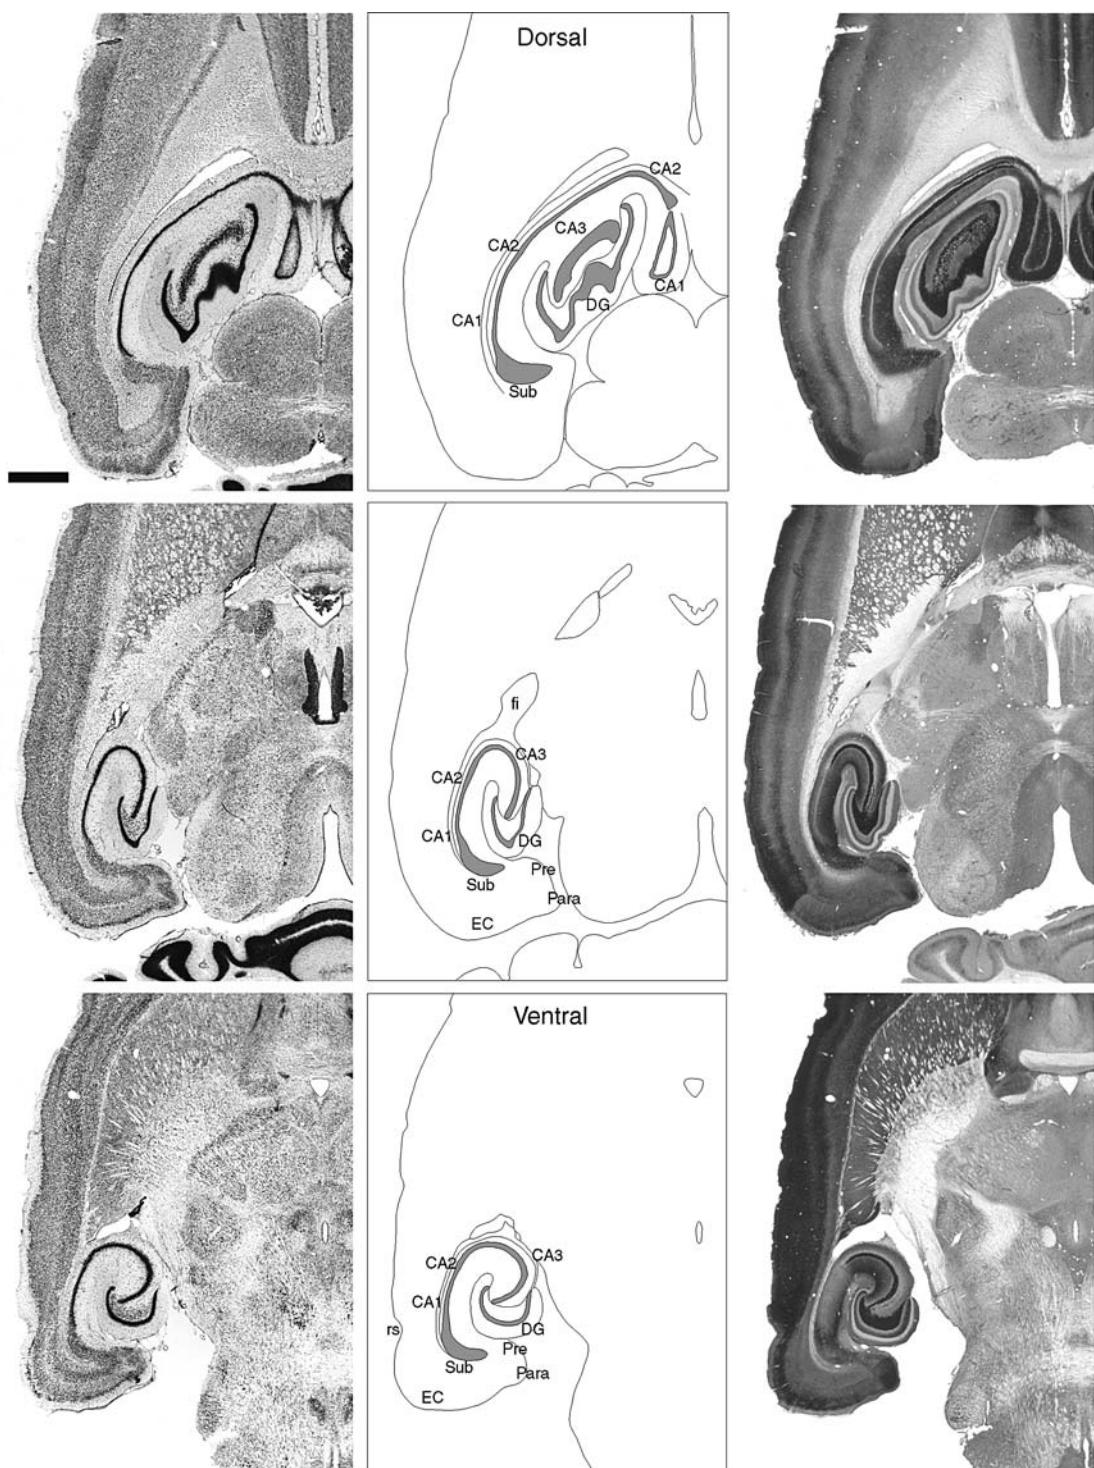

We have prepared a series of illustrations to demonstrate the cytoarchitectonic organization of the rat hippocampal formation (Figs. 3–11 through 3–14). The first figure (Fig. 3–11) is a photomicrograph of a section cut in the horizontal plane. This plane has the advantage of illustrating all components of the rat hippocampal formation. A Nissl-stained section is shown at the top, and a Timm's sulfide silver section is shown at the bottom. The latter has been used extensively for highlighting various fiber and terminal systems in the hippocampal formation. After Figure 3–11, we provide images of

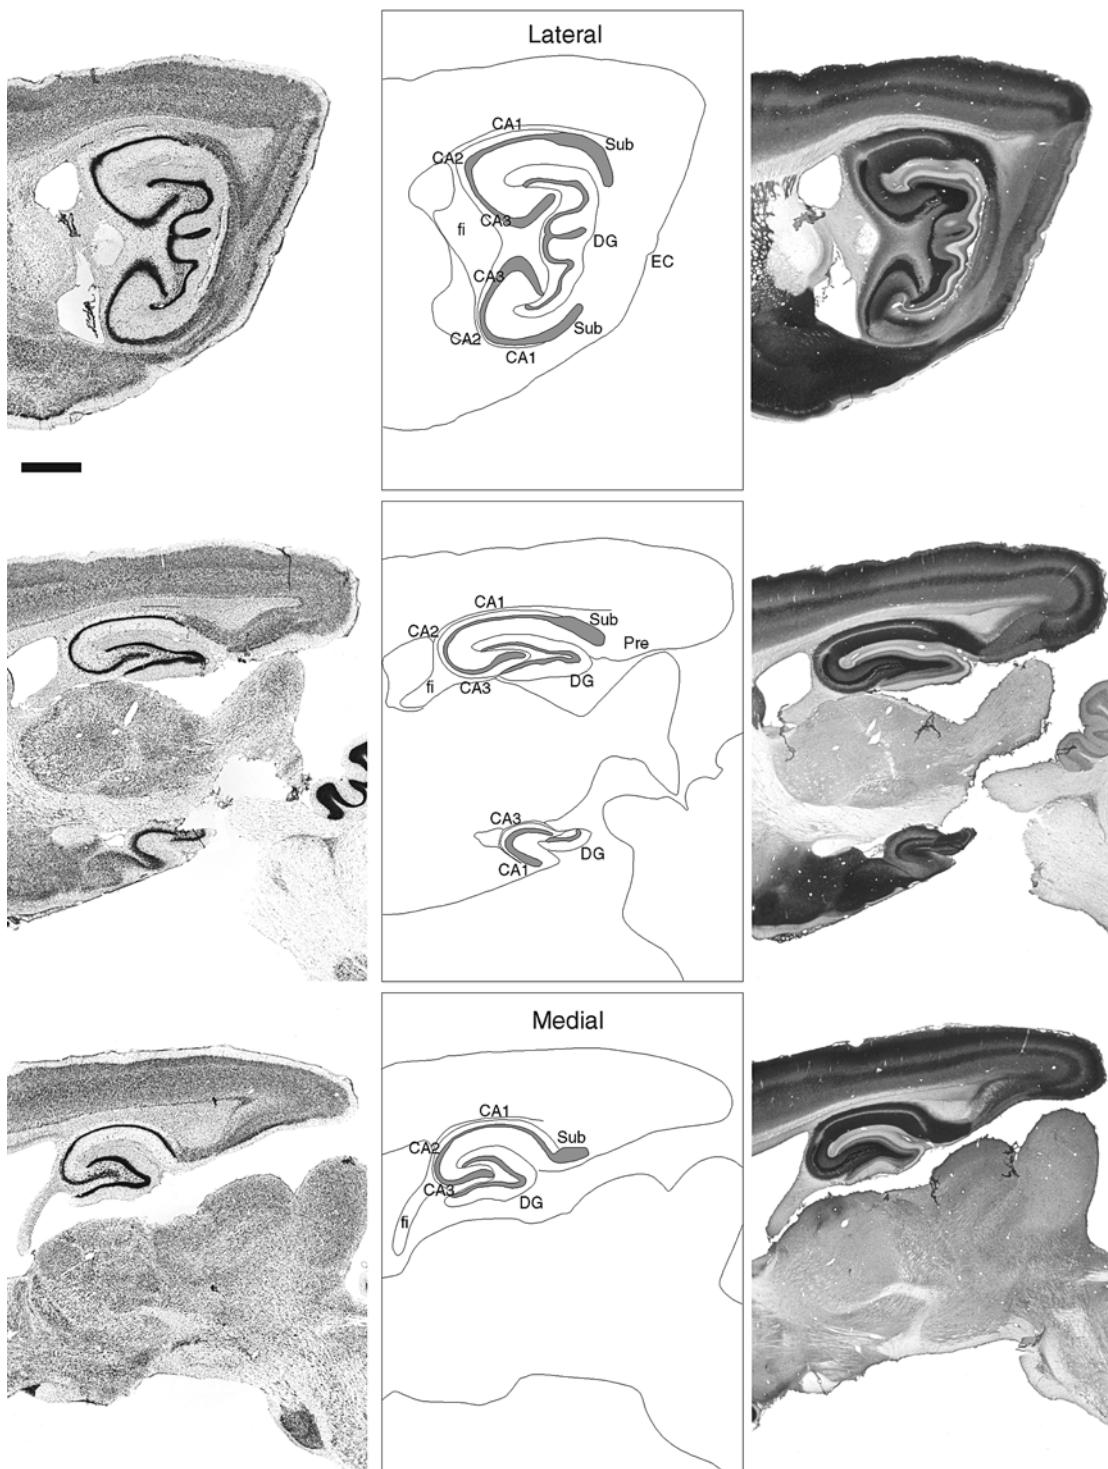

**Figure 3–11.** Horizontal section through the rat hippocampal formation. A. Nissl-stained section. B. Line drawing shows the various regions, layers, and fiber pathways. C. Timm's sulfide silver-stained section. Note the three bands of the molecular layer of the dentate gyrus in C. The outer band corresponds to the terminal zone of the lateral perforant pathway; the middle unstained region corresponds to the terminal zone of the medial perforant pathway; the inner band corresponds to the zone of termination of the associational and commissural pathways of the dentate gyrus. ab, angular bundle; al, alveus; CA1, CA1 field of the hippocampus; CA2, CA2 field of the hippocampus; CA3, CA3 field of the hippocampus; DG, dentate gyrus; EC, entorhinal cortex; fi, fimbria; gcl, granule cell layer of the dentate gyrus; hf, hippocampal fissure; ml, molecular layer of the dentate gyrus; Para, parasubiculum; pcl, pyramidal cell layer of the hippocampus; pl, polymorphic layer of the dentate gyrus; Pre, presubiculum; sl, stratum lucidum of CA3; sr, stratum radiatum of the hippocampus; sl-m, stratum lacunosum moleculare of the hippocampus. Roman numerals: cortical layers. Bar in A = 500  $\mu\text{m}$  and applies to all panels.

**Figure 3-12.** Coronal sections at three rostrocaudal levels through the rat brain show the relative position of the hippocampal formation. The three panels on the left are Nissl-stained sections; the three panels on the right are adjacent sections stained with Timm's sulfide silver stain; the line drawings (middle column) highlight the regions of the rat hippocampal formation seen in the stained sections. For abbreviations see Figure 3-11. Bar = 1 mm.

For abbreviations see Figure 3–11. Bar = 1 mm.

similar stains of coronal (Figure 3–12), horizontal (Fig. 3–13), and sagittal (Fig. 3–14) sections through different levels of the hippocampal formation. Finally, we must point out that to keep this chapter readable we have used citations sparingly. Detailed references for the information provided in this chapter can be found in Witter and Amaral (2004).

### 3.4.1 Dentate Gyrus

#### Cytoarchitectonic Organization

The dentate gyrus is comprised of three layers. Superficially, closest to the hippocampal fissure is a relatively cell-free layer called the molecular layer. In the rat, this layer has an average thickness of approximately 250  $\mu\text{m}$ . The principal cell layer (granule cell layer) lies deep to the molecular layer and is made up of a densely packed layer that is four to eight granule cells thick. The granule cell and molecular layers (which together are sometimes referred to as the fascia dentata) form a V- or U-shaped structure (depending on the septotemporal position) that encloses a cellular region, the polymorphic cell layer, which constitutes the third layer of the dentate gyrus (Fig. 3–11).

#### Neuron Types

##### Dentate Granule Cell

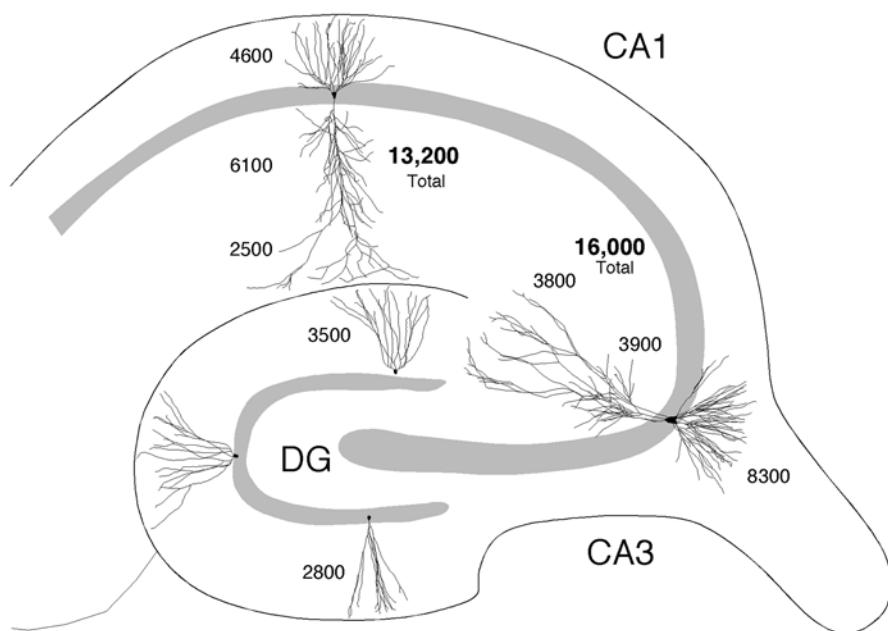

The principal cell type of the dentate gyrus is the granule cell (Figs. 3–15 and 3–16). The dentate granule cell has an elliptical cell body with a width of approximately 10  $\mu\text{m}$  and a height of 18  $\mu\text{m}$  (Claiborne et al., 1990). Each cell is closely apposed to other granule cells, and in most cases there is no glial sheath intervening between the cells. The granule cell has a characteristic cone-shaped tree of spiny dendrites with all

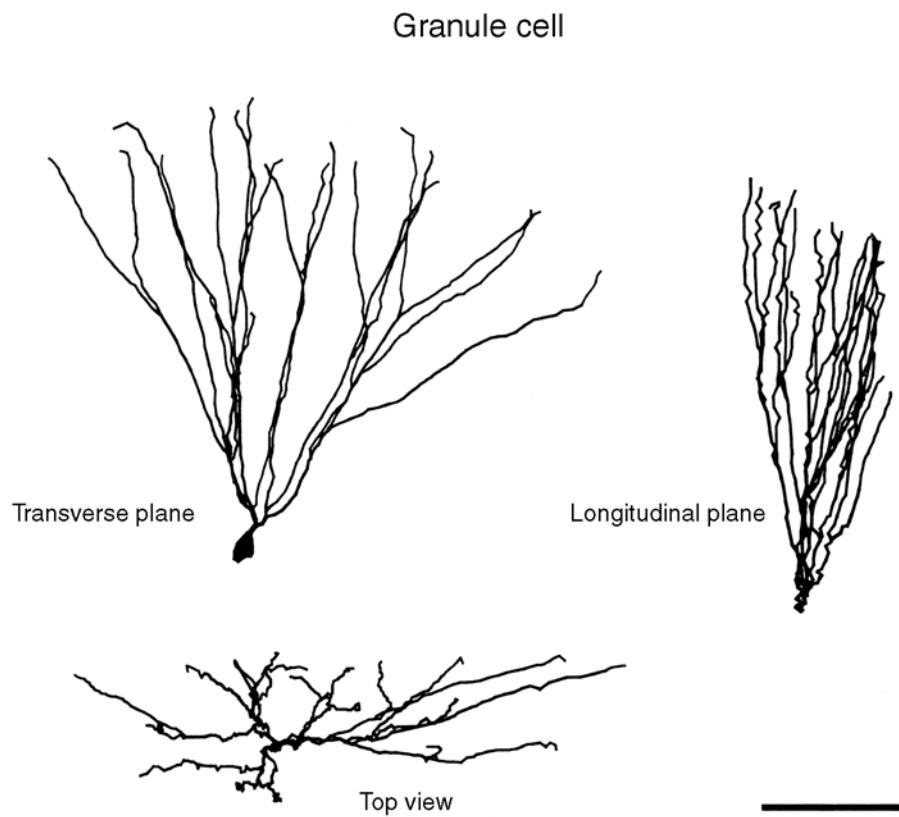

the branches directed toward the superficial portion of the molecular layer; most of the distal tips of the dendritic tree end just at the hippocampal fissure or at the ventricular surface. The dendritic trees of granule cells located in the suprapyramidal blade tend, on average, to be larger than those of cells located in the infrapyramidal blade (3500  $\mu\text{m}$  vs. 2800  $\mu\text{m}$ ). Desmond and colleagues (Desmond and Levy, 1985) provided estimates for the number of dendritic spines on the granule cell dendrites. They found that cells in the suprapyramidal blade have 1.6 spines/ $\mu\text{m}$ , whereas cells in the infrapyramidal blade have 1.3 spines/ $\mu\text{m}$ . With these numbers and the mean dendritic lengths given above, an estimate of the number of spines on the average suprapyramidal granule cell would be 5600 and for an infrapyramidal cell 3640.

The total number of granule cells in one dentate gyrus of the rat is about  $1.2 \times 10^6$  (West et al., 1991; Rapp and Gallagher, 1996). Although cell proliferation and neurogenesis in the dentate gyrus persist into adulthood and appear to be under environmental control, modern stereological studies have shown that the total number of granule cells does not vary in adult animals (Rapp and Gallagher, 1996). Only infant and juvenile mice exposed to running wheels or socially complex, “enriched” environments demonstrate a larger dentate gyrus and a greater number of granule cells that persist into adulthood than animals raised in standard laboratory cages (Kempermann et al., 1997). Similar manipulations performed in adult animals can affect cell proliferation and/or survival of newly generated neurons, but they have no significant impact on the volume of the dentate gyrus or the total number of granule cells (Kempermann et al., 1998).

Before leaving the topic of granule cell number, we should note that the packing density and thickness of the granule cell layers varies somewhat along the septotemporal axis of the dentate gyrus (Gaarskjaer, 1978a). The packing density of

**Figure 3–15.** Dendritic arborization of the principal cells in the rat dentate gyrus (granule cells) and hippocampus proper (pyramidal cells). See the text for details.

**Figure 3-16.** Dendritic organization of dentate granule cells. Computer-generated reconstructions of horseradish peroxidase (HRP)-filled granule cells from the suprapyramidal blade. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Claiborne et al., 1990.)

granule cells is higher septally than temporally. Because the packing density of CA3 pyramidal cells follows an inverse gradient, the net result is that at septal levels of the hippocampal formation the ratio of granule cells to CA3 pyramidal cells is something on the order of 12:1, whereas at the temporal pole the ratio drops to 2:3. Because the CA3 pyramidal cells are the major recipients of granule cell innervation and the number of mossy fiber synapses is roughly the same along the septotemporal axis, contact probability is much lower septally than temporally.

The granule cell is the only “principal” cell of the dentate gyrus; that is, it is the only cell type that gives rise to axons that leave the dentate gyrus to innervate another hippocampal field (i.e., CA3). There is one type of neuron, called the mossy cell, whose axon leaves the dentate gyrus of one side of the brain only to innervate the dentate gyrus of the other side. There are numerous other types of neuron, most of which are inhibitory interneurons. We describe them in turn.

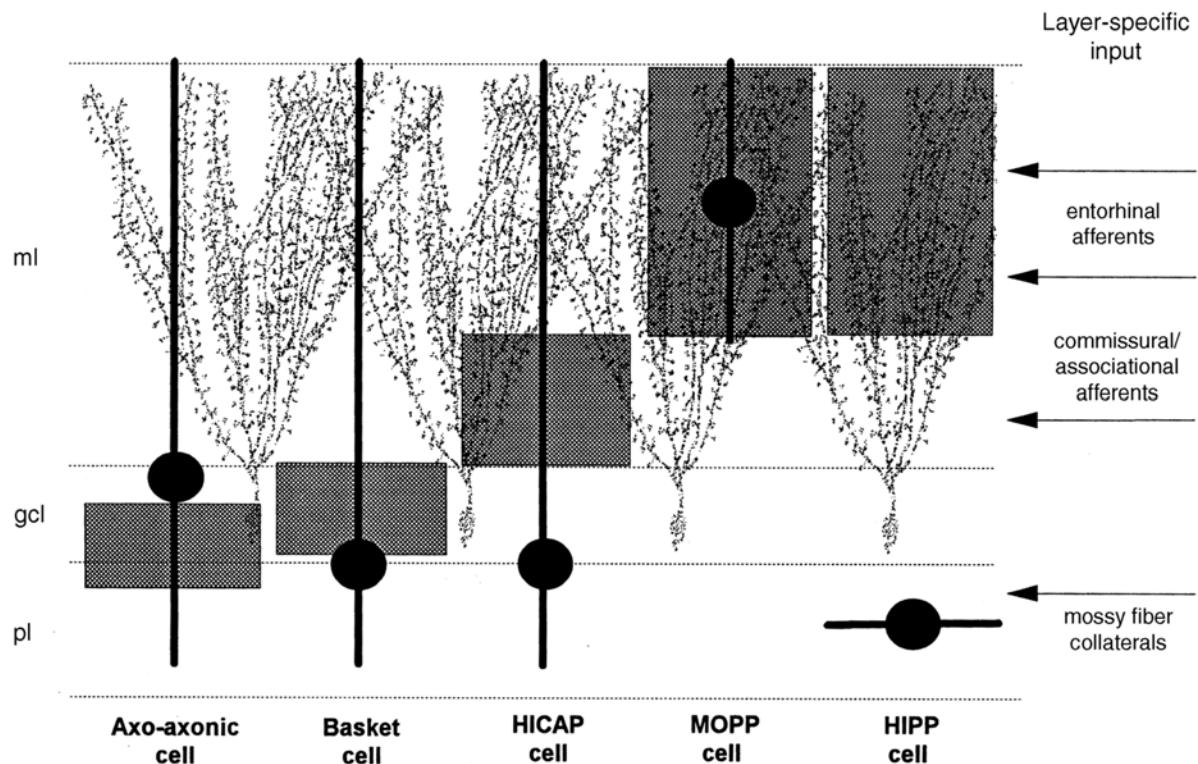

#### **Pyramidal Basket Cell**

The most intensively studied interneuron is the pyramidal basket cell (Fig. 3-17). These cells are generally located along the deep surface of the granule cell layer. They have pyramid-shaped cell bodies 25 to 35  $\mu\text{m}$  in diameter and are wedged slightly into the granule cell layer. The basket portion of the name refers to the fact that the axon of these cells forms pericellular plexuses that surround and form synapses with the cell bodies of granule cells. Ramon y Cajal first described the pyramidal basket cells as having a single, principal aspiny api-

cal dendrite directed into the molecular layer (where it divides into several aspiny branches) and several principal basal dendrites that ramify and extend into the polymorphic cell layer. Most of these cells contain biochemical markers for the inhibitory transmitter  $\gamma$ -aminobutyric acid (GABA) and are thus presumably inhibitory (Ribak et al., 1978; Ribak and Seress, 1983). The number of basket cells is not constant throughout the transverse or septotemporal extents of the dentate gyrus (Seress and Pokorny, 1981). At septal levels, the ratio of basket cells to granule cells is 1:100 in the suprapyramidal blade and 1:180 in the infrapyramidal blade. At temporal levels, the number is 1:150 for the suprapyramidal blade and 1:300 for the infrapyramidal blade. These data raise a theme that is repeated throughout the chapter: that despite the apparent cytoarchitectonic homogeneity of the hippocampal fields, there are several differences (especially regarding neurochemical innervation) at different septotemporal levels of the hippocampal formation.

#### **Other Interneurons**

There has been an explosion in the number of interneurons identified in the rat hippocampal formation. A detailed overview of the characteristics of the various hippocampal interneurons has been published by Freund and Buzsaki (1996). Hippocampal interneurons, which form a heterogeneous population, are designed to carry out different functions. Many of the cell types can be distinguished on the basis of the distribution of their axonal plexus. Some have axons that terminate on cell bodies, whereas others have axons that

**Figure 3-17.** Morphological classification of the interneurons of the rat dentate gyrus. Filled circles indicate the location of the cell bodies, and thick lines indicate the predominant orientation and laminar distribution of the dendritic tree. The dentate granule cells (principal neurons) are illustrated in the background, providing an indication of which domain is innervated by which interneuron groups. The laminar distribution of various inputs, often showing correspondence with the interneuron type or axon distribution, is also indicated. (Source: Adapted from Freund and Buzsaki, 1996.)

terminate exclusively on the initial segments of other axons. Interneurons have also been distinguished on the basis of their inputs. Some are preferentially innervated (e.g., by the serotonergic fibers originating from the raphe nuclei). Interneurons can also be differentiated from principal cells on the basis of their electrophysiological characteristics. At least some interneurons have high rates of spontaneous activity and fire in relation to the theta rhythm. For this reason, interneurons are often called theta cells (see Chapter 11). A major challenge is to determine if different classes of interneurons demonstrate distinct electrophysiological response profiles.

Within the same subgranular region occupied by the cell bodies of the pyramidal basket cells are several other cell types with distinctly different somal shapes, as well as different dendritic and axonal configurations (Amaral, 1978). Some of these cells are multipolar with several aspiny dendrites entering the molecular and polymorphic layers, whereas others tend to be more fusiform-shaped with a similar dendritic distribution. As Ribak and colleagues pointed out, many of these cells share fine structural characteristics such as infolded nuclei, extensive perikaryal cytoplasm with large Nissl bodies, and intranuclear rods. Moreover, it appears that all of these cells give rise to axons that contribute to the basket plexus in the granule cell layer. Many of these neurons are immunore-

active for GABA. They form symmetrical synaptic contacts with the cell bodies, proximal dendrites, and occasionally axon initial segments of granule cells and therefore function as inhibitory interneurons. These cells are not neurochemically homogeneous, however, as subsets appear to colocalize distinct categories of other neuroactive substances.

#### Neurons of the Molecular Layer

The molecular layer is occupied primarily by dendrites of the granule, basket, and polymorphic cells as well as axons and terminal axonal arbors from the entorhinal cortex and other sources. At least two neuron types are also present in the molecular layer. The first is located deep in the molecular layer, has a multipolar or triangular cell body, and gives rise to an axon that produces a substantial terminal plexus largely limited to the outer two-thirds of the molecular layer. This neuron, which has aspiny dendrites that remain mainly within the molecular layer, has been called the MOPP cell (molecular layer perforant path-associated cell). This terminology was proposed by Han et al. (1993) to bring some order to naming interneurons in the hippocampal formation. The lettering system refers to the location of the cell body and to the region where the axon is distributed.

Frotscher and colleagues described a second type of neuron in the molecular layer that resembles the so-called chan-

delier, or axo-axonic, cell originally found in the neocortex (Soriano and Frotscher, 1989). These cells are generally located immediately adjacent to or even within the superficial portion of the granule cell layer. The axo-axonic cell is named for the fact that its axon descends from the molecular layer into the granule cell layer, collateralizes profusely, and then terminates, with symmetrical synaptic contacts, exclusively on the axon initial segments of granule cells. Thus, their shape resembles that of a chandelier. Each axo-axonic cell may innervate the axon initial segments of as many as 1000 granule cells. Because these cells are immunoreactive for markers of GABAergic neurons and make symmetrical synapses, it is likely that they provide a second means of inhibitory control of granule cell output. The inputs to the axo-axonic cells are currently unknown although their dendrites remain mainly in the molecular layer, where they are likely to receive perforant path input from the entorhinal cortex.

Other neurons with cell bodies located in the molecular layer are members of the IS (interneuron-specific) class of interneuron, which are specialized for termination on other interneurons. These IS neurons are demonstrated using immunohistochemistry for vasoactive intestinal peptide (VIP), and their axons overlap with the dendrites of the O-LM and HIPP cells (these cell types are defined shortly).

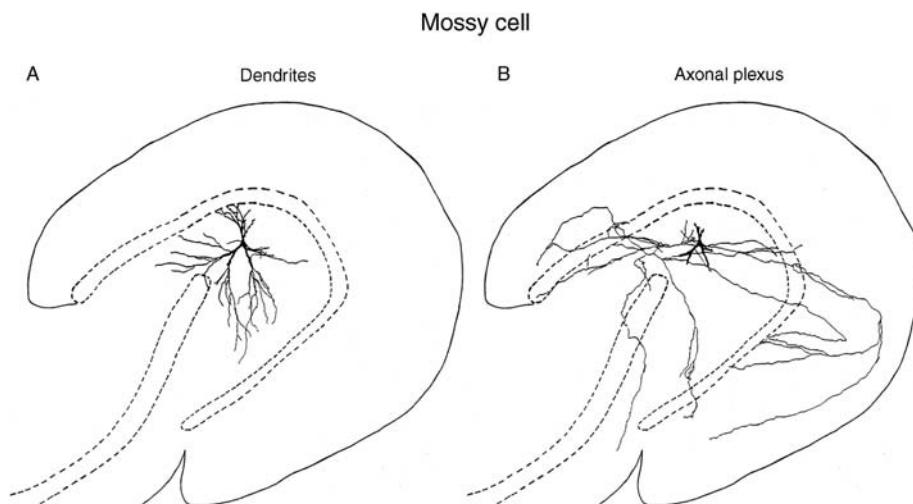

#### **Neurons of the Polymorphic Cell Layer**

The polymorphic layer harbors a variety of neuron types, but little is known about many of them (Amaral, 1978). The most common type, and certainly the most impressive, is the mossy cell (Fig. 3–18). This cell type is probably what Ramon y Cajal referred to as the “stellate or triangular” cells located in his subzone of fusiform cells; and it is undoubtedly what Lorente de Nó referred to as “modified pyramids.” The cell bodies of the mossy cells are large (25–35  $\mu\text{m}$ ) and are often triangular or multipolar in shape. Three or more thick dendrites originate from the cell body and extend for long distances in the polymorphic layer. Each principal dendrite bifurcates once or twice and generally gives rise to a few side branches. Although

most of the daughter dendritic branches remain within the polymorphic layer, an occasional dendrite pierces the granule cell layer and enters the molecular layer. The mossy cell dendrites virtually never enter the adjacent CA3 field.

The most distinctive feature of the mossy cell is that all of its proximal dendrites are covered by large, complex spines evocatively called thorny excrescences. These spines are the distinctive sites of termination of the mossy fiber axons (i.e., axons of the dentate granule cells). Although thorny excrescences are also observed on the proximal dendrites of pyramidal cells in CA3, they are never as dense as the ones on the mossy cells. The distal dendrites of the mossy cell have typical pedunculate spines that appear to be less densely distributed than those on the distal dendrites of the pyramidal cells in the hippocampus. The mossy cells are immunoreactive for glutamate and give rise to axons that project to the inner third of the molecular layer of the ipsilateral and contralateral dentate gyrus, making asymmetrical terminations on the dendrites of granule cells. The mossy cells thus appear to be the major source of the excitatory associational/commissural projection to the dentate gyrus. For this reason, the mossy cell does not fit the classic description of an interneuron.

There are also a number of fusiform cells in the polymorphic layer. The main difference between the fusiform cell types is whether they have spines. One type, the long-spined multipolar cell first described by Amaral (1978), has recently been called the HIPP cell (hilar perforant path-associated cell). This cell type has two or three principal dendrites that originate from the poles of the cell, run mainly parallel to the granule cell layer, and can extend for nearly the entire transverse length of one blade of the granule cell layer. The conspicuous feature of this cell is the distribution of copious, long, often branched spines over its cell body and dendrites. Intracellular staining techniques demonstrate that these cells have axons that ascend into the outer two-thirds of the molecular layer (i.e., the perforant path zone) and terminate with symmetrical and presumably inhibitory synapses on the dendrites of granule cells. An amazing feature of these neurons is that their

**Figure 3-18.** Mossy cell of the polymorphic layer of the rat dentate gyrus. A. Camera lucida drawing of the soma and dendritic arbor. Note that the dendrites extend widely in the polymorphic layer but do not penetrate the granule cell layer. B. Camera lucida drawing of the soma and axonal plexus. The axon ramifies throughout the polymorphic layer and enters the dentate granule cell layer at considerable distances from the soma. A single collateral projects through the CA3 cell body layer and toward the fimbria. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Buckmaster et al., 1992.)

axonal plexus can extend for as much as 3.5 mm along the septotemporal axis of the dentate gyrus (the entire length of the dentate gyrus in the rat is only about 10 mm) and may generate as many as 100,000 synaptic terminals. Because inhibitory interneurons typically have aspiny dendrites and relatively local axonal plexuses, this long-spined multipolar HIPP cell is a highly atypical interneuron. At least some of these HIPP cells appear to correspond to the somatostatin/GABA cells that give rise to the somatostatin innervation of the outer portion of the molecular layer.

There are also multipolar or triangular cells in the polymorphic layer with thin, aspiny dendrites that extend within both the hilus and the molecular layer. The axons of these HICAP cells (hilar commissural-associational pathway-related cells) extend through the granule cell layer and branch profusely in the inner third of the molecular layer. A variety of other neuron types exist in the polymorphic layer of the dentate gyrus whose axonal plexus has not yet been well described.

Before leaving the typing of interneurons in the dentate gyrus, it is perhaps worth noting that the field has come a long way from believing that interneurons merely damp down neuronal activity. Rather, most current hippocampologists highlight the heterogeneity of interneurons and see them as integral components of normal information processing in the hippocampal formation.

### Extrinsic Connections

#### *Entorhinal Cortex Projection to the Dentate Gyrus*

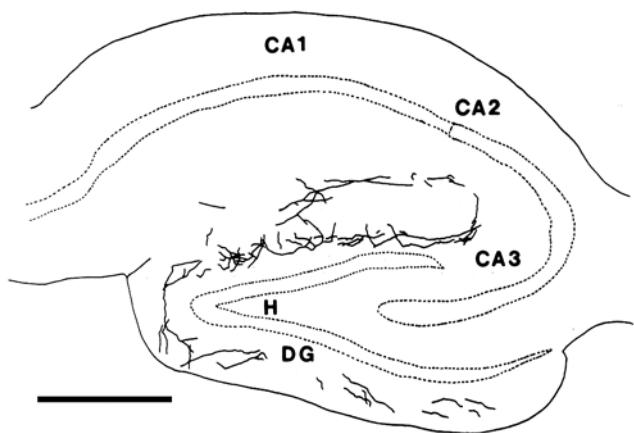

The dentate gyrus receives its major input from the entorhinal cortex via the so-called perforant pathway (Ramón y Cajal, 1893). The projection to the dentate gyrus arises mainly from cells located in layer II of the entorhinal cortex, although a minor component of the projection also comes from layers V and VI (Steward and Scoville, 1976). In the molecular layer of the dentate gyrus, the entorhinal terminals are strictly confined to the superficial (outer) two-thirds, where they form asymmetrical synapses that account for nearly 85% of the total axospinous terminations (Nafstad, 1967; Hjorth-Simonsen and Jeune, 1972). These contacts occur primarily on the dendritic spines of granule cells, although a small number of perforant path fibers also form asymmetrical synapses on the shafts of GABA-positive interneurons. The organization of the perforant path projection in the mouse is similar to that in the rat, although there are some detectable species differences, such as a paucity of commissural connections in the mouse (van Groen et al., 2002, 2003).

The perforant pathway can be divided into two parts based on the region of origin, pattern of termination, and appearance in histochemical and immunohistochemical preparations. In the rat, the two divisions have been called the lateral and medial perforant paths because they originate from the lateral and medial entorhinal areas, respectively. Perforant path fibers originating in the lateral entorhinal area terminate in the most superficial third of the molecular layer, whereas

the perforant path fibers originating from the medial entorhinal area terminate in the middle third of the molecular layer. These terminal zones are readily distinguished by the classic Timm's staining method for visualizing heavy metals; this method demonstrates dense staining in the outer third of the molecular layer, a near absence of staining in the middle third, and dark staining in the inner third that is associated with the commissural/associational connection (Fig. 3–11). Projections from both areas of the entorhinal cortex innervate the entire transverse extent of the molecular layer. The thin axon branches (0.1 μm) in the molecular layer of the dentate gyrus show periodic varicosities with a thickness of 0.5 to 1.0 μm. Most of entorhinal cortex layer II spiny stellate cells project up to 2 mm in the septotemporal direction, forming a sheet-like axon arbor in the molecular layer (Fig. 3–19) (Tamamaki and Nojyo, 1993). There is surprisingly little quantitative information about the termination of the perforant path projections.

Because the perforant path fibers terminate exclusively in the molecular layer, certain neurons of the dentate gyrus are not innervated by this input. Cells with dendrites confined to the polymorphic layer do not receive entorhinal input. The mossy cells, for example, are thus likely to receive little or no direct perforant path input.

It has often been assumed that the perforant path fibers from the entorhinal cortex are the only hippocampal input reaching the dentate gyrus, but it is now clear that at least a minor projection also arises in the presubiculum and parasubiculum (Kohler, 1985). These fibers enter the molecular layer of the dentate gyrus and ramify in a zone that is interspersed between the lateral and medial perforant path projections. The presubicular axons tend to be thicker than those from the entorhinal cortex and give rise to collaterals that take

**Figure 3–19.** Perforant path projections. Distribution of labeled axon branches of a layer II spiny stellate neuron in the molecular layer of the dentate gyrus and the stratum lacunosum-moleculare of the CA2-CA3 fields of the hippocampus observed in a parasagittal section. Bar = 500 μm. (Source: Tamamaki and Nojyo, 1993. With permission of Wiley-Liss, a subsidiary of John Wiley & Sons.)

a radial course in the molecular layer, in contrast to the predominantly transverse orientation of the entorhinal perforant pathway fibers. Virtually nothing is currently known about which cells these fibers innervate or what type of transmitter they use. Because the presubiculum receives the only direct input from the anterior thalamic nucleus, these fibers provide a potential link by which thalamic information could reach the dentate gyrus.

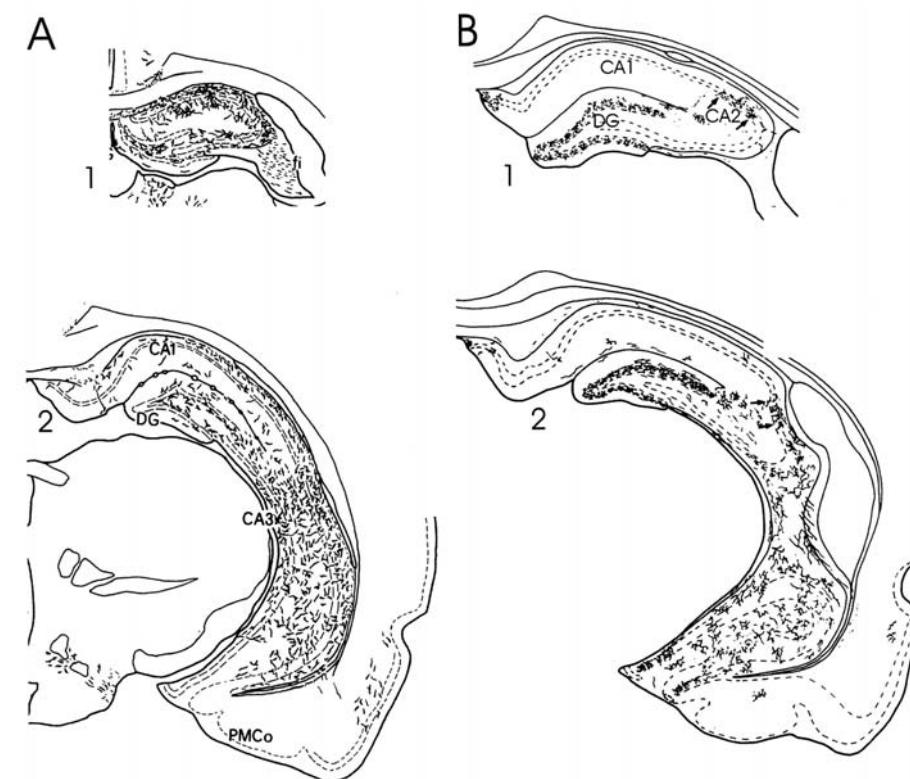

#### **Basal Forebrain Inputs: Projections from the Septal Nuclei**

The dentate gyrus receives relatively few inputs from subcortical structures. Certainly the most robust and longest studied is the projection from the septal nuclei (Mosko et al., 1973; Swanson, 1978a; Bainsden et al., 1984; Amaral and Kurz, 1985; Wainer et al., 1985; Nyakas et al., 1987). The septal projection arises from cells of the medial septal nucleus and the nucleus of the diagonal band of Broca, and it travels to the hippocampal formation via four routes: the fimbria, dorsal fornix, supracallosal stria, and a ventral route through and around the amygdaloid complex. Septal fibers heavily innervate cells of the polymorphic layer, particularly in a narrow region just subjacent to the granule cell layer. The large mossy cells are innervated by cholinergic fibers (Lubke et al., 1997). Septal fibers are lightly distributed throughout the molecular layer (Fig. 3–20a).

A large portion of the fibers of the septal projection to the dentate gyrus are cholinergic. Altogether, 30% to 50% of the cells in the medial septal nucleus and 50% to 75% of the cells in the nucleus of the diagonal band that project to the hip-

pocampal formation are cholinergic. Although it had long been assumed that the septal projection to the hippocampal formation was entirely cholinergic, it is now clear that many of the septal cells that project to the dentate gyrus are actually GABAergic. The most interesting facet of this heterogeneous septal projection is that the cholinergic and GABAergic components target different cell types. Fibers of the septal GABAergic projections terminate preferentially on other GABAergic nonpyramidal cells, such as the basket pyramidal cells of the dentate gyrus, and form symmetrical, presumably inhibitory, contacts. The heaviest GABAergic septal termination is on interneurons located in the polymorphic layer. The cholinergic septal projection to the dentate gyrus, in contrast, terminates mainly on granule cells, making asymmetrical, presumably excitatory, contacts on dendritic spines, chiefly in the inner third of the molecular layer; only 5% to 10% of the cholinergic synapses are on interneurons.

The septal projection to the dentate gyrus and to the remainder of the hippocampal formation is topographically organized. Cells located medially in the medial septal nucleus tend to project preferentially to septal or dorsal levels of the dentate gyrus, whereas cells located laterally in the medial septal nucleus tend to project to temporal levels. Because the medially situated neurons in the medial septal nucleus tend to be GABAergic rather than cholinergic, septal levels of the dentate gyrus receive most of their cholinergic input from the nucleus of the diagonal band. In contrast, temporal levels of the dentate gyrus receive their cholinergic innervation primarily from the medial septal nucleus. The ventral septal pathway

**Figure 3–20.** Septal and hypothalamic inputs to the rat hippocampal formation. A. Distribution of PHA-L-labeled fibers in the hippocampal formation resulting from an injection focused in the medial portion of the medial septal nucleus. B. Distribution of PHA-L-labeled fibers resulting from an injection in the supra-mammillary nucleus. Note the dense plexus of fibers located just superficial to the granule cell layer and in the CA2 region of the hippocampus (between the small arrows). (Sources: A. From Gaykema et al., 1990. B. Adapted from Haglund et al., 1984.)

appears to arise mainly from the nucleus of the diagonal band of Broca.

#### **Supramammillary and Other Hypothalamic Inputs**

The major hypothalamic projection to the dentate gyrus arises from a population of large cells, the supramammillary area, which caps and partially surrounds the medial mammillary nuclei (Wyss et al., 1979; Dent et al., 1983; Vertes, 1993; Magloczky et al., 1994). The supramammillary projection terminates heavily in a narrow zone of the molecular layer located just superficial to the granule cell layer and only lightly in the polymorphic layer or the rest of the molecular layer (Fig. 3–20b). Most of the supramammillary fibers terminate on the proximal dendrites of granule cells. There has been some controversy about the neurotransmitter of the supramammillary projection. There is substantial evidence that this projection is excitatory and is likely using glutamate as a primary neurotransmitter (Kiss et al., 2000). Most, but not all, of the glutamatergic supramammillary neurons that project to the dentate gyrus also colocalize calretinin; some of these cells also colocalize substance P (Borhegyi and Leranth, 1997).

In addition to the supramammillary cells, there are cells scattered in several hypothalamic nuclei (many of which are in a perifornical position or in the lateral hypothalamic area)

that project to the dentate gyrus. Although taken together these cells constitute a sizable input to the hippocampal formation, their diffuseness and lack of any distinguishing biochemical marker has made it difficult to study their patterns of termination in the hippocampal formation.

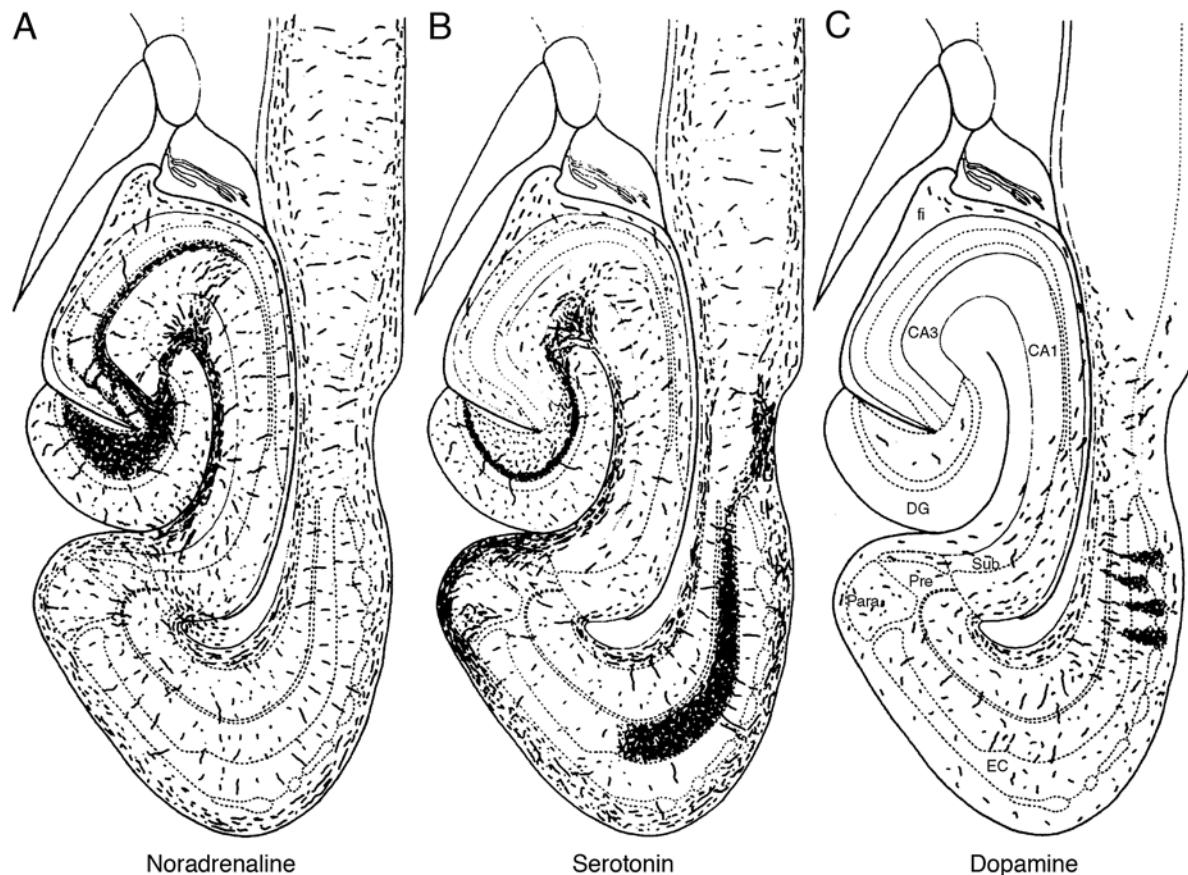

#### **Brain Stem Inputs**

The dentate gyrus receives a particularly prominent noreadrenergic input from the pontine nucleus locus coeruleus (Pickel et al., 1974; Swanson and Hartman, 1975; Loughlin et al., 1986). The noreadrenergic fibers terminate mainly in the polymorphic layer of the dentate gyrus and extend into the stratum lucidum of CA3, as if preferentially terminating in the zones occupied by mossy fibers (Fig. 3–21).

The dentate gyrus receives a minor, diffusely distributed dopaminergic projection that arises mainly from cells located in the ventral tegmental area. The dopaminergic fibers terminate mainly in the polymorphic layer.

The serotonergic projection that originates from median and dorsal divisions of the raphe nuclei also terminates most heavily in the polymorphic layer in an immediately subgranular portion of the layer (Conrad et al., 1974; Moore and Halaris, 1975; Köhler and Steinbusch, 1982; Vertes et al., 1999). A number of GABAergic interneurons appear to be

**Figure 3–21.** Line drawing of horizontal sections through the rat hippocampal formation shows the distribution of A. noreadrenergic, B. serotonergic, and C. dopaminergic fibers. (Source: Adapted from Swanson et al., 1987.)

preferentially innervated by the serotonergic fibers. The targets are often the pyramidal basket cells. Fusiform neurons in the region, particularly those that stain for the calcium-binding protein calbindin, are also heavily innervated. As with the cholinergic projection from the septum, many of the cells in the raphe nuclei that project to the hippocampal formation appear to be nonserotonergic, but their transmitter is not known.

### Intrinsic Connections

#### **Basket Cell and Axo-axonic Cell Innervation**

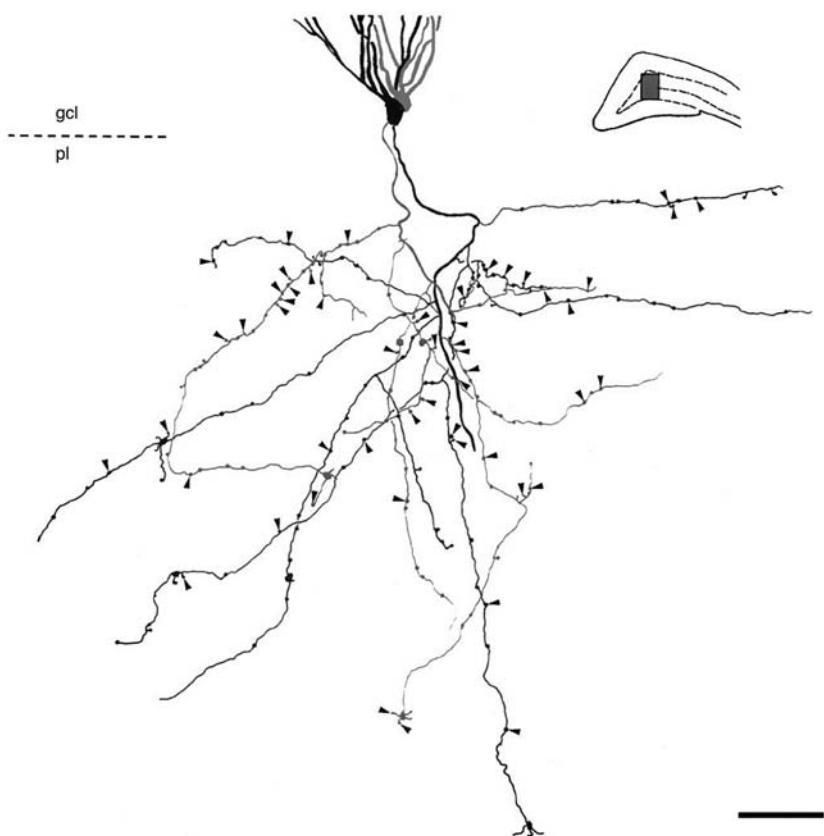

##### **of the Granule Cell Layer**

As already noted, a variety of basket cells are located just below the granule cell layer and appear to contribute to a extremely dense terminal plexus that is confined to the granule cell layer (Struble et al., 1978; Sik et al., 1997). The terminals in this basket plexus are GABAergic and form symmetrical, inhibitory contacts located primarily on the cell bodies and proximal dendritic shafts of apical dendrites of the granule cells. GABAergic neurons in the polymorphic layer are themselves innervated by other GABAergic terminals, some of which arise from extrinsic sources, such as the GABAergic septal input. This polysynaptic cascade of inhibitory interconnections indicates that the hippocampal circuitry provides intricate inhibitory and disinhibitory control of cell excitability, an issue discussed in Chapters 5 and 6.

Given the small number of basket cells relative to granule cells, the question arises as to how widespread the influence of a single basket cell is. Analysis of Golgi-stained axonal plexuses from single basket cells indicates that they extend for distances of more than 900  $\mu\text{m}$  in the transverse axis and about 1.5 mm in the septotemporal axis. This widely distributed axonal plexus would allow a single basket cell to influence as many as 10,000 granule cells (about 1%). The other inhibitory input to granule cells originates with the chandelier (axo-axonic) cells located in the molecular layer. These cells form symmetrical contacts exclusively with the axon's initial segment of granule cells.

#### **Granule Cell Projection to the Polymorphic Layer**

The granule cells give rise to distinctive unmyelinated axons that Ramon y Cajal called mossy fibers. The mossy fibers have unusually large boutons that form en passant synapses with the CA3 pyramidal cells; we describe this projection in more detail shortly. What is not generally appreciated is that the mossy fiber axons form a distinctive set of collaterals that also innervate cells in the polymorphic layer of the dentate gyrus (Fig. 3–22). Each principal mossy fiber (which is on the order of 0.2–0.5  $\mu\text{m}$  in diameter) gives rise to about seven thinner collaterals in the polymorphic layer before entering the CA3 field of the hippocampus. As much as 2300  $\mu\text{m}$  of the collateral axonal plexus is generated by a single mossy fiber in the polymorphic layer (Claiborne et al., 1986). In the polymorphic layer, the mossy fiber collaterals branch extensively, and

**Figure 3–22.** Granule cell projections to the polymorphic cell layer. Axon arbors of two adjacent granule cells (gray and black) and their mGluR1a immunoreactive targets reconstructed from three neighboring 60  $\mu\text{m}$  thick sections. Of the 175 small terminals and filopodiae (arrowheads) 52 innervated mGluR1a immunoreactive targets, whereas large mossy terminals contacted none. gcl, granule cell layer; pl, polymorphic layer. Bar = 50  $\mu\text{m}$ . (Source: Adapted from Acsady et al., 1998.)

the daughter branches bear two types of synaptic varicosity. Numerous small (approximately 2  $\mu\text{m}$ ) spherical synaptic varicosities are distributed unevenly along these collaterals. There are about 160 to 200 of these varicosities distributed throughout the axonal collateral plexus of a single granule cell, and they form contacts on dendrites located in the polymorphic layer. At the end of each of the collateral branches there are also larger (3–5  $\mu\text{m}$  diameter), irregularly shaped varicosities that resemble, although are smaller than, the mossy fiber boutons found in CA3. The mossy fiber terminals in the polymorphic layer establish contacts with the proximal dendrites of the mossy cells (Ribak et al., 1985), the basal dendrites of the pyramidal basket cells, and other, unidentified cells. Acsady et al. (1998) made the surprising discovery that most of the granule cell collaterals in the polymorphic cell layer terminate on GABAergic interneurons. Because there are 160 to 200 such varicosities (compared with about 20 of the larger thorny expansions), mossy fiber axons synapse on a larger number of interneurons than do mossy cells or CA3 pyramidal cells. Mossy fiber collaterals may enter the granule cell layer, but they virtually never enter the molecular layer. The collaterals that enter the granule cell layer appear to terminate preferentially on the apical dendritic shafts of pyramidal basket cells. This lack of mossy fiber innervation of the molecular layer is of some importance because in the presence of kindling and some pathological conditions, such as epilepsy, mossy fibers can be induced to sprout into the molecular layer.

**Mossy Cell Projection to the Associational/Commissural Zone**  
 The inner third of the molecular layer receives a projection that originates exclusively from neurons in the polymorphic layer (Laurberg and Sorensen, 1981; Buckmaster et al., 1992, 1996; Frotscher, 1992). Because in the rat this projection originates in both the ipsilateral and contralateral sides of the hippocampus, it has been called the associational/commissural projection. This projection was initially thought to arise from both the cells of the polymorphic layer and the CA3 pyramidal cells located within the confines of the dentate gyrus. If this were true, it would mean that at least one of the intrinsic hippocampal connections would be bidirectional. It is now clear, however, that the associational/commissural projection arises exclusively from cells in the polymorphic layer, and CA3 cells do not project to the molecular layer. Although this statement is generally true, it appears that at least some CA3 neurons in the most temporal extreme of the hippocampal formation might send collaterals into the molecular layer of the dentate gyrus. Aside from the existence of this projection, almost nothing is known concerning its magnitude. Nor is it known why this projection is observed only in the temporal portion of the hippocampal formation. Thus, the principle of unidirectionality, although generally true, may have exceptions to the rule. For all practical purposes, the organization of the commissural projection is similar to that of the ipsilateral associational connection.

Most of the synaptic terminals of the associational/commissural pathway form asymmetrical, presumably excitatory synaptic terminals on the spines of proximal dendrites of granule cells. Many, perhaps all, of the axons contributing to these synaptic terminals originate from the mossy cells of the polymorphic layer, and individual mossy cells contribute a projection to both the ipsilateral associational and commissural projections. The fact that the mossy cells are immunoreactive for glutamate adds credence to the notion that the associational/commissural projection is excitatory.

There are a number of interesting features of this “feedback” projection from the mossy cells to the granule cells. First, the projection from mossy cells located at any particular level of the dentate gyrus is distributed widely along the longitudinal axis, both septally and temporally from the point of origin. Axons from any particular septotemporal point in the dentate gyrus may innervate as much as 75% of the long axis of the dentate gyrus (Amaral and Witter, 1989). Second, the projection to the molecular layer at the septotemporal level of origin is extremely weak but becomes increasingly stronger at levels that are progressively more distant from the cells of origin. Remembering that mossy cells are the recipients of massive innervation from the granule cells at their same level (via the mossy fiber collaterals into the polymorphic layer), it appears that the mossy cells pass on the collective output of granule cells from one septotemporal level to granule cells located at distant levels of the dentate gyrus.

The full impact of this longitudinal organization of the associational projection cannot be fully appreciated without one further piece of information: The associational fibers contact not only the spines of the granule cell dendrites but also the dendritic shafts of the GABAergic basket cells, which in turn innervate the granule cells. Thus, the associational projection may function both as a feedforward excitatory pathway to distant granule cells and as a disynaptic feedforward inhibitory pathway, with the pyramidal basket cell as the intermediary.

#### **GABA/Somatostatin Projection from the Polymorphic Layer to the Outer Molecular Layer**

Although the neuroanatomy of the hippocampal formation has been analyzed for many years, new components of its intrinsic circuitry continue to be discovered. This is often the result of applying new neuroanatomical techniques. One example is the discovery of a second projection from the polymorphic layer to the molecular layer. Antibodies directed against the peptide somatostatin have revealed that neurons scattered throughout the polymorphic layer are immunoreactive for this peptide and account for approximately 16% of the GABAergic cells in the dentate gyrus (Morrison et al., 1982; Bakst et al., 1986; Freund and Buzsaki, 1996; Sik et al., 1997; Boyett and Buckmaster, 2001). As noted earlier, the somatostatin immunoreactive cells may correspond, in part, to the HIPP cells. The somatostatin-positive cells all colocalize with GABA and are the source of the somatostatin immunoreactive

fibers and terminals in the outer two-thirds of the molecular layer. This system of fibers, which forms contacts on the distal dendrites of the granule cells, provides a third means of releasing inhibitory control of granule cell activity (in addition to the basket cell plexus and the axo-axonic terminals provided by the chandelier cells). Because electron microscopic studies have demonstrated that somatostatin cells are contacted by mossy fiber terminals, the projection to the outer molecular layer thus constitutes a local feedback inhibitory circuit.

Interestingly, unlike the mossy cell associational projection, which terminates more heavily at distant levels of the dentate gyrus, the GABA/somatostatin projection terminates most heavily at the level of the cells of origin; moreover, termination rapidly decreases within approximately 1.5 mm septally and temporally to the cells of origin. Thus, the mossy cell projection and the somatostatin/GABA cell projection have terminal fields that are spatially complementary in both radial and horizontal axes; the distribution suggests that the two cell types mediate distal excitation and local inhibition, respectively.

#### Dentate Gyrus Efferent Projection: Mossy Fibers

The dentate gyrus does not project to any brain region other than the CA3 field of the hippocampus. The axons that project to CA3, the mossy fibers, arise exclusively from the granule cells and terminate in a relatively narrow zone mainly located just above the CA3 pyramidal cell layer (Blackstad et al., 1970; Gaarskjaer, 1978b; Swanson et al., 1978; Claiborne et al., 1986). In the proximal portion of CA3, mossy fibers are also located below and within the pyramidal cell layer. The layer of mossy fiber termination located just above the pyramidal cell layer is called the stratum lucidum because the lack of myelin on the mossy fibers gives the layer a relatively clear appearance in fresh tissue (as one might visualize in a hippocampal slice experiment). There is no indication that dentate neurons other than the granule cells project to CA3; in particular, cells in the polymorphic layer do not project to the hippocampus, at least in the rodent. The dentate projection to CA3 stops precisely at the border of CA3 with CA2, and the lack of granule cell input is one of the main features that distinguishes CA3 from CA2 pyramidal cells.

All dentate granule cells project to CA3, and the axon trajectory is partially correlated with the position of the parent cell body. Before describing features of the mossy fiber projection, it is worth making a few points concerning the organization of the terminal regions in CA3. In the proximal portion of CA3 (close to the dentate gyrus), mossy fibers are distributed below, within, and above the pyramidal cell layer. The fibers located below the layer (i.e., those that are in the area occupied primarily by basal dendrites) are generally called the infrapyramidal bundle. The fibers located in the pyramidal cell layer are called the intrapiramidal bundle, and those located above the pyramidal cell layer (i.e., in the area occupied mainly by proximal apical dendrites) are called the suprapiramidal bundle; the suprapiramidal bundle occupies the stratum lucidum. At mid and distal portions of CA3, the

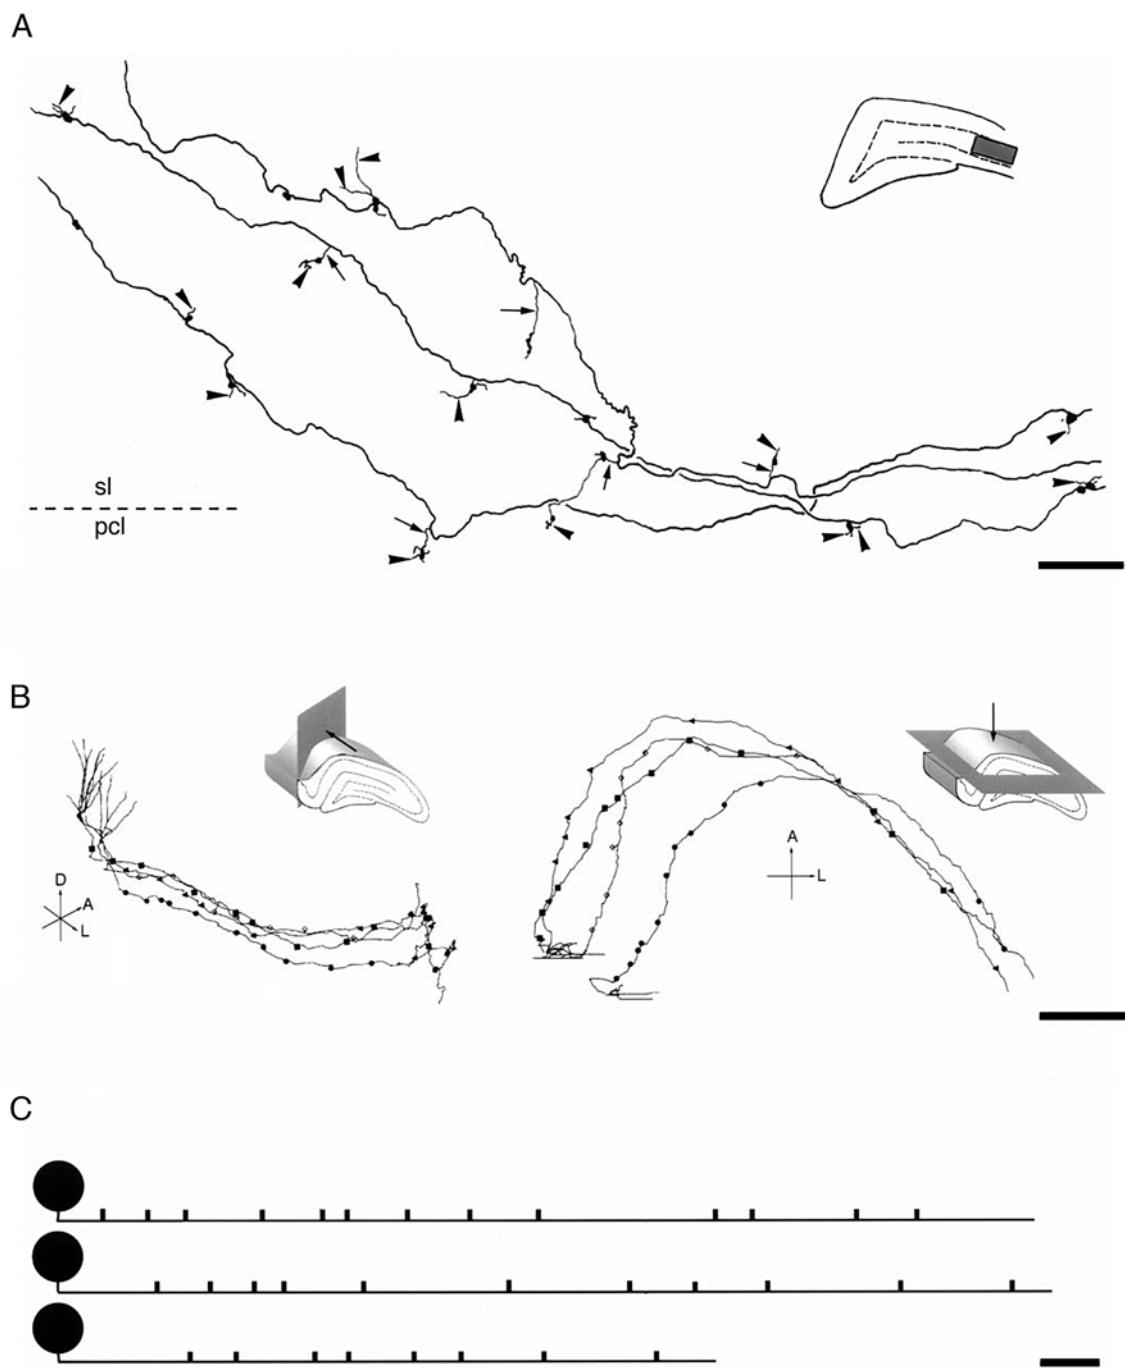

intra- and infrapyramidal bundles are largely eliminated, and virtually all mossy fibers travel in the stratum lucidum. Although our focus is primarily on human, monkey, and rat hippocampus in this chapter, it is worth noting in passing that variations in the relative size of the infrapyramidal mossy fibers have been noted across different strains of mice, including mouse strains used widely in transgenic experiments; this variation sometimes correlates with different behavioral profiles (Lipp et al., 1987; Hausheer-Zarmakupi et al., 1996).

Granule cells at all transverse positions in the granule cell layer generate mossy fibers that extend for the full proximo-distal distance of CA3 (Fig. 3–23). Cells located in the infrapyramidal blade of the granule cell layer have axons that tend to enter CA3 in the infrapyramidal bundle but ultimately cross the pyramidal cell layer to enter the deep portion of the stratum lucidum. The axons of granule cells located in the crest of the dentate gyrus tend to enter CA3 in the intrapiramidal bundle and also ultimately ascend into the stratum lucidum. Cells located in the suprapiramidal blade of the dentate gyrus give rise to axons that enter CA3 in the stratum lucidum and continue within the most superficial portion of the stratum lucidum (Claiborne et al., 1986).

The mossy fibers give rise to unique, complex en passant presynaptic terminals called mossy fiber expansions (Amaral and Dent, 1981). Part of the uniqueness of these terminals is their size; they can be as large as 8  $\mu\text{m}$  in diameter but more typically range from 3 to 5  $\mu\text{m}$  in greatest dimension. Their large size has attracted the attention of physiologists interested in using them for patch-clamp studies of transmitter release (Henze et al., 2000). The mossy fiber expansions form highly irregular, complex, interdigitated attachments with the intricately branched spines called thorny excrescences that are located on the proximal dendrites of the CA3 pyramidal cells. The thorny excrescences are so distinctive they clearly mark the location of mossy fiber synaptic termination. In the proximal portion of CA3, for example, thorny excrescences are located on both the basal and apical proximal dendrites of pyramidal cells, which are therefore in contact with both the infra- and suprapiramidal mossy fiber bundles. In the mid and distal portions of CA3, however, thorny excrescences are almost entirely restricted to the apical dendritic processes that traverse the stratum lucidum (Fig. 3–24). The CA2 pyramidal cells, which do not receive any mossy fiber input, are devoid of thorny excrescences (Fig. 3–25).

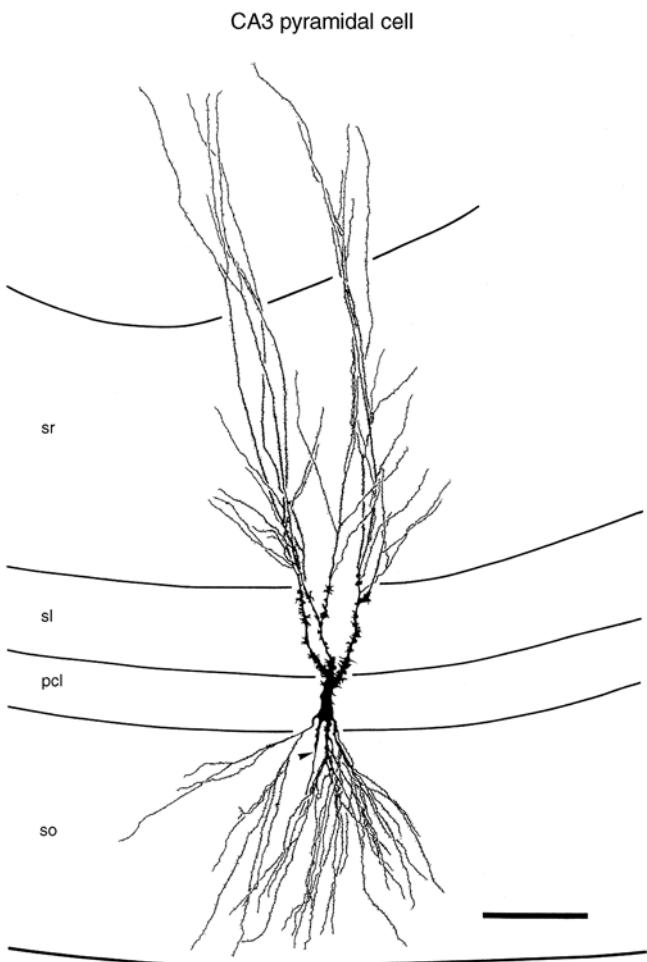

Another distinctive feature of the mossy fiber expansion is the number of active synaptic zones they demonstrate. A single mossy fiber expansion can make as many as 37 synaptic contacts with a single CA3 pyramidal cell dendrite. Three-dimensional analysis of serial sections through these synapses indicates that although a mossy fiber expansion may be in synaptic contact with more than one complex spine originating from the same parent dendrite it does not typically contact spines on two different dendrites. Thus, one mossy fiber expansion does not typically contact two pyramidal cells.

The large mossy fiber expansions occur approximately every 135  $\mu\text{m}$  along the parent axon (Fig. 3–23), and each mossy fiber axon forms about 15 of these complex boutons.

**Figure 3-23.** Topography of the mossy fibers in the CA3 region. *A*, Camera lucida drawing of mossy fibers of three adjacent granule cells (truncated). Note the numerous filopodial extensions of the large mossy terminals in *A* (arrowheads) and thin stalks of large mossy terminals (arrows). Boxed area in the inset in *A* shows the position of the fibers in CA3. *B*, Neurolucida reconstruction of the same three axons shown in *A* and an additional mossy fiber of a

fourth granule cell located posteriorly. The original coronal images are rotated to emphasize the spatial characteristics of the fibers. *C*, Wire diagram of the three mossy fibers shown in *A*, depicting the distribution of mossy terminals. Note that a shorter interbouton distance prevails in the proximal portion of CA3. sl, stratum lucidum; pcl, pyramidal cell layer. Bars: *A*, 50  $\mu$ m; *B*, 400  $\mu$ m; *C*, 200  $\mu$ m. (Source: Adapted from Acsady et al., 1998.)

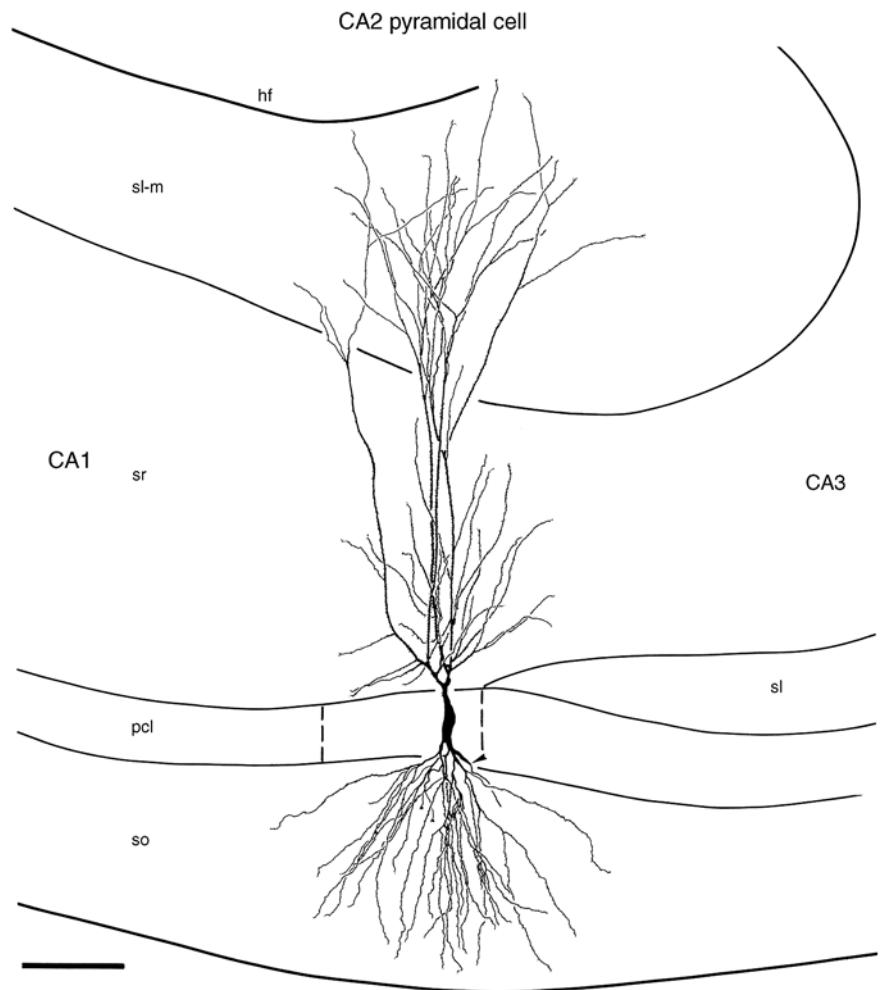

**Figure 3-24.** Camera lucida drawing of a CA3 pyramidal neuron located in the midportion of the field. As this neuron lies outside the zone of the infrapyramidal mossy fiber bundle, most of the thorny excrescences are located on the proximal apical dendrites. The axon of this neuron is indicated by an arrowhead. pcl, pyramidal cell layer; sl, stratum lucidum; so, stratum oriens; sr, stratum radiatum. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Ishizuka et al., 1995.)

Thus, each granule cell communicates with only 15 CA3 pyramidal cells. It is important to point out, however, that these 15 pyramidal cells are distributed throughout the full proximo-distal length (transverse axis) of CA3. Because there are approximately  $2.5 \times 10^5$  CA3 pyramidal cells and approximately  $1.2 \times 10^6$  granule cells, each pyramidal cell is expected to receive input from about 72 granule cells. That is, an individual dentate granule cell has the potential to activate about 15 CA3 pyramidal cells, whereas an individual pyramidal cell receives input from about 72 granule cells. This pattern, not seen elsewhere in the brain, has attracted considerable interest among computational neuroscientists. The fact that each of the mossy fiber expansions has many release sites might ensure highly efficient depolarization of the innervated pyramidal cells. This is, however, currently controversial (see Chapters 5 and 6).

Early Golgi anatomists indicated that the mossy fiber axons were mainly oriented perpendicular to the long axis of the hippocampus. Theodor Blackstad and colleagues confirmed the largely transverse trajectory of the mossy fibers using degeneration track tracing methods, and Andersen and colleagues demonstrated this electrophysiologically. Modern studies, such as those carried out by Claiborne and colleagues, also indicate that mossy fibers do not collateralize once they enter the hippocampus; they stay largely within the same septotemporal level as their cells of origin. There is one peculiarity of the mossy fiber projection, however, that has eluded explanation. Lorente de Nó (1934) and McLardy (McLardy and Kilmer, 1970) indicated that the mossy fibers actually do change their course and take a longitudinal direction but not until they reach the distal portion of CA3. The extent of this distal longitudinal projection was further clarified by Swanson and colleagues using the autoradiographic method of neural tract tracing (Swanson et al., 1978). They showed that granule cells located at septal levels give rise to mossy fibers that travel throughout most of the transverse extent of CA3 at the same septotemporal level. Just at the CA3/CA2 border, however, they abruptly change course and travel toward the temporal pole for nearly 2 mm. The extent of this longitudinal component appears to depend on the septotemporal location of the cells of origin. Granule cells in the mid to temporal portions of the dentate gyrus have mossy fibers that exhibit only a slight temporal inclination at their distal extremity; mossy fibers that originate at the extreme temporal pole of the dentate gyrus barely extend to the CA3/CA2 border and have little or no longitudinal component. Thus, in the septal half of the hippocampus, there appears to be some overlap of mossy fibers originating from different septotemporal levels, but it occurs only at a restricted distal portion of the CA3 field. On the face of it, this indicates that some CA3 pyramidal cells located extremely close to the border with CA2 may be contacted by mossy fiber axons from granule cells spread out over a much broader septotemporal extent of the dentate gyrus. They might therefore form a special class of integrator CA3 cells. Elegant neuroanatomical verification of this has come from the work of Acsady and colleagues (1998), who stained dentate granule cells using *in vivo* intracellular techniques. Not only do mossy fibers travel 2 to 3 mm in the longitudinal direction, they demonstrate typical mossy fiber expansions along this portion of their trajectory; these terminals do, in fact, make contact with thorny excrescences.

Before leaving this description of the mossy fibers, it should be noted that in addition to the mossy fiber expansions there are infrequent thin collaterals that emanate from the parent axon or from the mossy fiber expansions. These collaterals appear to terminate preferentially on cells other than the pyramidal cells, such as the GABAergic pyramidal basket cells in CA3.

There is substantial evidence indicating that the granule cells use glutamate as their primary transmitter, and the asymmetrical contacts made between the mossy fiber expansions and the thorny excrescences tend to confirm this notion.

**Figure 3-25.** Camera lucida drawing of a CA2 pyramidal neuron. Note that although the size and general characteristics of this neuron are similar to those in CA3, there are no thorny excrescences on the proximal apical dendrites. Two basal dendrites cut at the surface of the slice are indicated by asterisks. The axon of this neuron is indicated by an arrowhead. CA1, CA1 field of the hippocampus; CA3, CA3 field of the hippocampus; hf, hippocampal fissure; pcl, pyramidal cell layer; sl, stratum lucidum; sl-m, stratum lacunosum-moleculare; so, stratum oriens; sr, stratum radiatum. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Ishizuka et al., 1995.)

Nonetheless, the mossy fibers are also immunoreactive for several other neuroactive substances. At least some of the mossy fibers demonstrate immunoreactivity for the opioid peptide dynorphin and are also immunoreactive for GABA (Walker et al., 2002). Interestingly, although the granule cells do not normally demonstrate mRNA for the synthetic enzymes GAD65 or GAD67, prolonged stimulation of the perforant path can induce GAD messenger expression in rat granule cells. The possible role of GABA or opioid peptides in the synaptic economy of the mossy fibers is discussed in relation to synaptic plasticity at these synapses in Chapter 10.

### 3.4.2 Hippocampus

#### Cytoarchitectonic Organization

An overview of the major fields of the hippocampus was given earlier in the chapter. We now go into more detail about its laminar organization, which is generally similar for all the fields of the hippocampus. The principal cellular layer is called the pyramidal cell layer. The pyramidal cell layer is tightly packed in CA1 and more loosely packed in CA2 and CA3. The

narrow, relatively cell-free layer located deep to the pyramidal cell layer is called the stratum oriens. This layer contains the basal dendrites of the pyramidal cells and several classes of interneurons. Stratum oriens can be defined as the infrapyramidal region in which some of the CA3 to CA3 associational connections and the CA3 to CA1 Schaffer collateral connections are located. Deep to the stratum oriens is the thin, fiber-containing alveus. In the CA3 field, but not in CA2 or CA1, a narrow acellular zone, the stratum lucidum, is located just above the pyramidal cell layer and is occupied by the mossy fibers. There is a slight thickening of the stratum lucidum at its distal end, where, at least at septal levels of the hippocampus, the mossy fibers bend temporally and travel longitudinally. This zone, called the end bulb, is more prominent in species such as the guinea pig than in the rat; it marks the CA3/CA2 border. The stratum radiatum is located superficial to the stratum lucidum in CA3 and immediately above the pyramidal cell layer in CA2 and CA1. The stratum radiatum can be defined as the suprapyramidal region in which the CA3 to CA3 associational connections and the CA3 to CA1 Schaffer collateral connections are located. The most superficial layer of the hippocampus is called the stratum

lacunosum-moleculare. It is in this layer that fibers from the entorhinal cortex terminate. Afferents from other regions, such as the nucleus reuniens of the midline thalamus, also terminate in the stratum lacunosum-moleculare. Both the stratum radiatum and the stratum lacunosum-moleculare contain a variety of interneurons.

In the following sections, we sometimes deal with the organization of the CA3 and CA2 fields of the hippocampus first and then move on to the CA1 field. For other topics, such as the interneurons of the hippocampus, there is not enough known to warrant discussing CA3, CA2, and CA1 separately. For these topics, we discuss data for the entire hippocampus. Moving on from the dentate gyrus, we begin our discussion with the CA3 field.

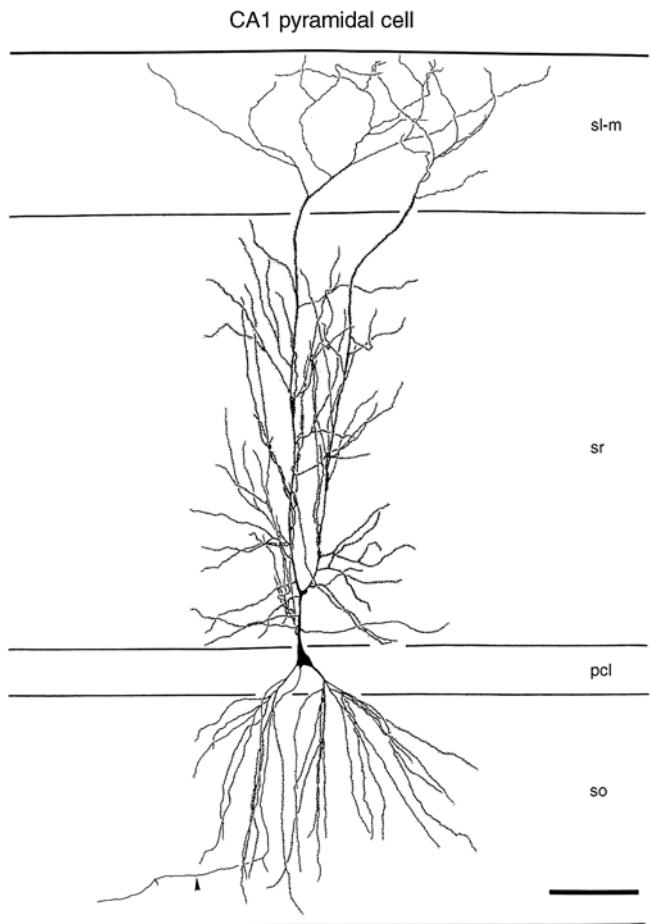

### Pyramidal Cells of CA3 and CA2

The principal neuronal cell type of the hippocampus is the pyramidal cell, which makes up most of the neurons in the pyramidal cell layer. Pyramidal cells have a basal dendritic tree that extends into the stratum oriens and an apical dendritic tree that extends to the hippocampal fissure.

Ishizuka and colleagues (Ishizuka et al., 1995) demonstrated that the dendritic length and organization of CA3 pyramidal cells are quite variable (Figs. 3–24 and 3–27). The smallest cells (with a soma size of about  $300 \mu\text{m}^2$  or  $20 \mu\text{m}$  in diameter) are located in the limbs of the dentate gyrus and have a total dendritic length of 8 to 10 mm. The largest cells (with a soma size of about  $700 \mu\text{m}^2$  or  $30 \mu\text{m}$  in diameter), which are located distally in the field, have total dendritic lengths of 16 to 18 mm. The distribution of the dendritic trees of CA3 pyramidal cells also varies depending on where the cell body is located. Cells located in the limbs of the dentate gyrus, for example, have few or none of their dendrites extending into the stratum lacunosum-moleculare, and thus these cells receive little or no direct input from the entorhinal cortex. The cells, however, receive a larger number of mossy fiber terminals on their apical and basal dendritic trees and are thus under greater influence of the granule cells than distally located CA3 cells, which receive only apical mossy fiber input.

### Pyramidal Cells of CA1

In contrast to the substantial heterogeneity of dendritic organization characteristic of CA3 pyramidal cells, investigators such as Norio Ishizuka and Dennis Turner and colleagues (Pyapali et al., 1998) demonstrated that the CA1 pyramidal cells show remarkable homogeneity of their dendritic trees (Figs. 3–26 and 3–27). As well as being more homogeneous, they are also, on average, smaller than CA3 cells. The total dendritic length averages approximately 13.5 mm, and the average size of CA1 cell somata is about  $193 \mu\text{m}^2$  or  $15 \mu\text{m}$  in diameter. Regardless of where a pyramidal cell is located in CA1, it has about the same total dendritic length and the same dendritic configuration. Some pyramidal cells have one apical

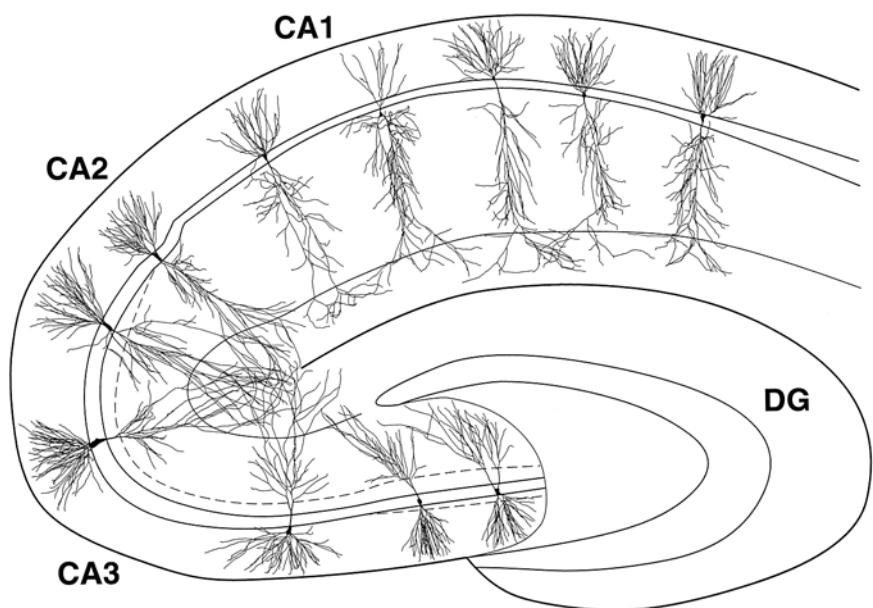

**Figure 3–26.** Camera lucida drawing of a CA1 pyramidal neuron from the midportion of the field. Note that side branches originate from the primary dendrites throughout the full extent of the stratum radiatum. Note also the curved and irregular trajectories of dendritic branches in the stratum lacunosum-moleculare. The axon of this neuron is indicated by an arrowhead. pcl, pyramidal cell layer; sl-m, stratum lacunosum-moleculare; so, stratum oriens; sr, stratum radiatum. Bar =  $100 \mu\text{m}$ . (Source: Adapted from Ishizuka et al., 1995.)

dendrite, and others have two. Cells with two apical dendrites tend to have slightly greater total dendritic length in the apical direction. Neurons with a single apical dendrite, however, tend to have slightly larger basal dendritic trees; thus, overall, the dendritic tree in all CA1 neurons have about the same total length. This anatomical homogeneity, however, cannot reflect functional homogeneity because, as we shall see shortly, there are differences in the entorhinal cortex inputs received at different locations along the transverse axis of CA1.

### Interneurons

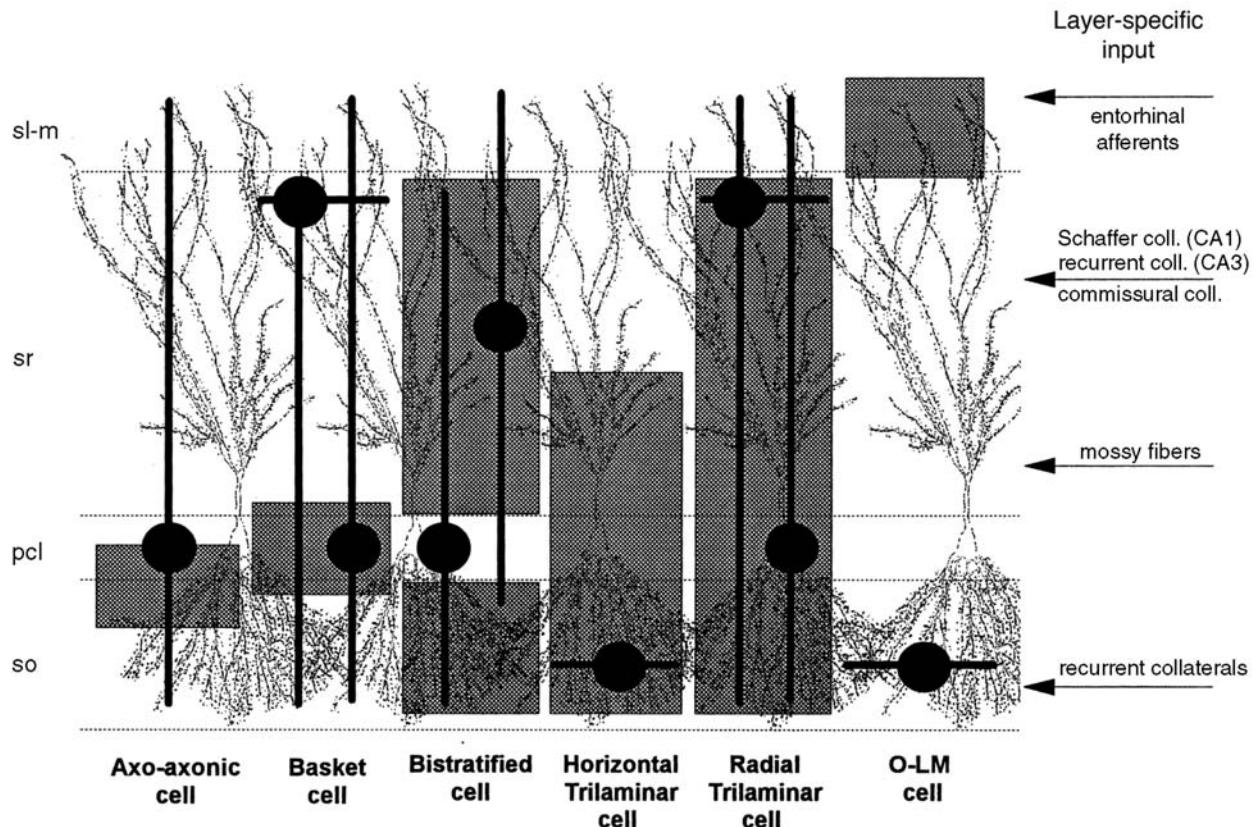

Pyramidal neurons are by far the most numerous neurons in the hippocampus. As in the dentate gyrus, however, there is a fairly heterogeneous group of interneurons that are scattered through all layers (Fig. 3–28) (Freund and Buzsaki, 1996).

**Figure 3-27.** Summary of the organization of hippocampal pyramidal cells produced as a composite of computer-generated line drawings of neurons from CA3, CA2, and CA1. Dashed line in CA3 marks the region occupied by the infrapyramidal and suprapyramidal mossy fibers. *Source:* (Adapted from Ishizuka et al., 1995.)

**Figure 3-28.** Morphological classification of the interneurons in the hippocampus proper. Filled circles indicate the location of the cell bodies, and thick lines indicate the predominant orientation and laminar distribution of the dendritic tree. The pyramidal cells (principal neurons) are illustrated in the background, providing an indication of which domain is innervated by the various interneu-

ron groups. The laminar distribution of the inputs, which often show correspondence with the interneuron type or axon distribution, is also indicated. pcl, pyramidal cell layer; sl-m, stratum lacunosum-moleculare; so, stratum oriens; sr, stratum radiatum. (*Source:* Adapted from Freund and Buzsaki, 1996.)

Most types of interneuron are found in all the hippocampal subfields. The pyramidal basket cell resides in or close to the pyramidal cell layer, and its dendrites extend into the stratum oriens, stratum radiatum, and stratum lacunosum-moleculare. The dendrites are beaded and aspiny, and they receive both asymmetrical and symmetrical synapses. Most of the excitatory inputs are known to arise from hippocampal pyramidal cells. In fact, the dendritic tree of a pyramidal basket cell receives at least 2000 excitatory inputs. Because each pyramidal cell contributes only a single synapse to a particular basket cell, the degree of pyramidal cell convergence on an individual basket cell is enormous. Neurons with basket cell-like axons have a variety of morphologies. There are fusiform-shaped basket cells in the stratum oriens and stellate-shaped basket cells in the stratum radiatum. In all cases, the axons of these cell types innervate the soma and proximal dendrites of the pyramidal cells. The transverse extent of the basket cell axonal plexus (in a 400- $\mu\text{m}$  *in vitro* slice preparation) is between 900 and 1300  $\mu\text{m}$ . Within this plexus, there are as many as 10,000 synaptic varicosities; and because a basket cell makes only 2 to 10 synapses on each pyramidal cell, a typical basket cell innervates as many as 1000-plus pyramidal cells. A single basket cell could thus have substantial inhibitory influence over a large population of pyramidal cells.

A second type of hippocampal interneuron is the chandelier, or axo-axonic, cell. The axo-axonic cells found in the hippocampus are similar to the ones described in the dentate gyrus. Their cell bodies, like those of the basket cells, are located in or adjacent to the pyramidal cell layer, and their dendrites span all the hippocampal strata. The axons of the chandelier cells have a transverse spread of approximately 1 mm. They travel just superficial to the pyramidal cell layer and periodically give rise to collaterals that enter the pyramidal cell layer and terminate on the proximal axons of the pyramidal neurons. Each axo-axonic cell terminates on approximately 1200 pyramidal cell axon initial segments, and each initial segment is innervated by 4 to 10 axo-axonic cells.

The early Golgi studies of Ramon y Cajal and Lorente de Nò made it abundantly clear that there are a variety of non-pyramidal cell types in the stratum oriens, stratum radiatum, and stratum lacunosum-moleculare of the hippocampus. Ribak and colleagues (1978) were the first to discover that most of these neurons are immunoreactive for GABAergic markers, and most are thought to be interneurons. Freund and Buzsaki (1996) described the location, dendritic organization, and axonal distribution of these cells based on a classification system that is dependent on the region of innervation. One class of cells (Lacaille et al., 1987) has been called the O-LM cell (*oriens lacunosum-moleculare*(associated cell) and has as its defining feature a dense axonal arbor that is confined to the stratum lacunosum-moleculare (also known as cells terminating in conjunction with entorhinal afferents). The location of the cell body of this class of interneuron varies depending on which hippocampal field it inhabits. The principle seems to be that the cell body and dendritic tree are

located in the zones occupied by recurrent pyramidal cell collaterals. In CA3 this includes all strata except the stratum lacunosum-moleculare, but in CA1 it includes only the stratum oriens. The axons of the O-LM cell leave the stratum oriens (or in whichever layer the cell body is located) and rise directly to the stratum lacunosum-moleculare, ramifying there to form a dense plexus. These axons form symmetrical synapses with the distal apical dendrites of pyramidal neurons. Because most of the excitatory input to the O-LM cells appears to arise from recurrent collaterals of the pyramidal cells, this class of interneuron inhibits activity in the distal dendrites of pyramidal cells in a disynaptic, feedback manner.

Another class of hippocampal interneuron, the bistratified cell, also has its cell body located close to the pyramidal cell layer. The dendritic trees of these neurons are multipolar but do not reach the stratum lacunosum-moleculare. The axon of the bistratified cell sends collaterals into the stratum oriens and the deep portion of the stratum radiatum, where a dense terminal plexus is produced. These neurons generate an enormous axonal plexus, on the order of 80 mm in total length and generating up to 16,000 synaptic varicosities. The bistratified cells have axons that terminate on both the dendritic shafts and the dendritic spines of pyramidal cells. Although the inputs to these cells have not been thoroughly investigated, their dendrites reside in the zone of associational connections in CA3 and the Schaffer collateral fibers in CA1. It is likely, therefore, that they are driven in both a feedforward and feedback manner.

There are other interneurons located in the stratum radiatum, and their stellate or multipolar dendritic plexus is confined to the layer. The axons of these cells tend to ramify locally in the stratum radiatum and terminate primarily on the dendrites of pyramidal cells.

A fairly sizable population of interneurons is located in the stratum lacunosum-moleculare or at the border between the stratum lacunosum-moleculare and the stratum radiatum (Lacaille and Schwartzkroin, 1988). These LM neurons (stratum lacunosum-moleculare interneurons) have dendrites that are oriented horizontally (i.e., within the layer) but occasionally have branches that extend into the pyramidal cell layer. The axon also takes a predominantly horizontal orientation and ramifies mainly in the stratum lacunosum-moleculare or the superficial portion of the stratum radiatum. Although the connectivity of this class of neurons is not well worked out, their axons do form symmetrical synapses on the distal dendrites of pyramidal cells.

An additional type of interneuron in the hippocampus is the IS neuron (interneuron-selective). The IS neurons' cell bodies are located in all layers and can be identified by staining with antibodies to the calcium-binding protein calretinin. The IS cells have a number of notable features, including the propensity for their dendrites to form bundles with dendrites of other IS neurons. The major unifying feature, however, is that their axons terminate exclusively on other interneurons. Little is yet known concerning their input/output characteris-

tics. Their dendrites, however, are disposed so they could be innervated by all major afferent and intrinsic connections of the hippocampus, and their axons could potentially innervate all of the interneurons described above.

All of the interneurons we have described are immunopositive for markers of GABA. As in other cortical regions, the interneurons of the hippocampus colocalize a number of other neuroactive substances. Thus, many of these neurons can be visualized with antibodies to peptides such as somatostatin, VIP, cholecystokinin, neuropeptide Y (NPY), and calcium-binding proteins such as parvalbumin, calbindin, and calretinin. It remains something of a mystery what these neuroactive substances are doing in GABAergic neurons, but at the very least they provide useful markers for establishing subcategories of the large population of GABAergic interneurons.

### **Extrinsic Connections**

One of the distinguishing features of the connectivity of the hippocampus is that most of its synaptic input arises from within its own boundaries. CA3 and CA2 are heavily innervated by collaterals of their own axons (i.e., associational connections) and from axons of the contralateral CA3 and CA2 (i.e., commissural connections). CA1, in turn, receives its heaviest input from CA3. A relatively lighter projection arises from the entorhinal cortex and terminates on the most distal dendrites of the pyramidal cells as well as on interneurons with dendrites in the stratum lacunosum-moleculare. There are relatively few other “extrinsic” inputs to the hippocampus, and the ones that do exist generally account for a relatively small number of synapses.

### **Entorhinal Cortex Projection to CA3/CA2**

Although the entorhinal innervation of CA3 is mentioned in most studies of the perforant path projection, the organization of this component of the projection is generally not dealt with in much detail. Indeed, there has been little in-depth research on the entorhinal projections to the hippocampus despite the fact that its prominence suggests that it is extremely important. The perforant path takes its name from the observation that it perforates the subiculum and hippocampal fissure en route to the dentate gyrus, but it is now quite clear that collaterals of fibers that project to the dentate gyrus also project to the hippocampus. In fact, the origin and laminar terminal distribution of the perforant path projection to CA3 are similar to those to the dentate gyrus (Witter, 1993). Entorhinal terminals are distributed throughout the width of the stratum lacunosum-moleculare. As with the projection to the molecular layer of the dentate gyrus, projections from the lateral entorhinal area terminate superficially in the stratum lacunosum-moleculare, and those from the medial entorhinal area terminate in the deep half of the layer. The laminar origin, types, and numbers of synaptic contacts of this projection are similar to those to the dentate gyrus. The entorhinal projections to CA3/CA2

originate from cells in layer II, and collaterals of the same layer II cells reach both the dentate gyrus and CA3/CA2, implying that similar information reaches these structures.

### **Entorhinal Cortex Projection to CA1**

Although the entorhinal cortex also projects to the CA1 field of the hippocampus, the organization of this projection is fundamentally different from the projection to CA3/CA2. First, the cells of origin are in layer III rather than in layer II. Second, the pattern of terminal distribution is organized in a topographical fashion rather than in a laminar fashion (Fig. 3–29). As in CA3/CA2, the entorhinal fibers terminate throughout the full width of the stratum lacunosum-moleculare of CA1. However, fibers originating in the lateral entorhinal area terminate in the distal portion of CA1 (close to the subiculum), whereas fibers originating in the medial entorhinal area terminate in the proximal portion of CA1 (close to CA2). Thus, depending on where a CA1 pyramidal cell is located in the transverse axis of the hippocampus, it receives inputs from a different portion of the entorhinal cortex. We noted earlier that CA1 cells are remarkably homogeneous in their dendritic length; the inputs they receive, however, differ as a function of their location along the proximo-distal axis.

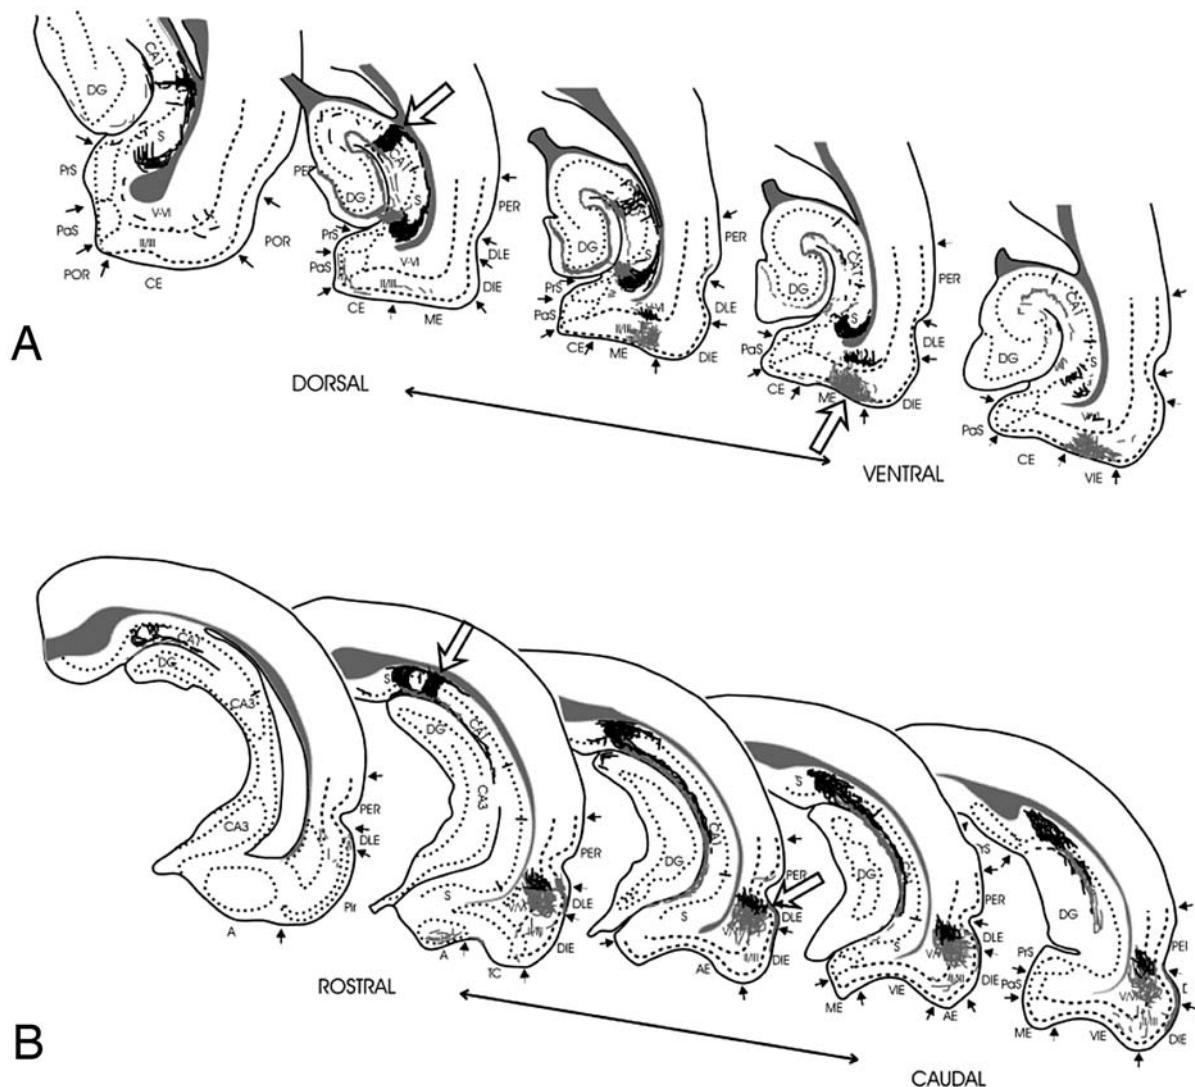

### **Hippocampal Projections to the Entorhinal Cortex**

Early studies using autoradiographic tract-tracing techniques suggested that all fields of the hippocampus send a return projection to the entorhinal cortex, but it is now clear that only cells located in CA1 give rise to this projection (Naber et al., 2001). The projecting cells appear to send their axons to roughly the same region of the entorhinal cortex from which they receive their input (Fig. 3–29). Thus, proximal CA1 cells project to the medial entorhinal cortex, whereas distal CA1 cells project to the lateral entorhinal area. We return to a more detailed description of these projections in Section 3.4.5.

### **Hippocampal Connections with the Neocortex and Amygdaloid Complex**

Although this book focuses on the hippocampal formation, we repeatedly emphasize that no brain structure can be seen in isolation. The hippocampus sends projections to and receives projections from numerous other brain regions, and these interconnections are vital to understanding its function. Having said that, and notwithstanding the extremely important functional relationship between hippocampus and neocortex, it turns out that only selected parts of the hippocampal formation have discrete, monosynaptic connections with the neocortex. The CA3 and CA2 fields of the hippocampus, for example, have no known connections with the neocortex.

Sensitive tracing methods have recently shown that CA3, in particular its temporal parts, receives input from the amygdaloid complex, which was previously thought to send projections only to CA1 and the subiculum (Pikkarainen et al., 1999; Pitkänen et al., 2000). These inputs originate mainly from the

**Figure 3-29.** Reciprocal entorhinal–hippocampal connections. **A.** Distribution of labeled fibers in the hippocampus and entorhinal cortex after combined anterograde tracer injections into the medial portion of the entorhinal cortex and the proximal portion of the CA1 field of the hippocampus. The terminal fibers originating in the entorhinal cortex overlap with the injection site in CA1, and the terminal fibers originating in CA1 overlap with the injection site in the entorhinal cortex. **B.** Distribution of labeled fibers in the hippocampus and entorhinal cortex after combined anterograde tracer

injections into the lateral entorhinal cortex and the distal portion of the CA1 field of the hippocampus. The terminal fibers originating in the entorhinal cortex overlap with the injection site in CA1, and the terminal fibers originating in CA1 overlap with the injection site in the entorhinal cortex. The subdivisions of the entorhinal cortex follow the nomenclature of Insausti et al. (1997). Areas CE and ME constitute the medial entorhinal cortex, whereas DLE, DIE, VIE, and AE constitute the lateral entorhinal cortex. (Source: Adapted from Naber et al., 2001.)

caudomedial portion of the parvicellular division of the basal nucleus and terminate heavily in the stratum oriens and stratum radiatum. The best-documented cortical connection, other than with the entorhinal cortex, which we have defined as part of the hippocampal formation, is with the perirhinal (areas 35 and 36) and postrhinal cortices. Cells in the perirhinal cortex give rise to a relatively selective projection to the most distal CA1 pyramidal cells (i.e., those located at the border with the subiculum). This projection terminates in the

stratum lacunosum-moleculare and overlaps the projection arising from the lateral entorhinal area. The same CA1 cells give rise to a return projection to the perirhinal cortex. CA1 cells located in the septal portion of the hippocampus have also been reported to project to the retrosplenial cortex, and those located at mid-septotemporal levels provide a fairly substantial projection to the medial frontal lobe.

The temporal two-thirds of the distal portion of CA1 is reciprocally connected with the amygdaloid complex.

Projections from the basal nucleus of the amygdala terminate in the stratum oriens and stratum radiatum of the CA1/subiculum border region. In addition, the accessory basal and cortical nuclei projects to the stratum lacunosum-moleculare. CA1 cells in the same region give rise to a return projection to the basal nucleus of the amygdala.

#### **Basal Forebrain Connections**

The septum provides the major subcortical input to CA3. As with the dentate gyrus, the septal projection originates mainly in the medial septal nucleus and the nucleus of the diagonal band of Broca. The projection terminates most heavily in the stratum oriens and to a lesser extent in the stratum radiatum (Fig. 3–20). The CA1 field receives a substantially lighter septal projection than CA3, but the fibers are also most densely distributed in the stratum oriens.

Until the mid-1970s, it was commonly assumed that the hippocampal fields gave rise to both the precommissural and postcommissural projections to the basal forebrain and diencephalon. Indeed, Ramon y Cajal's classic diagram of the hippocampus shows fibers from CA1 coursing toward the fimbria. Swanson and Cowan demonstrated, however, that most of these projections originate from the subiculum (Swanson and Cowan, 1975). It is now quite clear that the only sizable subcortical projection from CA3 is to the lateral septal nucleus. The CA3 projection to the lateral septal nucleus travels via the fimbria and precommissural fornix. The CA3 projection to the septal complex is bilateral; and some CA3 fibers cross in the ventral hippocampal commissure to innervate the homologous region of the contralateral lateral septal nucleus. This pathway is topographically organized such that septal portions of CA3 project dorsally in the lateral septal nucleus, and progressively more temporal portions of CA3 project more ventrally; proximal CA3 cells tend to project medially in the lateral septal nucleus, and distally situated CA3 cells terminate more laterally. Interestingly, virtually all CA3 cells give rise to projections to both CA1 and the lateral septal nucleus.

Essentially all CA1 pyramidal cells also project to the lateral septal nucleus. However, the CA1 projection is strictly ipsilateral, and some of the fibers travel to the septal nuclei via the dorsal fornix rather than through the fimbria.

#### **Hypothalamic Connections**

There has been little work dealing specifically with the extrinsic inputs and outputs of CA2. In general, CA2 appears to have the same connections as CA3. However, the CA2 field receives particularly prominent innervation from the posterior hypothalamus, in particular from the supramammillary area (Fig. 3–20B) and the tuberomammillary nucleus. These projections terminate mainly in and around the pyramidal cell layer and mainly on principal cells (Magloczky et al., 1994). There is no evidence that CA2 returns the projection to the supramammillary region. In fact, none of the hippocampal fields appears to project into the postcommissural fornix.

The supramammillary region projects weakly, if at all, to CA3 and CA1.

#### **Thalamic Connections: Nucleus Reuniens and Other Midline Nuclei**

The thalamic inputs to the hippocampal formation have received relatively little attention. It has been known for some time that the anterior thalamic complex is intimately interconnected with the presubiculum. However, Herkenham and others demonstrated fairly prominent projections from midline ("nonspecific") regions of the thalamus to several fields of the hippocampal formation (Herkenham, 1978; Wouterlood et al., 1990; Dolleman-Van der Weel and Witter, 2000). The nucleus reunions, located on the midline, gives rise to a prominent projection to the stratum lacunosum-moleculare of CA1, where it overlaps with fibers from the entorhinal cortex. The nucleus reunions projection travels to CA1 via the internal capsule and cingulum bundle rather than through the fornix and fimbria. This projection innervates all septotemporal levels of CA1, with a preference for the mid-septotemporal levels. The nucleus reunions fibers terminate with asymmetrical synapses on spines and thin dendritic shafts in the stratum lacunosum-moleculare on both principal neurons and GABAergic interneurons.

#### **Brain Stem Inputs**

The hippocampus, like the dentate gyrus, receives noradrenergic and serotonergic inputs from brain stem nuclei (Fig. 3–21). Noradrenergic fibers and terminals arising from the locus coeruleus are most densely distributed in the stratum lucidum and the most superficial portion of stratum lacunosum-moleculare. A much thinner plexus of axons is distributed throughout the other layers of CA3. Serotonergic fibers are distributed more diffusely and sparsely in CA3 than in the noradrenergic fibers. Despite the rather low number of fibers, the serotonergic innervation of the hippocampus demonstrates several interesting features. First, there are two calibers of axon, thick and thin, arising from the raphe nuclei that innervate the hippocampus. Most of the serotonergic varicosities, which are located on the thin fibers, do not appear to have standard synaptic junctions and may release transmitter into the extracellular space. The varicosities on the thicker fibers, in contrast, form standard asymmetrical synapses that preferentially terminate on GABAergic inhibitory neurons, specifically on the classes of interneuron that project to the dendrites of hippocampal neurons. Thus, even the relatively few serotonergic fibers that innervate the hippocampus may have a profound action by enhancing the GABAergic inhibitory activity of the hippocampal interneurons. There are few, if any, dopaminergic fibers in CA3. In general, CA1 receives much lighter monoaminergic innervation than CA3. The functional implications of monoaminergic inputs to the hippocampus, particularly in relation to long-term potentiation (LTP), is considered in more detail in Chapters 5, 6 and 7.

### Intrinsic Connections: CA3 Associational Connections and Schaffer Collaterals

As mentioned earlier, the major source of input to the hippocampus is the hippocampus itself. The CA3 to CA3 associational connections and the CA3 to CA1 Schaffer collateral connections are unique in many respects. Perhaps the major distinguishing feature of these projections, however, is their extensive spatial distribution. Through these connections a particular pyramidal cell in CA3 can, in theory, interact with other hippocampal neurons distributed throughout much of the ipsilateral and contralateral hippocampus. The massive potential for association in the hippocampus is undoubtedly linked to its function. The hippocampal connections, although widely distributed, are nonetheless systematically organized. These projections have been studied by Ishizuka and colleagues (Ishizuka et al., 1990) and Buzsaki and colleagues (Li et al., 1994).

All CA3 and CA2 pyramidal cells give rise to highly divergent projections to all portions of the hippocampus. CA3 pyramidal cells give rise to highly collateralized axons that distribute fibers both within the ipsilateral hippocampus (to CA3, CA2, and CA1), to the same fields in the contralateral hippocampus (the commissural projections), and subcortically to the lateral septal nucleus. Some CA3 (especially those located proximally) and CA2 cells contribute a small number of collaterals that innervate the polymorphic layer of the dentate gyrus. Although claims of other hippocampal connections are found in the literature, it is now quite clear that CA3 does not project to the subiculum, presubiculum, parasubiculum, or entorhinal cortex.

The CA3 projections to CA3 and CA2 are typically called the associational connections, and the CA3 projections to the CA1 field are typically called the Schaffer collaterals. This terminology, however, may be misleading, as one should remember that these two projections are true collaterals and thus potentially carry the same information. Both the CA3 to CA3 associational projections and the CA3 to CA1 Schaffer collaterals demonstrate a systematic gradient-like projection pattern. Although it is somewhat out of sequence to discuss the CA3 to CA1 projections first, we do so because they have been worked out in somewhat better detail and provide a clear model for understanding CA3 projections. Moreover, the organization of the CA3 to CA1 projection shares many organizational similarities with the CA3 to CA3 projection.

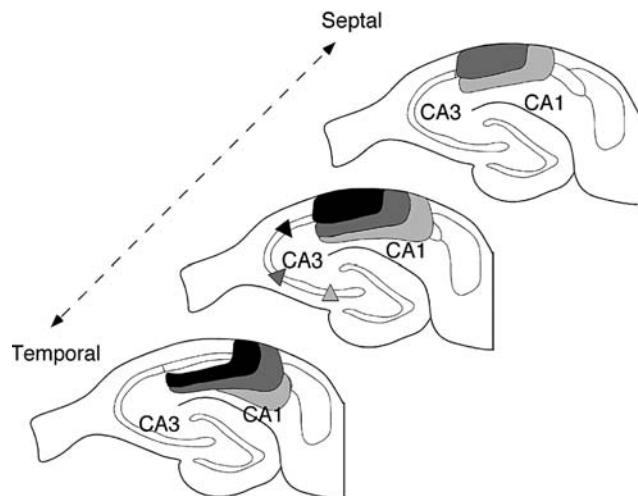

#### CA3 to CA1 Connections: Schaffer Collaterals

All portions of CA3 and CA2 project to CA1. The pattern of terminal distribution, however, depends on the location of the CA3/CA2 cells of origin. The older notion that a typical CA3 pyramidal cell sends a single axon to CA1, traveling linearly through the field with equal contact probability at all regions in CA1 is clearly incorrect. In fact, each CA3 pyramidal cell gives rise to highly collateralized axons that follow both transverse and oblique orientations through CA1 (Ishizuka et al., 1990). Although Schaffer collaterals are typically illustrated

as extending only through the stratum radiatum, it should be emphasized that both the stratum radiatum and stratum oriens of CA1 are heavily innervated by CA3 axons. Thus, the Schaffer collaterals are as highly associated with the apical dendrites of CA1 cells in the stratum radiatum as they are with the basal dendrites in the stratum oriens. Moreover, CA3 cells located at any particular septotemporal level distribute some of their collaterals to much of the full septotemporal extent of CA1. This projection is not chaotic, however, and its topographical organization develops a network in which certain CA3 cells are more likely to contact certain CA1 cells.

The major organizational features of this projection are as follows: CA3 cells located close to the dentate gyrus (proximal CA3), although projecting both septally and temporally, project more heavily to levels of CA1 located septal to their location. CA3 cells located closer to CA1, in contrast, project more heavily to the levels of CA1 located temporally (Fig. 3–30). At or close to the septotemporal level of the cells of origin, those cells located proximally in CA3 give rise to collaterals that tend to terminate superficially in the stratum radiatum. Conversely, cells located more distally in CA3 give rise to projections that terminate deeper in the stratum radiatum and stratum oriens. At or close to the septotemporal level of origin, CA3 pyramidal cells located near the dentate gyrus tend to project somewhat more heavily to distal portions of CA1 (near the subiculum), whereas CA3 projections arising from cells located distally in CA3 terminate more heavily in portions of CA1 located closer to CA2. The truly thick Schaffer collaterals (those that Schaffer originally described) originate only from the proximal CA3 cells. These cells give rise to a thick axon that ascends from the stratum oriens into the most superficial portion of the stratum radiatum and travels to the distal part of CA1, where it contributes many collaterals.

**Figure 3–30.** Organization of the projections from the CA3 field to the CA1 field of the hippocampus—the Schaffer collaterals. The location of the cells of origin is indicated by small triangles in the middle coronal section. Terminals from these cells are indicated by different shades of gray similar to those in the triangles.

The axons of distal CA3 cells tend to be much thinner and to project directly to CA1, either within the stratum oriens or through the deep portion of the stratum radiatum.

The position of the terminal field in CA1 varies in a systematic fashion relative to the distance from the cells of origin. Regardless of the septotemporal or transverse origin of a projection, the highest density of terminal and fiber labeling in CA1 shifts to deeper parts of the stratum radiatum and stratum oriens at levels septal to the cells of origin and shifts away from the stratum oriens and into superficial parts of the stratum radiatum at levels temporal to the cells of origin. Moreover, the highest density of fiber and terminal labeling in CA1 shifts proximally (toward CA3) at levels septal to the origin and distally (toward the subiculum) at levels temporal to the origin.

The entire axonal plexus of several CA3 pyramidal cells have been labeled by intracellular staining techniques devised by Buzsaki and colleagues (Li et al., 1994). These studies provide convincing evidence that the axons of individual CA3 cells can distribute to as much as two-thirds of the septotemporal extent of the ipsilateral and contralateral CA1 fields. The plexus from a single CA3 neuron comprises as much as 150 to 300 mm of total axonal length, on which 30,000 to 60,000 synaptic varicosities are formed. Although single neurons have not been evaluated at all septotemporal levels, it appears that the extent of the CA3 connections is more restricted at temporal levels. Here neurons may give rise to axonal plexuses that innervate only the temporal third of the CA1 field.

A number of pieces of fundamental information concerning the CA3 projection to CA1 are still unknown. For example, it is not clear how many synapses a single CA3 cell makes on a typical CA1 cell. To answer this question using neuroanatomical procedures would be a monumental task. First, a CA3 and CA1 neuron would have to be impaled with dye-bearing pipettes, and the two cells would have to be tested for connectivity by electrophysiological methods. The two cells would then have to be filled and processed histologically for visualization. That is the easy part. The neurons would then have to be sectioned serially for electron microscopy and all putative synapses evaluated. Only in this way would one be able to determine how many synapses are made by all of the collaterals of a particular CA3 neuron on an identified CA1 pyramidal cell. A number of laboratories have estimated the extent of connectivity between CA3 and CA1 cells, and the numbers are always quite low. Work from Harris and colleagues (Sorra and Harris, 1993), which has been replicated by Trommaid et al. (1996), indicates that there are perhaps as few as two to four contacts between a single axon in the stratum radiatum and a particular dendritic tree and certainly no more than 10 synapses between typical CA3 and CA1 neurons. The surprising state of affairs, however, is that we simply do not know with certainty how many contacts a single CA3 neuron makes with a single CA1 cell. These data are critical for interpreting some of the quantal analysis studies described in Chapter 10.

To summarize, the CA3 to CA1 projection is the major input to CA1 pyramidal cells. The projection terminates on the basal dendrites in the stratum oriens and the apical dendrites in the stratum radiatum. Individual CA3 axons distribute extensively and may innervate neurons throughout as much as two-thirds of the entire septotemporal extent of the hippocampus. The probability that a particular CA1 cell is contacted by a particular CA3 cell depends, in part, on the transverse positions of the two cell bodies and their septotemporal distance. At one particular septotemporal level, a distal CA3 cell is more likely to interact with a proximal CA1 cell, whereas a proximal CA3 cell is more likely to interact with a distal CA1 cell. The proximal CA3 cells are the only ones with classic thick Schaffer collaterals, and the thickness of these initial axons is likely to reflect the longer distance the axon must travel to innervate distal CA1 cells.

#### **CA3 to CA3 Associational Connections**

The associational projections from CA3 to CA3 are also organized in a highly systematic fashion. One somewhat idiosyncratic facet of this projection is that cells located proximally in CA3 communicate only with other proximally located CA3 cells. Associational projections arising from mid and distal portions of CA3, however, project throughout much of the transverse extent of CA3 and also project much more extensively along the septotemporal axis. The density of CA3 associational projections also shifts along the septotemporal axis. The radial gradient of termination (superficial to deep in the stratum radiatum and stratum oriens) is similar to that described for the CA3 to CA1 projection. The transverse gradient, however, is the reverse; CA3 projections shift proximally in CA3 at levels located temporal to the cells of origin and shift distally in CA3 at more septal levels.

#### **Commissural Connections of the Hippocampus**

In the rat, the CA3 pyramidal cells give rise to commissural projections to the CA3, CA2, and CA1 fields of the contralateral hippocampal formation (Blackstad, 1956; Fricke and Cowan, 1978). In fact, the same CA3 cells give rise to both the ipsilateral and commissural projections. Although the commissural projections follow roughly the same topographical organization as the ipsilateral projections and generally terminate in homologous regions on both sides, there are minor differences in the distribution of terminals. If a projection is heavier to the stratum oriens on the ipsilateral side, for example, it may be heavier in the stratum radiatum on the contralateral side. The detailed topography of the commissural connections has not been as thoroughly investigated as the ipsilateral connections. As with the commissural projections from the dentate gyrus, CA3 fibers to the contralateral hippocampus form asymmetrical synapses on the spines of pyramidal cells in CA3 and CA1 but also terminate on the smooth dendrites of interneurons. As noted earlier, hippocampal commissural connections are much less abundant in the monkey and are likely to be absent in humans.

### CA1 Lacks Associational Connections

Unlike CA3, pyramidal cells in CA1 give rise to a much more limited associational projection. As the CA1 axons travel in the alveus or the stratum oriens toward the subiculum (see below), occasional collaterals are generated that enter the stratum oriens and the pyramidal cell layer, most likely contacting interneurons such as basket cells in the stratum oriens and in turn inhibiting CA1 pyramidal cells. It is also conceivable that these collaterals might contact the basal dendrites of other CA1 cells. What is clear, however, is that the massive associational network, which is so apparent in CA3, is largely missing in CA1. Similarly, although a weak commissural projection to the contralateral CA1 appears to be present, there is no extensive commissural projection originating in CA1, as is the case in CA3.

### CA1 Projection to the Subiculum

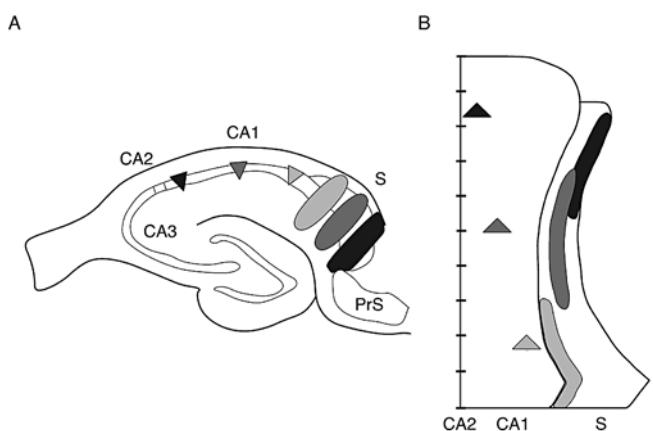

The CA1 field gives rise to two intrahippocampal projections. The first is a topographically organized projection to the adjacent subiculum. The second is to the deep layers of the entorhinal cortex. The latter projection is discussed in Section 3.4.5.

Axons of CA1 pyramidal cells descend into the stratum oriens or the alveus and bend sharply toward the subiculum (Amaral et al., 1991). The fibers reenter the pyramidal cell layer of the subiculum and ramify profusely in the pyramidal cell layer and the deep portion of the molecular layer. Unlike the CA3 to CA1 projection, which distributes throughout CA1 in a gradient fashion, the CA1 projection ends in a topographical fashion in the subiculum. Proximally located CA1 cells project to the distal portion of the subiculum, whereas distally located CA1 cells project just across the border into the proximal portion of the subiculum; the midportion of CA1 projects to the midportion of the subiculum (Fig. 3–31). Nobuaki Tamamaki (Tamamaki et al., 1987) injected horseradish peroxidase into single CA1 pyramidal cells and demonstrated that individual axonal plexuses distribute to about one-third of the transverse extent of the subicular pyramidal cell layer and for approximately one-third of the septotemporal length. It appears, therefore, that the CA1 to subiculum projection segments these structures roughly into thirds. The CA1 to subiculum projection, like the CA3 to CA1 projection, is organized in a divergent fashion, as even a small portion of CA1 projects to about a third of the septotemporal extent of the subiculum.

### 3.4.3 Subiculum

#### Cytoarchitectonic Organization

The cytoarchitectonic characteristics of the rat subiculum have been studied to a limited extent (O'Mara et al., 2001). The CA1/subiculum border is marked by abrupt widening of the pyramidal cell layer and an increased staining intensity with the Timm stain (Fig. 3–11). The stratum radiatum of

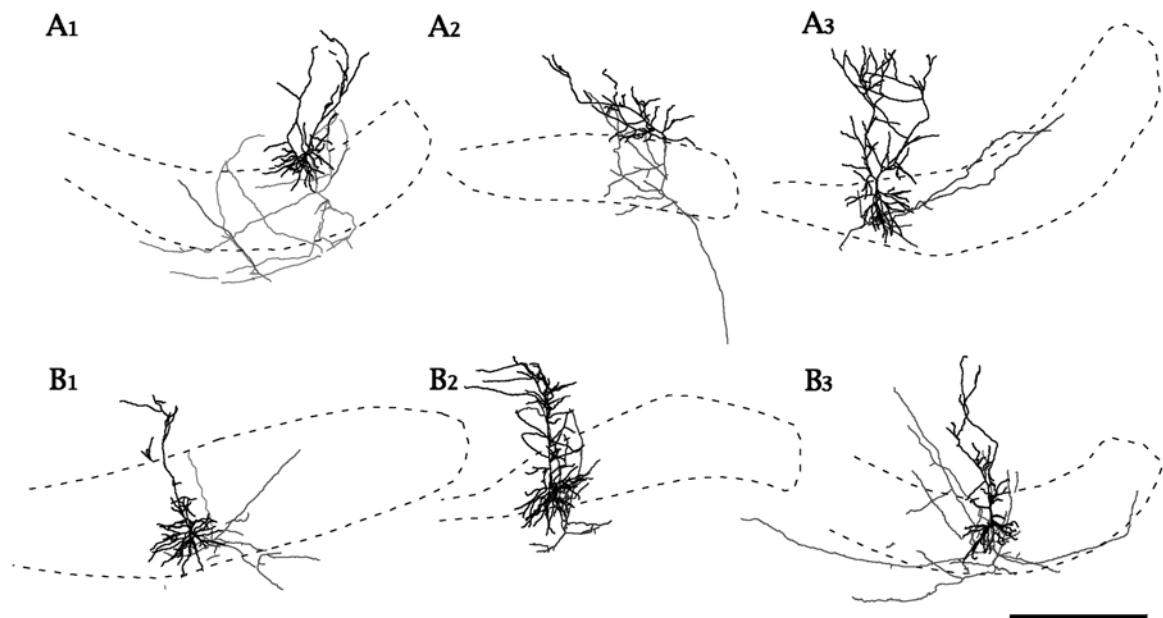

**Figure 3–31.** Organization of the projections from the CA1 field of the hippocampus to the subiculum. *A*, Coronal section shows the cells of origin (triangles) and their respective terminal fields, indicated by similar shades of gray. *B*, Two-dimensional unfolded map of CA1 and the subiculum. The septal portion of these fields is at the top of the figure, and the temporal pole is at the bottom; the border between CA2 and CA1 is on the left.

CA1 (defined as the region that receives CA3 projections) also ends at this border and is replaced with the molecular layer of the subiculum. This layer can be subdivided into a deep portion that is continuous with the stratum radiatum of CA1 and a superficial portion that is continuous with the stratum lacunosum-moleculare of CA1 and the molecular layer of the presubiculum. The deep portion receives fibers from CA1, whereas the superficial portion receives fibers from the entorhinal cortex. The stratum oriens of CA1 is no longer present in the subiculum.

#### Neuron Types

Research on the cytology and connectivity of the subiculum has lagged behind the research on other areas of the hippocampal formation; and until recently (Funahashi and Stewart, 1997a,b; Harris et al., 2001) much of the information on subicular cell types came from the classic Golgi studies of Ramon y Cajal and Lorente de Nò in young mice. The principal cell layer of the subiculum is populated by large pyramidal neurons (Fig. 3–32). This layer starts just underneath the distal end of CA1 and continues in a position deep to layer II of the presubiculum. These cells are relatively uniform in shape and size, and they extend their apical dendrites into the molecular layer and their basal dendrites into deeper portions of the pyramidal cell layer. A subdivision into at least two cell types has been proposed based on their firing characteristics: regular spiking cells and intrinsically bursting cells (Greene and Totterdell, 1997). Although these two cell types do not exhibit distinct morphological characteristics (but see below), they show a differential distribution in the pyramidal cell layer. Bursting cells are more numerous deep in the pyramidal cell layer, whereas regular spiking cells are more common superficially. The two populations can also be distinguished by

**Figure 3-32.** Neurolucida reconstructions of superficial and deep subiculum cells. Somata and dendrites are shown in black. Axons are shown in gray. Local collaterals tend to be longer in the cell layer for superficially located cells; deep cells tend to have axon collaterals that ascend close to the primary dendrite. CA1 is at the left, and the presubiculum is at the right. Bar = 500  $\mu$ m. (Source: Adapted from Harris et al., 2001.)

preferential staining for either NADPH-diaphorase/nitric oxide synthetase (regular spiking neurons) or somatostatin (bursting cells). Both cell types are projection neurons, but they might differ with respect to their connectivity because there is evidence suggesting that only bursting cells project to the entorhinal cortex. Intermingled among the pyramidal cells are many smaller neurons, presumably representing the interneurons of the subiculum. Little is known, however, about whether the interneurons seen in the subiculum are similar to those observed in the hippocampus. Subpopulations of these neurons appear to have characteristics similar to those described for CA1; among these subpopulations are GABAergic cells that stain for the calcium-binding protein parvalbumin.

#### Intrinsic Connections

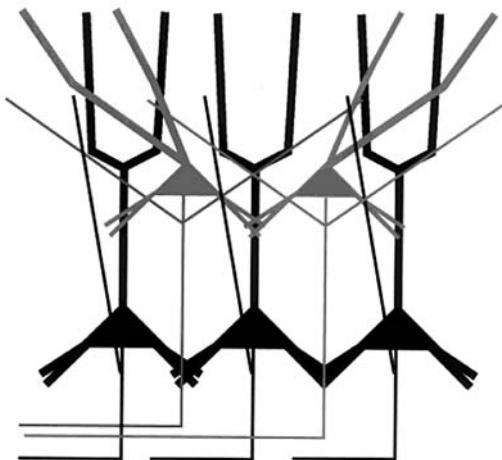

The subiculum gives rise to a longitudinal associational projection that extends from the level of the cells of origin to much of the subiculum lying temporally (or ventrally). Interestingly, this projection seems to be largely unidirectional, as few if any associational projections course septally or dorsally from their point of origin (Harris et al., 2001). The associational fibers terminate diffusely in all layers of the subiculum. Recent studies have consistently found that the rat subiculum neither gives rise to nor receives commissural connections.

Subiculum pyramidal cells provide a strong local input in the pyramidal cell layer and just superficial to it, targeting proximal portions of the apical dendrites. Interestingly, the

density of this local intrinsic connection, as estimated by the number of varicosities on locally distributed axon collaterals, is much higher than in CA1. In addition, the two types of subiculum pyramidal neurons differ with respect to their local connectivity. Intracellular labeling of electrophysiologically identified bursting cells generally show an axonal distribution that remains in the region circumscribed by their apical dendrites (i.e., a columnar organization), whereas the regular spiking cells generally give rise to an axon that shows more widespread distribution along the transverse axis (Fig. 3-33). It is not known whether differences exist with respect to possible septotemporal spread. Although much work remains to be done, available data indicate that the organization of the intrinsic connectivity of the subiculum is different from that of CA3 and CA1. There is both crude columnar and laminar organization, such that the bursting cells form a set of columns and the regular spiking neurons integrate columnar activity along the transverse axis.

#### Extrinsic Connections: Subiculum, a Major Output Structure

The subiculum is a major source of efferent projections from the hippocampal formation. Following the discovery by Swanson and Cowan that the subiculum, rather than the hippocampus, is the origin of the major subcortical connections to the diencephalon and brain stem (via the postcommissural fornix), evidence has mounted that the subiculum is one of the two primary output structures of the hippocampal formation (Swanson and Cowan, 1975; Swanson et al., 1981;

**Figure 3-33.** Model of intrinsic organization of the subiculum. Deep cells have ascending axon collaterals that remain in close proximity to their apical dendrites, giving rise to a columnar pattern for the deep cells. Superficial cells have axon collaterals that can run long distances in the cell layer perhaps serving to integrate activity between columns. (Source: Adapted from Harris et al., 2001.)

Donovan and Wyss, 1983; Groenewegen et al., 1987; Witter and Groenewegen, 1990; Witter et al., 1990; Canteras and Swanson, 1992; Naber and Witter, 1998; Ishizuka, 2001; Kloosterman et al., 2003).

#### **Subiculum Projects to the Presubiculum and Parasubiculum**

The subiculum projects to the presubiculum, but this projection is not of the magnitude of other intrinsic hippocampal formation projections. It is probably better to think of the subiculum projection to the presubiculum as one of a series of pathways that distributes information processed in the dentate gyrus, hippocampus, and subiculum to a series of cortical and subcortical structures. The subiculum can be viewed, therefore, as the last step in the large loop of processing through the hippocampal formation.

Subicular fibers terminate mainly in layer I of the presubiculum. The projection to the dorsal part of the presubiculum, however, terminates deep to the prominent layer II, with weaker projections to layers I and II. The projections from the subiculum to the parasubiculum mainly terminate in layer I and the superficial portion of layer II. These projections are topographically organized. Septal (or dorsal) portions of the subiculum project to dorsal and caudal aspects of both the presubiculum and the parasubiculum, and temporal (or ventral) portions of the subiculum project to ventral and rostral aspects of the pre- and parasubiculum.

#### **Subiculum Reciprocally Connected with the Entorhinal Cortex**

Because the perforant path fibers traverse the subiculum on their way to the dentate gyrus and hippocampus, the question of whether some of these fibers might terminate in the subiculum has long been a matter of controversy. Until recently, the

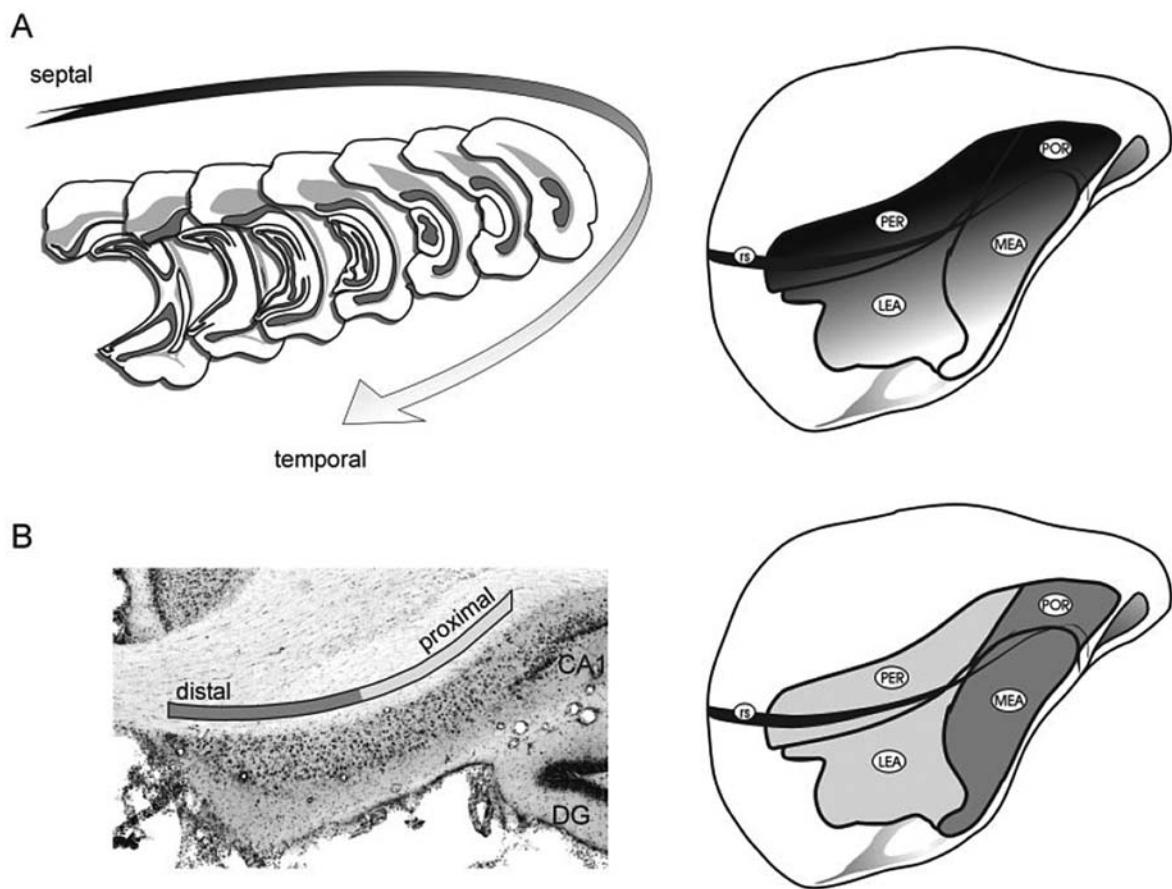

collective hunch was that fibers simply passed through the subiculum and probably did not terminate in it. Earlier anterograde tracer studies indicated that perforant path fibers are directed toward the molecular layer of the subiculum, but proof that these fibers formed a terminal plexus among the subicular pyramidal cells was lacking. Witter and colleagues, however, have provided evidence, at both light and electron microscopic levels, that the subiculum receives a strong projection from the entorhinal cortex. The topography of the projection is similar to that described for CA1. Fibers are directed toward restricted transverse portions of the subiculum and terminate in the outer two-thirds of the molecular layer. The lateral component of the perforant pathway preferentially projects to the proximal part of the subiculum (i.e., the part of the subiculum that borders CA1), and the medial component distributes to more distal portions of the subiculum (i.e., closer to the presubiculum). The projection originates mainly from layer III, although some of the axons of layer II cells that cross the subiculum on their way to the dentate gyrus and CA3 may also give off collaterals that terminate in the subiculum. Entorhinal fibers target dendritic spines of presumed principal neurons with asymmetrical synapses (80%), whereas 5% to 10% of the asymmetrical synapses terminate on dendritic shafts, most likely belonging to interneurons. Subicular interneurons may also receive a minor inhibitory perforant path input in view of the symmetrical synapses onto dendritic shafts.

The subiculum reciprocates the entorhinal input (Fig. 3-34). Projections from the subiculum reach all parts of the entorhinal cortex and terminate in the deep layers; termination is particularly dense in layer V. A minor component of the subicular projection also extends superficial to the lamina dissecans, predominantly to layer III. Subicular fibers generally form asymmetrical synapses with spines and dendrites located in these layers. A small number of these fibers form symmetrical synapses, suggesting small inhibitory input from the subiculum to layer V. Therefore, the overall organization of the subiculo-entorhinal projection mimics that of the CA1-entorhinal projection. The presence of asymmetrical synapses at the termination of this pathway is consistent with its reported excitatory influences on the entorhinal cortex.

#### **Subicular Connections with the Neocortex and Amygdaloid Complex**

The subiculum gives rise to prominent projections to the medial and ventral orbitofrontal cortices and to the prelimbic and infralimbic cortices (Verwer et al., 1997). In the orbitofrontal and prelimbic cortices subicular fibers mainly innervate the deep layers, whereas in the infralimbic cortex the projection extends into the superficial layers. Subicular projections also reach medial portions of the anterior olfactory nucleus.

The subiculum provides a meager projection to the anterior cingulate cortex, whereas the projection to the retrosplenial cortex is substantial (Wyss and Van Groen, 1992). The

**Figure 3-34.** Topographical organization of the subiculum projections to the parahippocampal region (entorhinal, perirhinal, and postrhinal cortices). *A*. Relation between the septotemporal origin in the subiculum with a lateral-to-medial termination in the parahippocampal region. The septal portion of the subiculum projects to the perirhinal and postrhinal cortices and the lateral portion of both the lateral and medial entorhinal cortex. The temporal por-

tion of the subiculum projects to medial portions of the lateral and medial entorhinal cortex. *B*. Relation between the proximo-distal origin in the subiculum with a rostrocaudal termination in the parahippocampal region. The proximal subiculum projects to the perirhinal and lateral entorhinal cortex; the distal subiculum projects to the postrhinal and medial entorhinal cortex. (Source: Adapted from Kloosterman et al., 2003.)

subiculo-retrosplenial projection terminates predominantly in layers II and III. The projections to the retrosplenial cortex originate predominantly from the septal two-thirds of the subiculum. The perirhinal cortex receives a strong input from the subiculum, which terminates in both superficial and deep layers.

In the rat, there is a paucity of detailed information regarding direct cortical inputs to the subiculum. Many of the cortical regions that project fairly heavily to the entorhinal cortex (see below) do not project to the subiculum. No inputs, for example, have been reported from the pre- and infralimbic cortices. Similarly, no portion of the retrosplenial cortex projects to the subiculum. Reports of projections from the cingulate cortex have been somewhat contradictory. In a combined electrophysiological and neuroanatomical study, White et al. (1990) reported a projection from the anterior cingulate cortex to the subiculum. However, this projection has not been observed consistently. The perirhinal cortex projects to the

subiculum, but this projection terminates only in the proximal third of the field (i.e., at the border region with CA1).

The proximal portion of the subiculum also receives an input from the parvicellular portion of the basal nucleus of the amygdaloid complex, the posterior cortical nucleus, and the adjacent amygdalohippocampal area. These amygdaloid inputs terminate mainly at the CA1/subiculum border region, where they preferentially innervate the molecular layer of the subiculum and stratum lacunosum-moleculare of CA1 (Pitkänen et al., 2000).

The temporal one-third of the subiculum gives rise to return projections to the amygdaloid complex. The major component of this projection terminates in the accessory basal nucleus, with more moderate projections reaching several other nuclei but not the lateral nucleus. The ventral subiculum also projects heavily to the bed nucleus of the stria terminalis and moderately to the ventral part of the claustrum or endopiriform nucleus.

### **Basal Forebrain Connections: Septal Nucleus and Nucleus Accumbens**

The most prominent subcortical subiculum projections are those to the septal complex, the adjacent nucleus accumbens, and the mammillary nuclei. The projection to the septal area terminates predominantly in the lateral septal nuclei. Closely associated with the septal projection is the equally robust projection to the nucleus accumbens and adjacent portions of the olfactory tubercle. Subiculum fibers terminate throughout the nucleus accumbens, with the projection to its caudo-medial part being most dense. As with other striatal structures, the subiculum projection to the nucleus accumbens is unidirectional. Whereas the subiculum projections to the lateral septal nucleus are almost entirely confined to the ipsilateral side, those to the nucleus accumbens show a weak contralateral component. The subiculum receives a relatively weak cholinergic projection from the septal complex; fibers originating from the medial septal nucleus and the nucleus of the diagonal band terminate in the pyramidal cell and molecular layers.

### **Hypothalamic Connections: Mammillary Nuclei**

The subiculum provides the major input to the mammillary nuclei. The projection is heavy and is distributed bilaterally in nearly equal density. The subiculum-mammillary fibers originate mainly from the septal two-thirds of the subiculum. Although the temporal one-third of the subiculum also contributes to the mammillary projection, the major hypothalamic target of this portion of the subiculum is the ventromedial nucleus of the hypothalamus. The subiculum projections to the mammillary nuclei reach all portions of the medial nucleus but are topographically organized; the lateral mammillary nucleus is only sparsely innervated by the subiculum. Subiculum fibers also project to the lateral hypothalamic region located adjacent to the lateral mammillary nucleus.

Whereas the subiculum does not receive a return projection from the medial or lateral mammillary nuclei, the supramammillary region projects heavily to the subiculum, particularly to its temporal levels. This portion of the subiculum also receives an input from the premammillary nucleus. It is not clear whether there are any local connections between the medial mammillary nucleus and the supramammillary area or the premammillary nucleus that might complete the subiculohypothalamic loop.

### **Thalamic Connections: Nucleus Reuniens and Other Midline Nuclei**

The thalamic inputs to the subiculum are similar to those to CA1. Thalamic inputs originate mainly in the nucleus reuniens, the paraventricular nucleus, and the parataenial nucleus. The septal and temporal extremes of the subiculum appear to be devoid of input from the nucleus reuniens. The midline thalamic projections terminate mainly in the molecular layer of the subiculum, whereas in CA1 they are coextensive with the projections from the entorhinal cortex.

Interestingly, the projections to the subiculum and to CA1 originate from different but intermingled populations of neurons in the nucleus reuniens. Although earlier studies had indicated that the subiculum was interconnected with the anterior nuclear complex, it is now clear that the anterior nucleus projects almost exclusively to the pre- and para-subiculum.

Some of the thalamic regions that project to the subiculum receive a return projection from the subiculum. Subiculum fibers terminate bilaterally in the nucleus reuniens, the nucleus interanteromedialis, the paraventricular nucleus, and the nucleus gelatinosus. Although subiculum projections to parts of the anterior thalamic complex have been described in the literature, more recent retrograde tracing studies have shown that these projections arise from the presubiculum.

### **Brain Stem Inputs**

Monoaminergic ascending pathways from the noradrenergic locus coeruleus, the dopaminergic ventral tegmental area, and the serotonergic median and dorsal raphe nuclei reach the subiculum, but they do not show preferential innervation of this region. Few details are available concerning the regional localization of these pathways in the subiculum.

### **Topography of Subiculum Efferent Projections**

As with the projections from CA3 to CA1 and from CA1 to the subiculum, the subiculum efferent projections are topographically organized. In large part, the subiculum projections preserve the transverse topography established by the CA1 to subiculum projection. It is clear that different projections originate from at least the proximal and distal halves of the subiculum. The subiculum also demonstrates marked septotemporal topography, such that the projections that arise from the septal or dorsal two-thirds of the subiculum are different from those that arise from the temporal or ventral third (Witter and Amaral, 2004).

Turning first to the septotemporal topography, it appears that the projections to the entorhinal cortex, the lateral septal complex, the nucleus accumbens, and the medial mammillary nucleus originate from the entire septotemporal extent of the subiculum (Witter and Groenewegen, 1990; Ishizuka, 2001). Different septotemporal levels of the subiculum, however, project to different portions of these fields. In the entorhinal cortex, for example, the septal-to-temporal origin in the subiculum is related to a lateral-to-medial termination in the entorhinal cortex. Septal levels of the subiculum project preferentially to lateral and caudal parts of the entorhinal cortex (i.e., the parts that lie adjacent to the rhinal sulcus). Progressively more temporal levels of the subiculum project to more medially located parts of the entorhinal cortex. Although addressed in more detail below, it is important to point out that this topography is completely in register (i.e., they are point-to-point reciprocal) with the projections from the entorhinal cortex to the subiculum. Thus, cells in the subiculum that receive input from a subregion in the entorhi-

nal cortex give rise to a return projection to the same region in the entorhinal cortex. In some respect this breaks the rule that all structures in the hippocampal formation have unidirectional connectivity, but other aspects of the neuroanatomy of these areas completely justify their inclusion in the functionally defined hippocampal formation.

In the nucleus accumbens, the septotemporal axis of origin in the subiculum determines a caudomedial to rostralateral axis of termination. Dorsomedial portions of the lateral septal complex receive inputs from septal levels of the subiculum, and ventral portions of the lateral septal complex are innervated by fibers originating in more temporal parts of the subiculum.

Similar septotemporal topography has also been described for the subicular projections to the presubiculum and the medial mammillary nuclei. The latter projection arises mainly from the septal two-thirds of the subiculum, whereas the ventral one-third gives rise to projections to other hypothalamic regions such as the ventromedial nucleus.

This dichotomy between the septal two-thirds and the temporal one-third of the subiculum is reflected in the organization of other projections. Projections to the amygdala and the bed nucleus of the stria terminalis, for example, originate exclusively from the temporal one-third of the subiculum, whereas projections to the retrosplenial and perirhinal cortices originate predominantly from the septal two-thirds. The subicular projections to the midline thalamus demonstrate even greater septotemporal topography. The most septal part of the subiculum projects preferentially to the interanteromedial nucleus; mid-septotemporal levels of the subiculum preferentially project to the nucleus reunions; and the temporal third of the subiculum projects most heavily to the paraventricular nucleus.

Whereas the septotemporal topography appears to be organized in a gradient, or gradual, fashion, the transverse organization of subicular efferents is remarkably discrete. Along the transverse axis of the subiculum, two essentially nonoverlapping populations of cells can be differentiated that give rise to projections to specific sets of brain structures. This transverse organization of the outputs of the subiculum is consistently observed along its entire septotemporal axis, although it is clearer septally than temporally.

Neurons in the proximal half of the subiculum (closest to CA1) project to the infralimbic and prelimbic cortices, the perirhinal cortex, the nucleus accumbens, the lateral septum, the amygdaloid complex, and the core of the ventromedial nucleus of the hypothalamus. Cells in the distal half of the subiculum project mainly to the retrosplenial cortex and the presubiculum. Cells projecting to the midline thalamic nuclei are mainly located in the midportion of the subiculum.

The subicular projections to the entorhinal cortex and to the medial mammillary nucleus do not follow a strictly transverse organization, as cells in all proximo-distal portions of the subiculum project to these areas. However, the topography of these projections indicates a more subtle transverse organ-

ization. Thus, the proximal portions of the subiculum project to rostral medial mammillary nuclei, and distal portions of the subiculum project more caudally. A similar situation exists for the subicular projections to the entorhinal cortex. The proximal half of the subiculum projects to the lateral entorhinal area, and the distal half of the subiculum projects to the medial entorhinal area.

Because the proximal third of the subiculum gives rise to projections to at least several cortical and subcortical regions, the question arises as to whether it is the same or different populations of subicular cells that innervate each structure. The answer initially appeared to be that projections to the septal complex, entorhinal cortex and mammillary complex arise, at least in part, as collaterals from single subicular neurons; but it now appears that largely independent populations of intermixed neurons in the subiculum project to each of its terminal regions (Naber and Witter, 1998). Given our earlier assertion that the subiculum is the last staging post of hippocampal processing, this state of affairs seems to create the possibility that the outputs destined for different target structures can be carrying distinctly different information.

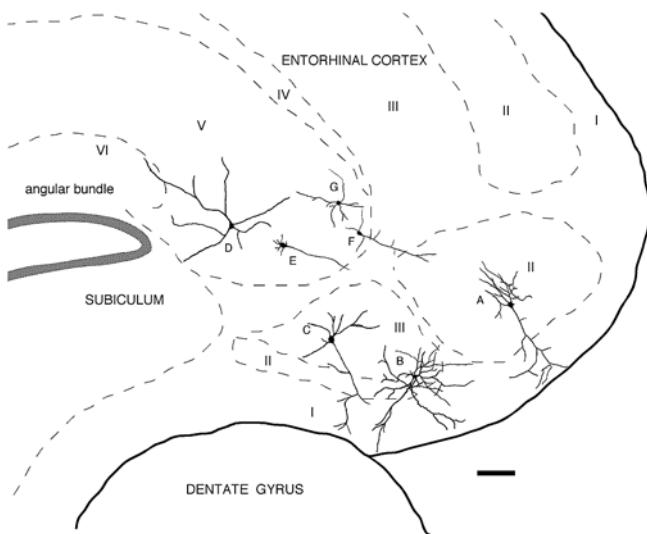

### 3.4.4 Presubiculum and Parasubiculum

#### Cytoarchitectonic Organization and Neuron Types

The presubiculum, Brodmann's area 27, is relatively easily differentiated from the subiculum in standard Nissl-stained material. It has a distinct, densely packed external cell layer that consists mainly of darkly stained, small pyramidal cells. The most superficial cells are the most densely packed (layer II), whereas the deeper cells have a somewhat looser arrangement (layer III). The differentiation between layers II and III is more clear-cut at dorsal levels of the presubiculum.

The dorsal presubiculum (sometimes called the postsubiculum) has clearly distinguishable superficial and deep cell layers. In the ventral portion of the presubiculum, however, the deep layers are difficult to distinguish from the deep layers of the entorhinal cortex or from the principal cell layer of the subiculum. Deep to the lamina dissecans there are one or two layers of large, darkly stained pyramidal cells; and deep to these cells is a rather heterogeneous collection of pyramidal and polymorphic cells. The latter cells have not been studied anatomically in great detail (Fig. 3–35), although electrophysiological discoveries about their receptive field characteristics are important to one prominent theory of hippocampal function (see Chapter 8).

The parasubiculum (Brodmann's area 49) lies adjacent to the presubiculum. Layers II and III of the parasubiculum consist of rather densely packed, lightly stained, large pyramidal cells. This and other characteristics, such as the distinctive staining for heavy metals observable with the Timm's stain method, are the major features that differentiate the parasubiculum from the presubiculum (Fig. 3–11). There is no clear differentiation between layers II and III; and as with the

**Figure 3-35.** Cell types of the presubiculum and parasubiculum. Camera lucida drawings of neurobiotin-filled cells in a horizontal section through the hippocampal formation. A. Pyramidal cell in layer II of the parasubiculum. B. Stellate cell in layer II of the presubiculum. C. Pyramidal cell in layer III of the presubiculum. D. Stellate cell in layer V of the presubiculum. E. Pyramidal cell in layer V of the presubiculum. F. Pyramidal cell in layer V of the parasubiculum. G. Stellate cell in layer V of the parasubiculum. Bar = 100  $\mu$ m. (Source: Adapted from Funahashi and Stewart, 1997a.)

presubiculum, the deep layers are continuous with those of the entorhinal cortex.

#### Intrinsic Connections

There are well developed associational connections in the presubiculum that interconnect all dorsoventral levels in a highly directional manner. Layer II cells in ventral portions of the presubiculum project to more dorsal levels of the presubiculum. Projections in the opposite direction (dorsal to ventral), however, arise preferentially from cells in the deep layers.

The parasubiculum also gives rise to associational connections that distribute both dorsally and ventrally from the cells of origin. The dorsally directed projections extend for short distances and are quite weak. The ventrally directed projections are substantially denser and extend for long distances along the long axis of the parasubiculum. The parasubiculum gives rise to a particularly dense projection to the dorsally located area 29e. This small wedge-shaped region was initially described by Blackstad (1956) and later characterized in more detail by Haug (1976). Although the neuroanatomy of area 29e remains sketchy, it might be part of the parasubiculum.

#### Commissural Connections

The presubiculum gives rise to strong commissural projections to layers I and III of the homotopic part of the contralateral presubiculum (Van Groen and Wyss, 1990).

Commissural projections from the dorsal portion of the presubiculum are relatively sparse. The parasubiculum also gives rise to a commissural projection that terminates most densely in layers I and III.

#### Extrinsic Connections

##### *Presubiculum and Parasubiculum Reciprocally Connected with Anterior Thalamic Nuclei*

The presubiculum and parasubiculum receive a number of subcortical inputs, but the one that is unique to these portions of the hippocampal formation is their interconnection with the anterior thalamic nuclear complex, primarily the anteroventral and anterodorsal nuclei and the closely related laterodorsal nucleus (Kaitz and Robertson, 1981; Robertson and Kaitz, 1981). Although earlier studies had suggested that the presubiculum also receives inputs from the anteromedial nucleus, the principal projections of this nucleus appear to be directed to the anterior parts of the cingulate cortex rather than to the presubiculum or parasubiculum.

There are topographical differences in the thalamic connections of the ventral and dorsal portions of the presubiculum. The ventral portion receives most of its input from the laterodorsal and anteroventral nuclei, whereas the dorsal part receives projections mainly from the laterodorsal and anterodorsal nuclei. The thalamic projections mainly terminate in layers I, III, and IV. The nucleus reuniens also projects to layer I of the presubiculum, but this is a much lighter projection.

Like most other thalamocortical connections, the presubiculum sends a return projection back to the thalamus. The presubiculum projects massively and bilaterally to the anterior nuclear complex. The presubicular projections arise mainly from cells located deep to the lamina dissecans (layer VI). The fact that these deep cells are related to the anterior nuclei of the thalamus lends some credibility to the idea that they are, in fact, deep layers of the pre- and parasubiculum rather than of the entorhinal cortex.

##### *Presubiculum Projection to Layer III of the Entorhinal Cortex*

The most prominent intrahippocampal projection from the presubiculum is to the entorhinal cortex (Shipley, 1975; Caballero-Bleda and Witter, 1993). This projection has a number of interesting features. First, the presubicular projection is directed only to the medial entorhinal area. Second, the projection terminates almost exclusively in layer III and to a much lesser extent in the deep part of layer I. Third, the crossed homotopic projection from the presubiculum to the contralateral entorhinal cortex is every bit as dense as the ipsilateral projection. The projection to the entorhinal cortex is topographically organized. The location of the presubicular terminal field in the entorhinal cortex is determined by both the proximo-distal and dorsoventral location of the presubiculum cells of origin.

The parasubiculum selectively innervates layer II of the entorhinal cortex. In contrast to the presubiculum, the para-

subiculum projects to both the medial and lateral entorhinal areas, although the projection to the lateral entorhinal area is less robust. The parasubiculum projects to the contralateral entorhinal cortex, but these projections are much weaker than the ipsilateral ones. The topographical organization of the parasubiculum projection to the entorhinal cortex is comparable to that of the presubiculo-entorhinal projection.

#### **Presubiculum and Parasubiculum Connected**

##### **with Some Neocortical Regions**

The presubiculum receives relatively few extrahippocampal cortical inputs. The most prominent one originates in the retrosplenial cortex (Van Groen and Wyss, 1990; Wyss and Van Groen, 1992). Cells located in layer V of the retrosplenial cortex give rise to projections that terminate in layers I and III/V of the presubiculum. A second cortical input originates from layer V of the visual area 18b. This projection mainly distributes to the dorsal half of the presubiculum and terminates in layers I and III. Minor cortical inputs originate in the prelimbic cortex and in a dorsal portion of the medial prefrontal cortex.

Extrahippocampal projections from layer V of the presubiculum reach the granular retrosplenial cortex, where they terminate preferentially in layers I and II. These projections are topographically organized, such that the ventral presubiculum projects mainly to the ventral part of the granular retrosplenial cortex, and the dorsal part of the presubiculum projects more dorsally. These projections also exhibit a rostro-caudal organization, such that rostral portions of the presubiculum project to rostral parts of the retrosplenial cortex, and caudal portions of the presubiculum project to caudal parts of the retrosplenial cortex. It has been suggested that the dorsal presubiculum projects to the deep layers of the most caudal portion of the perirhinal cortex, although an alternative interpretation is that this projection is directed to the most caudodorsal portion of the medial entorhinal cortex, which is difficult to differentiate from the caudal perirhinal cortex. The work of Burwell et al. (1998a,b) supports the latter idea.

With the exception of the relatively light projections from the retrosplenial cortex and the occipital visual cortex, there are no other known extrahippocampal cortical inputs to the parasubiculum. The laminar distribution of these inputs is similar to that described for the presubiculum.

#### **Other Intrahippocampal Connections**

The presubiculum projects to layers I and II of the parasubiculum bilaterally. Anterograde tracing studies with the lectin tracer PHA-L have demonstrated that the presubiculum and perhaps to a greater extent the parasubiculum contribute projections, albeit modest ones, to many of the other regions of the hippocampal formation. For example, there is a modest bilateral projection from the presubiculum to the subiculum. There is also a weak projection to all fields of the hippocampus and to the molecular layer of the dentate gyrus. The presubiculum fibers to the dentate molecular layer are arranged in

a radial manner, which is quite distinct from the predominantly transverse orientation of the entorhinal perforant pathway fibers.

A fact that has not been generally appreciated is that the parasubiculum gives rise to a fairly substantial projection to the molecular layer of the dentate gyrus (Kohler, 1985). Like the lighter projection from the presubiculum, this projection occupies the superficial two-thirds of the molecular layer (with a preference for the midportion of the molecular layer), and the fibers have a predominantly radial orientation. Because the parasubiculum receives a projection from the anterior thalamic nuclei, its projection to the molecular layer provides a route by which thalamic input might influence the very early stages of hippocampal information processing. The parasubiculum projects weakly to the stratum lacunosum-moleculare of the hippocampus and to the molecular layer of the subiculum. The parasubiculum also projects bilaterally to layers I and III of the presubiculum.

#### **Basal Forebrain Connections**

The presubiculum and parasubiculum receive heavy cholinergic input. The medial septal nucleus and the vertical limb of the diagonal band of Broca mainly innervate layer II of the presubiculum.

#### **Hypothalamic Connections: Mammillary Nuclei**

The deep layers of the presubiculum project bilaterally to the medial and lateral mammillary nuclei. The projections to the medial mammillary nuclei are topographically organized in a manner similar to those that originate in the subiculum (Thompson and Robertson, 1987; Allen and Hopkins, 1989; Van Groen and Wyss, 1990).

The presubiculum receives input from the area surrounding the mammillary nuclei. Fibers from the supramammillary nucleus terminate preferentially in the deeper cell layers of the presubiculum, although those characterized as being positive for  $\alpha$ -melanocyte-stimulating hormone (an opiate peptide expressed in neurons whose somata are located in the lateral hypothalamic area) terminate in the molecular layer.

#### **Brain Stem Inputs**

The presubiculum receives input from various nuclei in the brain stem. A particularly dense innervation arises from the dorsal and ventral raphe nuclei; at least a component of this projection is serotonergic and innervates layer I. The noradrenergic locus coeruleus innervates the plexiform layer.

#### **3.4.5 Entorhinal Cortex**

The entorhinal cortex plays an extraordinarily important role in the flow of information through the hippocampal formation. It is not only the main entry point for much of the sensory information processed by the hippocampal formation, it provides the main conduit for processed information to be relayed back to the neocortex. As portrayed in this chapter, the entorhinal cortex is the beginning and the end point of an

extensive loop of information processing that takes place in the hippocampal formation. Although neuroanatomical investigation of the entorhinal cortex has historically lagged behind the work conducted in other fields of the hippocampal formation, many new findings have been forthcoming in recent years. This progress has been spurred on, in part, by the appreciation, initially by van Hoesen et al. (1991), that the entorhinal cortex is a site of early, devastating pathology in degenerative diseases such as Alzheimer's disease. It has also been fostered by the reemergence of the notion first put forth by Ramon y Cajal that (to paraphrase) whatever the rest of the hippocampal formation is doing depends on what the entorhinal cortex has done. We begin our description of the entorhinal cortex with a discussion of some lingering controversies concerning its laminar and regional organization.

### Cytoarchitectonic Organization

#### Laminar Organization

There are currently two schemes of cortical lamination applied to the entorhinal cortex. As one might expect, this causes substantial confusion, especially to the neophyte hippocampologist. One nomenclature, which divided the entorhinal cortex into seven layers, was first suggested by Ramón y Cajal and later modified to more closely resemble the standard six-layer scheme applied to the isocortex. According to this scheme, there are four cellular layers (II, III, V, VI) and two acellular or plexiform layers (I, IV). The acellular layer IV is also called lamina dissecans. Ramon y Cajal's scheme with slight modification has been employed by Amaral and colleagues in several primate studies. The other commonly used scheme was proposed by Lorente de Nó, who also differentiated six layers. Five of Lorente de Nó's layers were cellular (II, III, IV, V, VI) with a cell-free lamina dissecans (layer IIIb) between layers III and IV. This scheme was used in most of the older studies of the entorhinal cortex. It is still used in rodent studies and in at least some studies of the human entorhinal cortex, particularly those of Van Hoesen and colleagues.

Primarily to emphasize the lack of an internal granular cell layer in the entorhinal cortex, we have decided to adopt Ramon y Cajal's nomenclature and have labeled the cell-poor layer IV lamina dissecans. Starting from the pial surface, the layers include layer I, the most superficial plexiform or molecular layer, which is cell-poor but rich in transversely oriented fibers; layer II, containing mainly medium-sized to large stellate cells and a population of small pyramidal cells that tend to be grouped in clusters (cell islands) particularly in the lateral entorhinal area; layer III, containing cells of various sizes and shapes but predominantly pyramidal cells; layer IV (or lamina dissecans), a cell-free layer located between layers III and V that is most apparent in those portions of the entorhinal cortex that lie close to the rhinal fissure, particularly at the caudal levels of the entorhinal cortex. In the remainder of the entorhinal cortex, groups of cells invade this layer so it has an incomplete or patchy appearance. Next are layer V, a cellular

layer that can be subdivided into bands, and layer Va, which forms a band of large, darkly stained pyramidal neurons and is most conspicuous in the central parts of the entorhinal cortex. At other levels, the packing density of cells is not high, and the smaller cells of the deeper part of this layer (Vb) intermingle with it. Finally there is layer VI, containing a highly heterogeneous population of cell sizes and shapes. This cell density decreases toward the border with the white matter. The cells of layer VI appear to blend gradually into the subjacent subcortical white matter and the overlying layer V.

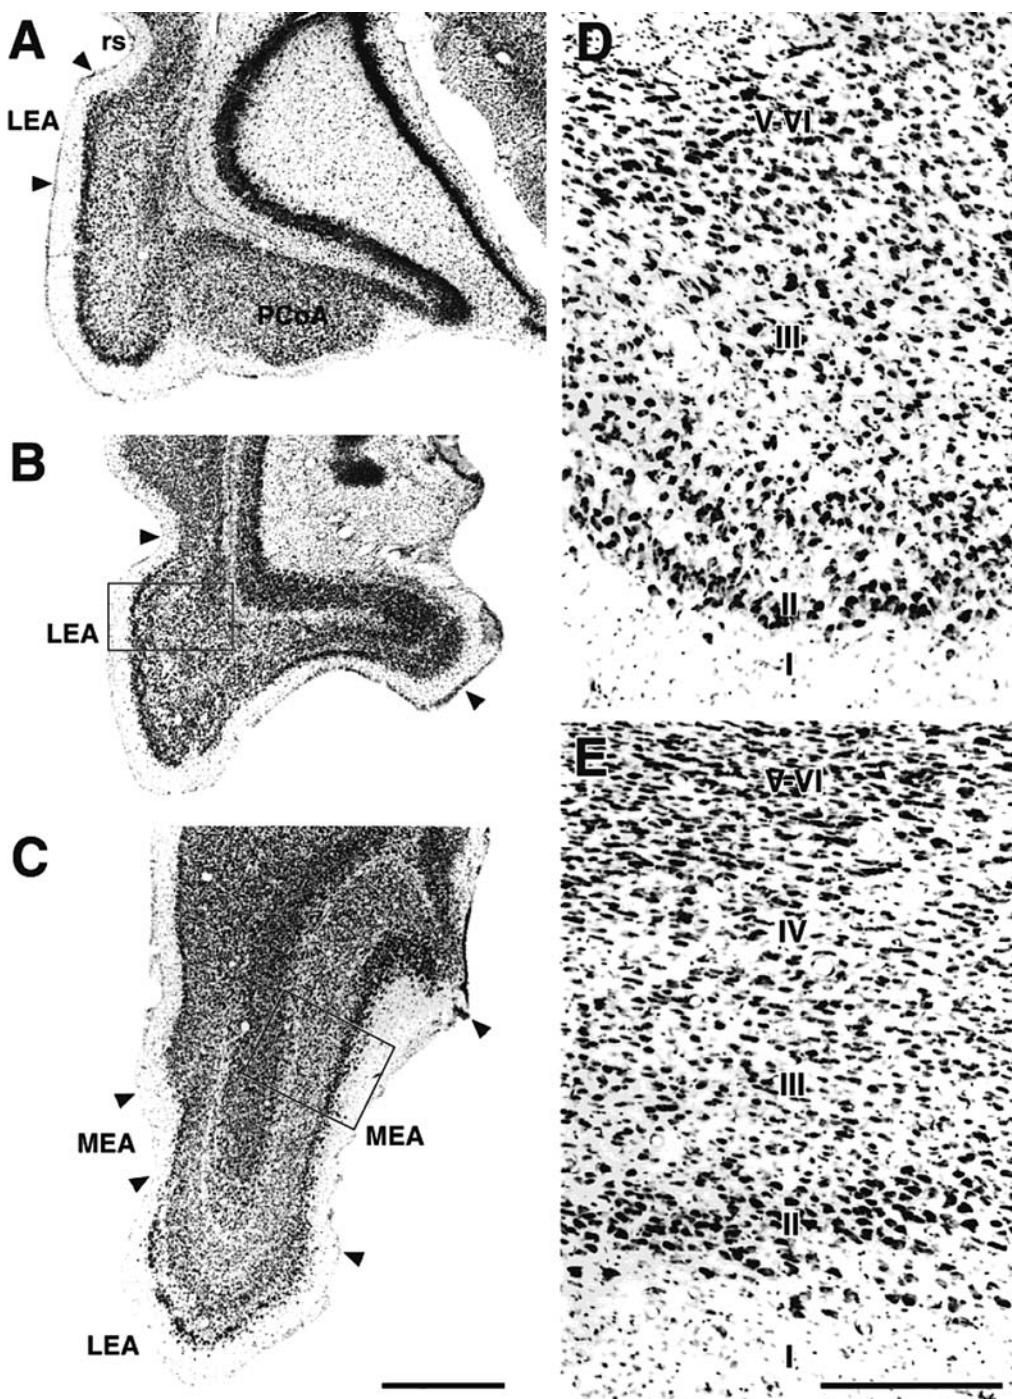

#### Regional Organization

There have been several attempts to subdivide the rat entorhinal cortex, and unfortunately there have been almost an equal number of differing opinions concerning the number and terminology of the subfields. The subject has been discussed and reviewed by Menno Witter, Ricardo Insausti, and their colleagues (Witter, 1993; Insausti et al., 1997; Witter et al., 2000; Burwell and Witter, 2002). Nevertheless, it is now generally accepted that the entorhinal cortex can be subdivided into two general areas: the lateral entorhinal area (LEA) and the medial entorhinal area (MEA) (Fig. 3-36). Layer II is more clearly demarcated in the LEA than in the MEA, and the cells are extremely densely packed and tend to be clustered in islands. The cells in layer II of the MEA are somewhat larger and do not show a distinct clustering into islands; the border between layers II and III is not as sharp as in the LEA. In both entorhinal areas, however, the overall differences in cell size between layers II and III facilitate the delineation of the two layers. The other cell layers, particularly layers IV to VI, can be better differentiated from each other in the MEA than in the LEA, and cells in the MEA generally show a more radial or columnar arrangement. The lamina dissecans of the MEA is sharply delineated but is less clear in the LEA.

It should also be stressed that the terms lateral and medial entorhinal areas do not relate in a simple manner to the cardinal transverse plane of the rat brain (Fig. 3-37). Both the LEA and the MEA have a more or less triangular shape. The LEA occupies the rostral-lateral part of the entorhinal cortex; its base is oriented rostrally and its tip caudolaterally, next to the rhinal fissure. The MEA occupies the remaining triangular area, which has its base caudally and its tip rostromedially such that the tip lies medial to the LEA. A different nomenclature has recently been proposed by Insausti and colleagues to accommodate the oblique orientation of the rat entorhinal cortex and to address the need for subdemarcation of the LEA and MEA (Insausti et al., 1997).

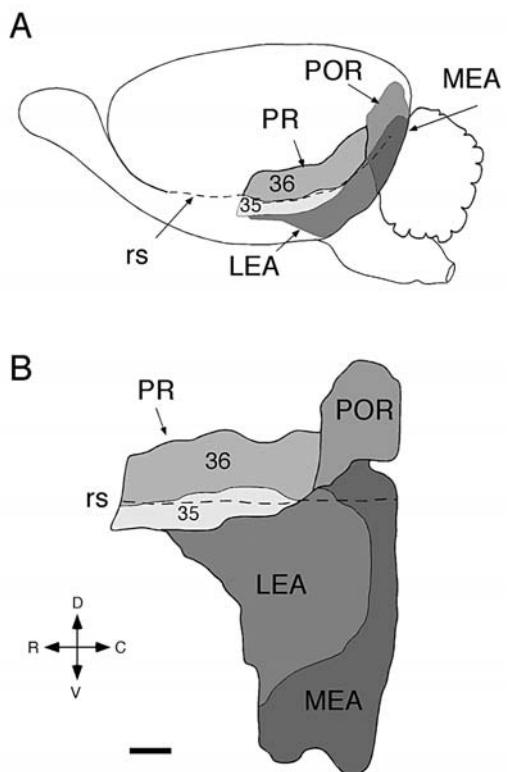

#### Neuron Types

Our current knowledge of the cytology of the entorhinal cortex is based largely on the classic Golgi studies of Ramon y Cajal and Lorente de Nó in young mice. A few intracellular labeling studies have also been conducted in rats, and they have contributed important new information concerning entorhinal cell types (Hamam et al., 2000, 2002). It is proba-

bly safe to predict that a number of new entorhinal cell types will be discovered as these techniques are applied more intensively to analysis of the entorhinal cortex. Other recent studies have focused on determining which particular neuron types project to the dentate gyrus, hippocampus, and subiculum. These studies have employed retrograde tracing techniques either alone or in conjunction with intracellular filling. The following description provides a short overview of the various cell types of each of the entorhinal layers and a brief comment on the major characteristics of their dendritic and axonal organization.

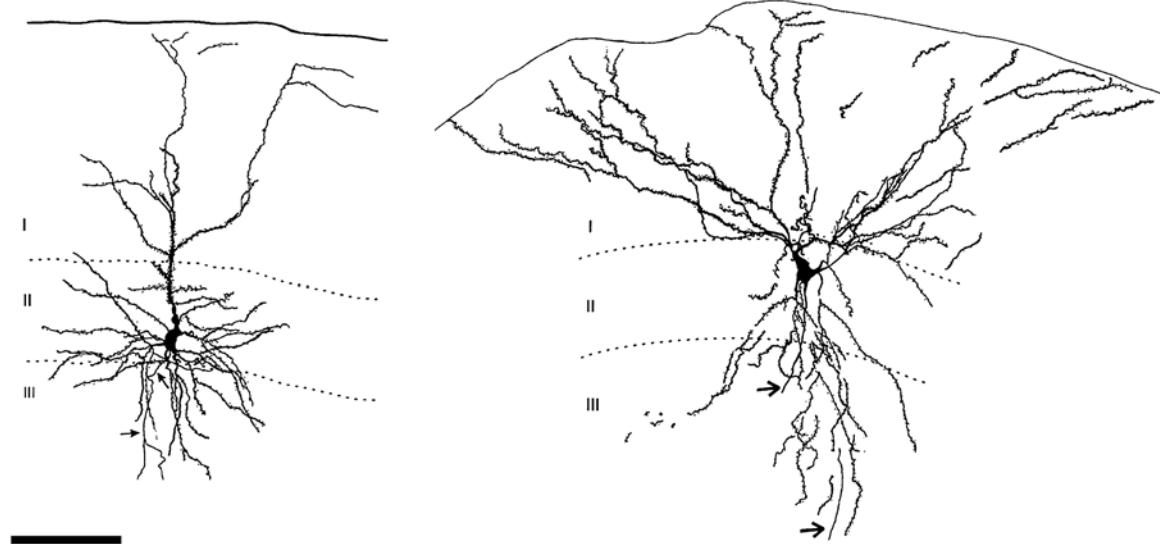

Layer I is populated by a small number of widely dispersed neurons that have been further differentiated using various criteria. There are stellate and horizontal GABAergic neurons that have been shown electrophysiologically to terminate on the dendrites of layer II cells that project to the dentate gyrus.

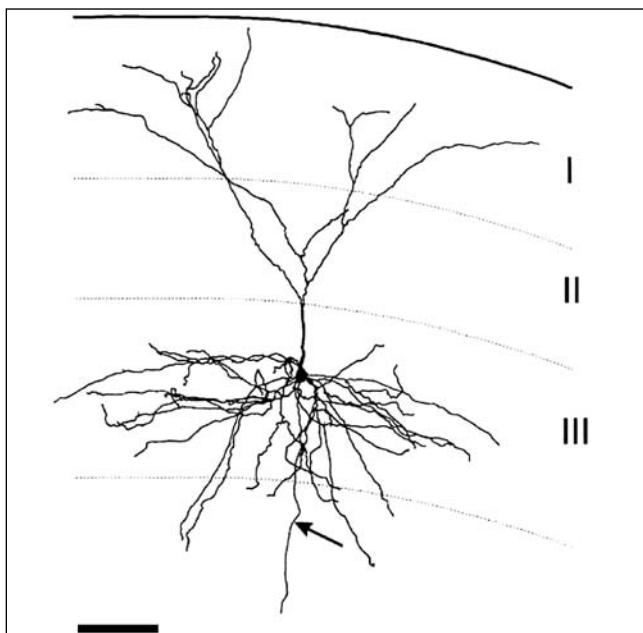

Layer II is populated by stellate and pyramidal cells (Fig. 3-38), both of which project to the dentate gyrus and CA3. These cells give rise to extensive associational projections to layer II of other regions of the entorhinal cortex, and they contribute a few collaterals to deeper layers of the entorhinal cortex. Although there are some exceptions, most layer II cells have a dendritic tree that is confined to superficial layers I and II. A class of axo-axonic cells, similar to the cortical chandelier cell, is also located in layer II; although some of these cells are present in layer III, they have not been observed in the deep layers.

In layer III, the most numerous neurons are the pyramidal cells (Fig. 3-39), which give rise to the perforant and alvear

**Figure 3-38.** Morphological characteristics of entorhinal cortex layer II neurons. *A*. Camera lucida drawing of a typical layer II pyramidal cell. **Figure 3-39.** Morphological characteristics of entorhinal cortex layer III neurons. Camera lucida of a typical layer III pyramidal cell. The axon is indicated by an arrow. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Gloveli et al., 1997.)

path projections to CA1 and the subiculum. Their axons give rise to collaterals that distribute mainly to layers I to III. The apical dendrites of layer III pyramidal cells ascend, give off branches to layer II, and ultimately form a terminal tuft in layer I. Layer III also contains multipolar, stellate, fusiform, horizontal, and bipolar cells, all of which appear to contribute to the perforant pathway. This large, heterogeneous group of cells undoubtedly coincides with what Lorente de Nó described as atypical layer III neurons.

Layer IV, the lamina dissecans, although generally referred to as a cell-free layer, does contain scattered cell bodies described as fusiform or pyramidal cells that have apical dendrites reaching up to layer I and an axon reaching the deep white matter, a characteristic of projection neurons. Some of the cells in the lamina dissecans stain positively with antibodies against GABA, NPY, calretinin, calbindin, or somatostatin.

Layer V contains three main classes of neuron—pyramidal cells, small spherical cells, and fusiform neurons—according to the Golgi-based description of Lorente de Nó. Layer Va is characterized by its large, darkly staining pyramidal cells. These cells have large apical dendrites that ascend toward the superficial portion of layer II and into layer I. The axons of these cells run into the deep white matter and the angular bundle, and additional collaterals innervate the superficial layers of the entorhinal cortex. According to Lorente de Nó, the collaterals of such cells form a column-like plexus situated close to the location of the parent cell body and span the entire thickness of the entorhinal cortex. These collaterals mainly distribute to the deep cell layers (V/VI), although occasional collaterals reach layer II. Layer Va also contains various small neurons that have been characterized as horizontal, stellate, and multipolar cells. Golgi studies indicate that the axonal plexus of the latter group either remains in layer Va or extends to the superficial layers I to III. Angel Alonso and colleagues have used intracellular staining techniques to study the morphology of layer V neurons, particularly in the deeper portion of layer V, or layer Vb (Fig. 3-40). They also found that there are three main types of neuron. Large and small pyramidal cells, neurons with dendrites oriented horizontally and mainly confined to layer V, and an atypical form of multipolar neuron with long wavy dendrites. A surprising aspect of the latter neurons is that some of their dendrites meander from the entorhinal cortex, through the angular bundle, and

**Figure 3-40.** Morphological characteristics of entorhinal cortex layer V neurons. Computer-aided reconstructions of pyramidal, horizontal, and polymorphic cells. Dashed lines represent the borders of the indicated layers. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Hamam et al., 2002.)

into the subiculum. Some of these cells may thus contribute to the projections to the dentate gyrus and the hippocampus. The overall picture emerging from these recent studies is that all three types of layer V neuron should be considered projection neurons in that they send an axon to the white matter. They also may function as local circuit neurons, connecting the deep layers to the superficial layers.

Layer VI contains a wide variety of neuron types. Based on the predominant distribution of their axonal plexus, these cells can be grouped into three categories: cells that mainly influence other cells in layer VI or Vb; cells that by means of their highly collateralized axons can influence a vertical column of cells in layers I to III; and cells whose axons are directed toward the deep white matter and are therefore likely to be projection neurons. Some of these cells contribute to the projections to the dentate gyrus and the hippocampus.

On the basis of their restricted axonal distribution, several of the smaller cell types in the entorhinal cortex have been classified as interneurons. Most of these interneurons are likely GABAergic. GABAergic neurons are found in all layers of the entorhinal cortex, although they are most abundant in the superficial layers. GABAergic interneurons can be subcategorized on the basis of their colocalization with various neuroactive substances (e.g., peptides) or their expression of one or more of the various calcium-binding proteins. The superficial layers contain a large number of cells that are immunoreactive for parvalbumin, whereas the number of calbindin-D28-positive neurons is much lower. Although most of the GABAergic neurons are undoubtedly interneurons, at least some of the GABAergic neurons in layers II and III project to the dentate gyrus.

### **Intrinsic/Associational Connections**

The entorhinal cortex contains a substantial system of associational connections. Intraentorhinal fibers are organized in three rostrocaudally oriented bands, and connections that link different transverse (or mediolateral) regions of the entorhinal cortex are rather restricted (Dolorfo and Amaral, 1998b). Associational connections originate in both superficial and deep layers. Projections originating from layers II and III tend to terminate mainly in the superficial layers, whereas projections originating from the deep layers terminate in both the deep and superficial layers.

The global organization of the associational connections in the entorhinal cortex can be best understood in relation to the topography of the entorhinal projections to other fields of the hippocampal formation (Fig. 3–41). As we describe shortly, different parts of the entorhinal cortex project to different septotemporal levels of the dentate gyrus. The portions of the lateral and medial entorhinal areas that project to the septal half of the dentate gyrus, for example, are located laterally and caudally in the entorhinal cortex, close to the rhinal sulcus. Cells located in this region give rise to associational connections to other cells in the same region but not in any substan-

tial way to the portions of the entorhinal cortex that project to other levels of the dentate gyrus. Thus, the associational connections seem to be organized to integrate all of the information that comes into a particular portion of the entorhinal cortex and are relayed to a particular septotemporal level of the dentate gyrus.

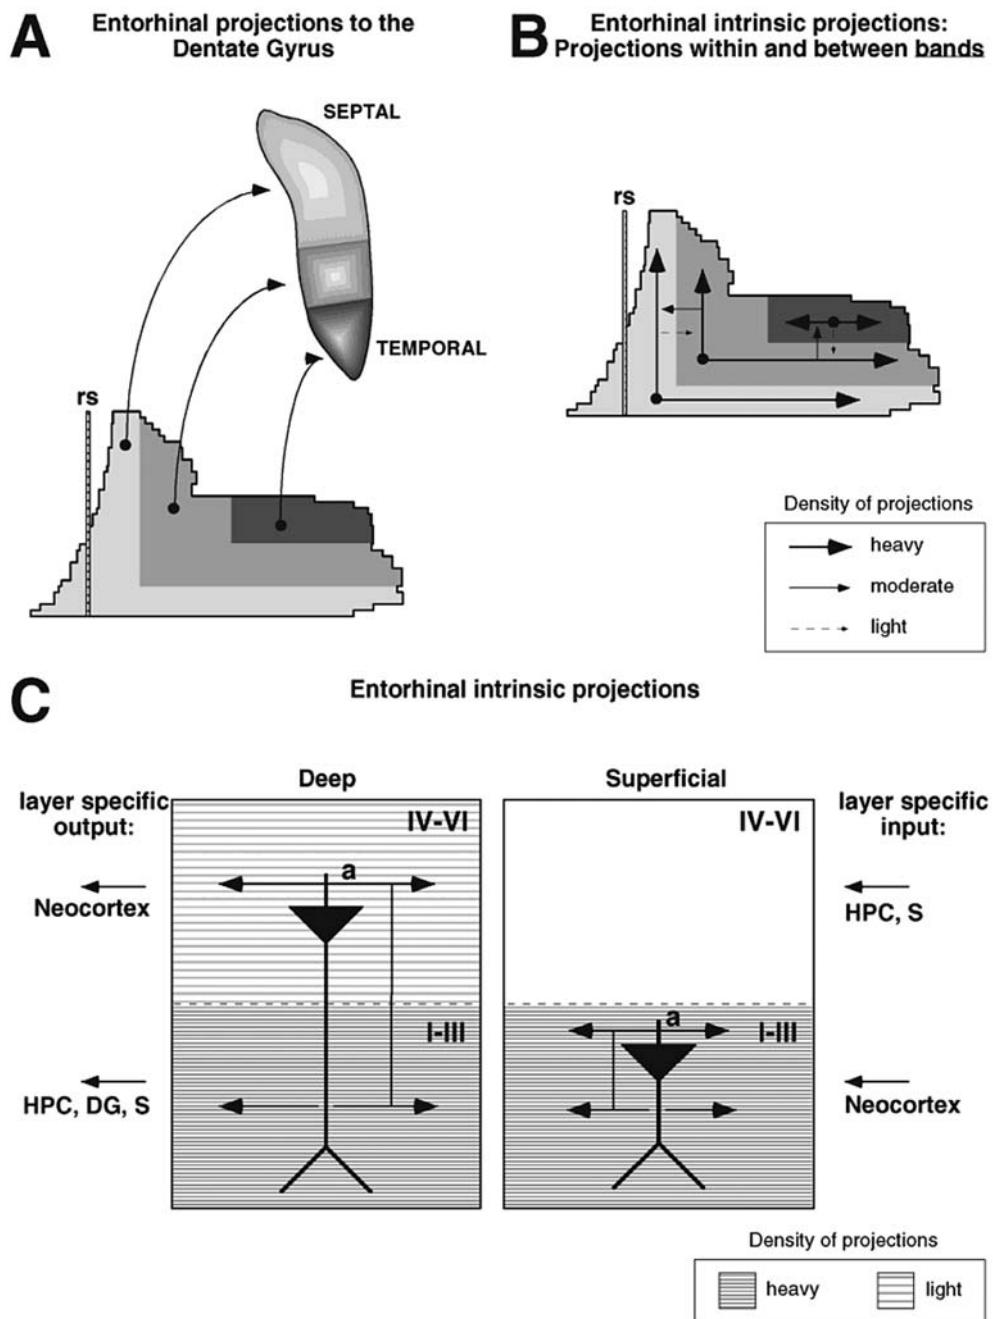

Not much is known about the detailed microcircuitry of the entorhinal associational connections. Presumably, the layer II cells that project to other portions of layer II terminate on the same stellate and pyramidal cells that give rise to the perforant path projection. It is not known, however, if associational connections also terminate on interneurons in layer II. Of even greater functional significance is the issue of whether the deep layer cells project to the cells of layers II and III that give rise to the perforant pathway. This is a critical missing piece of information. Because the deep layer neurons receive feedback projections from CA1 and the subiculum, an associational connection from deep cells to superficial cells would provide the link for completing the loop through the hippocampal formation. Another issue is whether these associational connections are excitatory or inhibitory. If a substantial portion of the deep to superficial pathway originates from GABAergic neurons, or if the pathway is excitatory but terminates preferentially on inhibitory cells located in layer II, the output of the hippocampal formation from CA1 and the subiculum could inhibit layer II or III neurons that project to the dentate gyrus, hippocampus, and subiculum.

### **Commissural Connections**

Relatively strong commissural connections, arising from all portions of the entorhinal cortex, terminate predominantly in layers I and II of the homotopic area of the entorhinal cortex (Goldowitz et al., 1975; Hjorth-Simonsen and Zimmer, 1975; Deller, 1998). The entorhinal cortex also gives rise to a commissural projection to other components of the contralateral hippocampal formation. The largest component of this projection is directed toward the dentate gyrus, but fields CA3 and CA1 of the hippocampus and the subiculum also receive a contralateral input. The crossed entorhinal projection is heaviest to septal portions of the hippocampal subfields and rapidly diminishes in strength at more temporal levels. This crossed projection apparently arises exclusively from layer III cells.

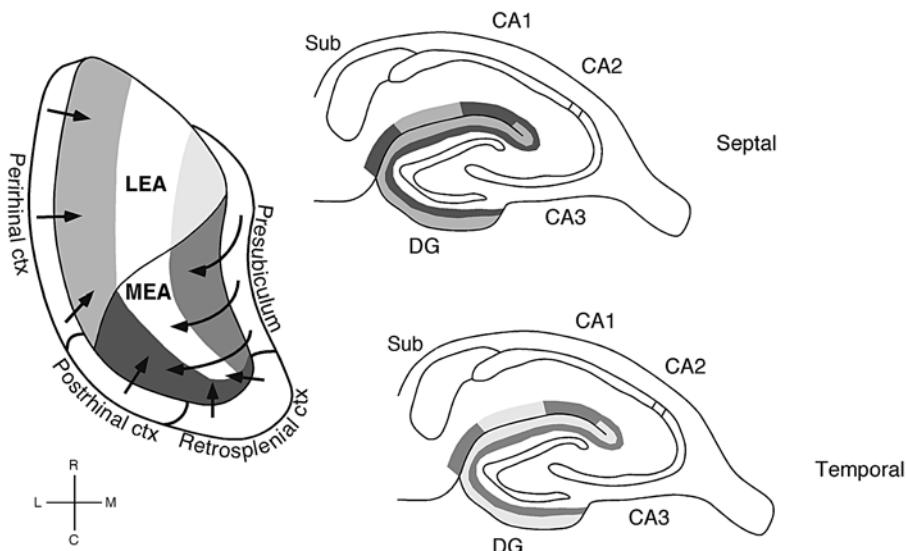

### **Organization of the Perforant and Alvear Pathway Projections**

As a reminder of our earlier description of the perforant path input to the dentate gyrus, hippocampus, and subiculum, both the lateral and medial entorhinal areas project to all three areas. The lateral and medial components of the perforant path terminate along the superficial-to-deep gradient in the molecular layer of the dentate gyrus and the stratum lacunosum-moleculare of CA3 and along the transverse axis of CA1 and the subiculum (Fig. 3–42). Layer II cells give rise to the

**Figure 3–41.** Summary of the intrinsic connections of the entorhinal cortex and the association of the entorhinal cortex with the hippocampal formation and neocortex. *A*, Organization of entorhinal projections to the dentate gyrus. A “band” of layer II cells located in the lateral and caudomedial portion of the entorhinal cortex (light gray) projects to the septal half of the dentate gyrus; a band in the mid-mediolateral entorhinal cortex (medium gray) projects to the third quarter of the dentate gyrus; and a band located in the most rostromedial entorhinal cortex (dark gray) projects to the temporal pole of the dentate gyrus. *B*, Organization of entorhinal intrinsic projections: projections within and between bands. Each of these

projection zones has substantial associational connections (large arrows) that remain largely in the zone of origin. Projections between each band are less prominent (small arrows). *C*, Entorhinal intrinsic projections and entorhinal afferent and efferent projections. Entorhinal associational connections arise from both the deep and superficial layers of the entorhinal cortex (arrows in the boxes) and terminate mainly in the superficial layers. A less prominent associational connection in the deep layers is apparent primarily in lateral portions of the entorhinal cortex. (Source: Adapted from Dolorfo and Amaral, 1998b.)

**Figure 3-42.** Laminar and topographical organization of the entorhinal projection to the dentate gyrus, the hippocampus, and the subiculum. The surface of the entorhinal cortex is represented on the left (the rhinal sulcus is to the left). Layer II entorhinal cortex projections to the dentate gyrus and the CA3 and CA2 fields of the hippocampus terminate in a laminar fashion; the LEA projects superficially in the molecular layer and the stratum lacunosum-moleculare, and the MEA projects deeper. In contrast in CA1 and

the subiculum, layer III entorhinal cortex projections are organized topographically; the LEA projects to the distal CA1 and proximal subiculum (i.e., at the CA1/subiculum border), and the MEA projects to the proximal CA1 and distal subiculum. Laterally situated portions of the entorhinal cortex project to septal levels of the hippocampal formation, whereas progressively more medial portions of the entorhinal cortex project to more temporal levels of the hippocampal formation.

projection to the dentate gyrus and CA3, and layer III cells project to CA1 and the subiculum. Although current usage applies the term perforant path to all entorhino-hippocampal projections, entorhinal fibers also reach CA1 via the alveus (i.e., the alvear pathway originally described by Ramon y Cajal). In the temporal portion of the hippocampus, most of the entorhinal fibers reach CA1 after perforating the subiculum (classic perforant pathway). At more septal levels, however, the number of entorhinal fibers that take the alvear pathway increases; and in the septal portion of the hippocampus, most of the entorhinal fibers reach CA1 via the alvear pathway. These fibers make a sharp turn in the alveus, perforate the pyramidal cell layer, and terminate in the stratum lacunosum-moleculare. Both pathways demonstrate the same septotemporal organization of their projections. Thus, certain portions of the entorhinal cortex project to certain septotemporal levels of the other hippocampal fields. Following this brief overview, we now delve more deeply into the topographical organization of the perforant path projection.

Dolorfo and Amaral (1998a) have shown that cells located laterally and caudally in the entorhinal cortex project to septal levels of the hippocampal fields, whereas cells located progressively more medially and rostrally (in the medial entorhinal cortex) project to more temporal levels of the hippocampal subfields (Fig. 3-41). It now appears that there may be three largely nonoverlapping domains of the entorhinal cortex that project to three distinct levels of the dentate gyrus. The laterally situated domain (encompassing cells of both the lateral

and medial entorhinal areas) projects to the septal half of the dentate gyrus. Most of the cells in this domain project to all portions of the septal half of the dentate gyrus; thus, the projection is both divergent and convergent. The next domain is more medially situated and projects to the third quarter of the dentate gyrus. The last domain is medially and rostrally situated and projects to the temporal quarter of the dentate gyrus.

There are a number of functional implications of the organization of these projections. First and foremost, because the associational connections of the entorhinal cortex seem to respect this tripartite organization, it is reasonable to think of three functional, parallel systems encompassed within the entorhino-hippocampal system. Second, when conducting stimulation or lesion experiments designed to evaluate the contributions of the medial and lateral perforant paths to hippocampal function, one must be careful to bear in mind that the cells giving rise to the medial perforant path are located caudal (not medial) to the cells that give rise to the lateral perforant path.

One final comment must be made on the medial and lateral perforant path projections. Although the cellular characteristics of layers II and III of the medial and lateral entorhinal areas are similar, the lateral and medial perforant path projections demonstrate a number of differential features. Both components of the perforant path use glutamate as their primary transmitter, but they exhibit differential distributions of glutamate receptors. The medial perforant path fibers, for

example, are immunoreactive for the metabotropic glutamate receptor mGLUR 2/3, whereas the lateral fibers are not. In contrast, the lateral perforant path demonstrates dynorphin immunoreactivity, whereas the medial perforant path does not. One would have thought that some of these differences would show up more clearly in the cells of origin, but thus far there is no distinctive marker at the level of the entorhinal cortex for cells that give rise to the lateral and medial perforant path projections.

### **Feedback Projections from the Hippocampus and Subiculum**

We already mentioned that the dentate gyrus and the CA3 field of the hippocampus do not project back to the entorhinal cortex. Thus, the recipients of the layer II projection do not have any direct influence over the activities of the entorhinal cortex. It is only after the layer II and layer III projection systems are combined in CA1 and the subiculum that return projections to the entorhinal cortex are generated. The return projections mainly terminate in the deep layers (V and VI), although some fibers ascend into layer I (Witter et al., 1988; Naber et al., 2001; Kloosterman et al., 2003). It is not known which entorhinal neurons are the recipients of these return projections. What is clear, however, is that the projections from CA1 and the subiculum to the entorhinal cortex are also topographically organized (Figs. 3–29 and 3–34). Septal portions of CA1 and the subiculum project chiefly to lateral parts of the entorhinal cortex, and more temporal parts of CA1 and the subiculum project to more medial parts of the entorhinal cortex. Moreover, the transverse location of the cells of origin in CA1 and the subiculum also determines whether these projections terminate in the medial or lateral entorhinal cortex. The projections from the proximal part of CA1 and the distal part of the subiculum distribute exclusively to the medial entorhinal cortex, whereas cells located in the distal part of CA1 and the proximal part of the subiculum project mainly to the lateral entorhinal cortex.

The important point about these return projections is that they are exactly in register (i.e., they are point-to-point reciprocal) with the entorhinal inputs to these areas. Thus, at the global level, all of the circuitry is available for reverberatory circuits to be established through the loop, starting and ending at the entorhinal cortex. This remarkable topography confirms the critical role of the entorhinal cortex with respect to the input to and output from the hippocampal formation.

### **Extrinsic Connections**

#### ***Interconnections of the Entorhinal Cortex with Neocortical Regions***

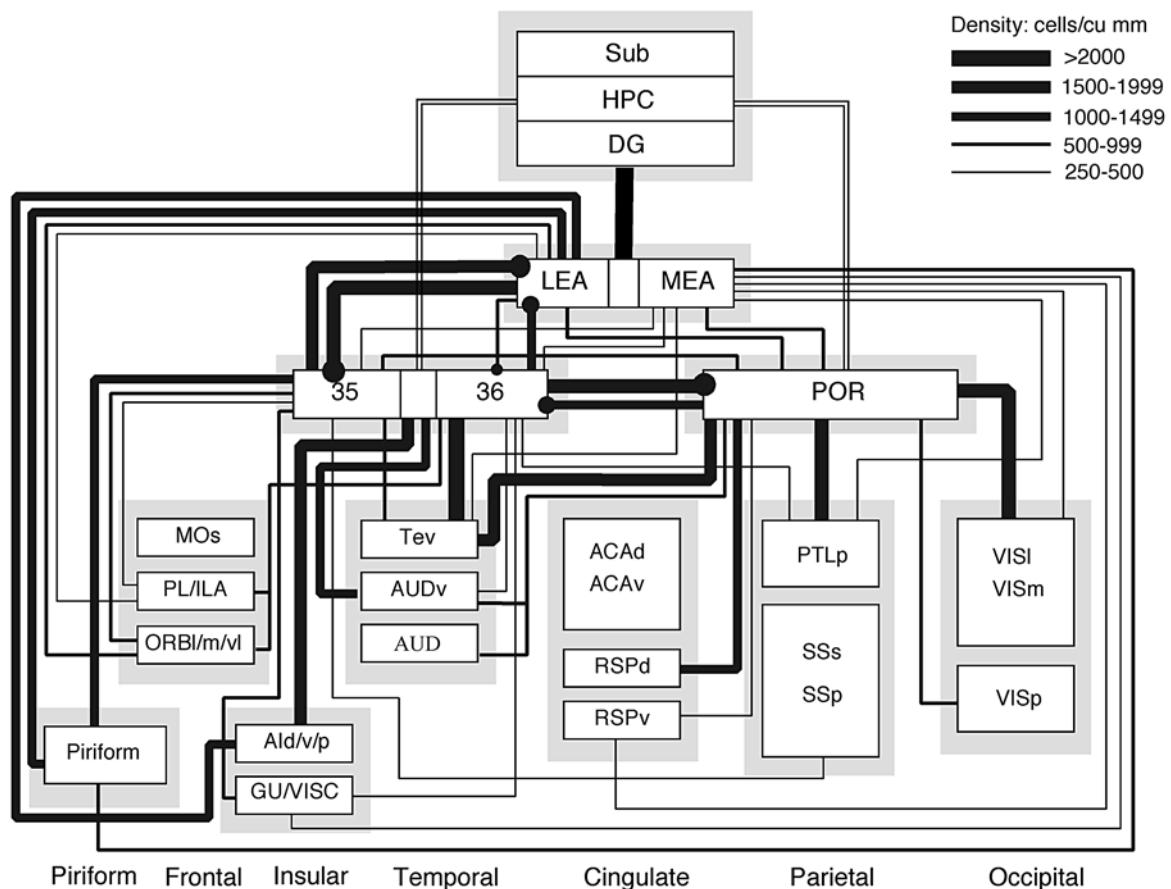

If the entorhinal cortex is viewed as the first step of processing in the hippocampal formation, it is reasonable to wonder what types of information it receives. In other words, what is

the “raw material” the hippocampal formation uses to accomplish its purported function(s). This is an area in which there are substantial species differences. Keeping to the format that we have followed so far, we give an overview of the inputs to the rat entorhinal cortex. However, doing so does a disservice to the significance of the connections between the entorhinal cortex and the neocortex, as these connections are so much more prominent in the monkey brain. Thus, when we provide our comparison of the organization of the hippocampal formation in the rat, monkey, and human in a later portion of the chapter, we return to a detailed overview of the cortical inputs of the monkey entorhinal cortex.

Burwell has carried out a thorough quantitative analysis of the organization of cortical inputs to the rat entorhinal cortex and compared the results with inputs to the perirhinal and postrhinal cortices (Fig. 3–43) (Burwell and Amaral, 1998a). She found many similarities in the complement of cortical inputs to the lateral and medial entorhinal areas. Each receive about one-third of its total input from the piriform cortex (LEA 34%, MEA 31%). These areas also receive roughly equal proportions from temporal (LEA 26%, MEA 21%) and frontal (LEA 11%, MEA 10%) regions. Some differences are observed in the proportions of insular, cingulate, parietal, and occipital inputs. The lateral entorhinal area receives more input from insular cortex (LEA 21%, MEA 6%). In contrast, the medial entorhinal area receives more input from cingulate (LEA 3%, MEA 11%), parietal (LEA 3%, MEA 9%), and occipital (LEA 2%, MEA 12%) regions. Not all portions of the rat entorhinal cortex receive substantial cortical input. In fact, it is only the lateral and caudal parts of the entorhinal cortex (those projecting to septal levels of the dentate gyrus) that are heavily innervated by the neocortex. This neuroanatomical organization has strong functional implications and likely underlies the behavioral dissociations observed with dorsal (septal) versus ventral (temporal) hippocampal lesions.

The neocortical inputs to the entorhinal cortex of the rat comprise two groups: those that terminate in the superficial layers (I–III) and those that terminate in the deep layers (IV–VI). The first category delivers information to the superficially located entorhinal neurons, which are the source of the projections to the dentate gyrus, hippocampus, and subiculum. The second group has greater influence on the deeply located cells of the entorhinal cortex, which receive processed information from the other hippocampal fields and give rise to feedback projections to certain cortical regions. In general, the cortical afferents that reach the deep layers terminate rather diffusely, whereas those that terminate superficially have a more restricted mediolateral and/or rostrocaudal distribution. Although speculative, the first group may constitute a set of information-bearing inputs, whereas the second group may have more of a modulatory influence on the output of the hippocampal formation.

A substantial input to the superficial layers of the entorhinal cortex originates from olfactory structures such as the olfactory bulb, the anterior olfactory nucleus, and the piri-

**Figure 3–43.** Pattern and strength of cortical and intrinsic connectivity of the rat parahippocampal region (entorhinal, perirhinal, and parahippocampal cortices). The thickness of the solid lines represents the relative strength of the connections based on the densities of retrogradely labeled neurons. Open lines represent reported connections for which no comparable quantitative data are available. The weakest projections (< 250 labeled cells/mm<sup>3</sup>) are not shown here. ACAd and ACAv, dorsal and ventral anterior cingulate cortex;

Ald/v/p, dorsal, ventral, and posterior agranular insular cortices; AUD, primary auditory cortex; MOs, secondary motor area; Pir, piriform cortex; PTLp, posterior parietal cortex; RSPd and RSPv, retrosplenial cortex, dorsal and ventral; SS<sub>s</sub> and SS<sub>p</sub>, primary and supplementary somatosensory areas; Te<sub>v</sub>, ventral temporal area; VISC, visceral granular insular cortex; VIS1 and VISm, lateral and medial visual association cortex; VISp, primary visual cortex. (Source: Adapted from Burwell and Amaral, 1998b.)

form cortex. These olfactory projections terminate throughout most of the rostrocaudal extent of the entorhinal cortex, mainly in layer I and the superficial portion of layer II. Only the most caudal portion of the rat medial entorhinal area does not receive any olfactory input. In addition to terminating on the principal cells of these layers, olfactory fibers also terminate on layer I GABAergic neurons, which presumably interact with the principal cells in layers II and III.

A second prominent cortical input to the superficial layers of the entorhinal cortex arises from the laterally adjacent perirhinal and postrhinal cortices. The perirhinal and postrhinal cortices are polysensory convergence areas that receive inputs from a variety of unimodal and polymodal sensory cortices. The perirhinal cortex terminates mainly in the lateral entorhinal area, and the postrhinal cortex terminates heavily, though not exclusively, in the medial entorhinal area. In both cases, the projections terminate preferentially in layers I and III of the entorhinal cortex.

We address the issue of the perirhinal cortex more exten-

sively in our discussion of the monkey entorhinal cortex, but it is important to give an overview of this area because it provides major input to the rat entorhinal cortex. The perirhinal cortex in the rat is made up of two areas, 35 and 36, which appear to receive slightly different complements of neocortical inputs (Fig. 3–43) (Burwell et al., 1995; Burwell, 2001). Area 36 of the perirhinal cortex receives more, higher-level cortical input than does area 35. Most of this input comes from the ventral temporal associational area (Te<sub>v</sub>), which is located dorsally adjacent to area 36. Other major inputs are from the postrhinal cortex and the entorhinal cortex. The predominant inputs to area 35 arise from the piriform, entorhinal, and insular cortices. Area 35 receives more than one-fourth of its input from the piriform cortex and only slightly less from the lateral entorhinal area. About one-fifth of the total input arises from insular cortices. Interestingly, the perirhinal projections to the entorhinal cortex arise preferentially from area 35, and the intrinsic projections of the perirhinal cortex seem to be organized to funnel information into

area 35, which in turn gives rise to the main perirhinal projections to the entorhinal cortex.

Cortical afferents to the deep layers of the entorhinal cortex arise from a variety of cortical areas. These areas include projections from the agranular insular cortex, the medial prefrontal region (particularly the infralimbic, prelimbic, and anterior cingulate cortices and the retrosplenial cortex (Insausti et al., 1997).

Efferents of the entorhinal cortex return projections to many of the cortical areas that provide input to the entorhinal cortex. There are projections to olfactory areas, originating predominantly from layers II, III, and Va. An important issue is whether the entorhinal cortex of the rat, like that of the monkey (see below), gives rise to prominent, widespread projections to multimodal association cortices. Initial studies in the rat indicated that the entorhinal cortex projects mainly to adjacent, limited portions of the temporal cortex. Swanson and Köhler (1986), however, suggested that the rat entorhinal cortex gives rise to projections that reach a much larger domain of the cortical surface. Whether one believes that the entorhinal cortex has widespread neocortical connections seems to hinge on the demarcation of the entorhinal cortex from the adjacent perirhinal cortex. Insausti and colleagues confirmed the report by Sarter and Markowitsch (1985) that the only cells that give rise to the extensive connections reported by Swanson and Köhler are located in the most dorsolateral region of the entorhinal cortex (i.e., on the border of the entorhinal and perirhinal cortices). Whether these cells indeed belong to the deep layers of the entorhinal cortex or form a population of perirhinal cells is not yet clearly established. Based on the distribution of immunoreactivity for parvalbumin or for certain glutamate receptor subunits, the border between the entorhinal and perirhinal cortex appears to be oblique and perhaps intermixed in this critical region. Thus, it remains unresolved at this point whether it is the entorhinal cortex or the perirhinal cortex that projects widely to the neocortex. One can safely conclude, however, that the major portion of the entorhinal cortex does not contribute projections to the unimodal areas of the neocortex, and that the bulk of neocortically directed projections are to higher-order associational and polysensory cortices and not to sensory or motor regions. In this respect, the situation in the rat closely resembles the connectivity observed in the monkey. Among the cortical areas that do receive entorhinal input are the infralimbic, prelimbic, orbitofrontal, agranular insular, perirhinal, and postrhinal cortices; these projections originate mainly from cells in layer Va. Only weak projections have been reported to the retrosplenial cortex.

#### **Other Telencephalic Connections:**

##### **Amygdala, Claustrum, Striatum**

In addition to the cortical inputs just described, the entorhinal cortex receives a number of subcortical inputs. Whereas some of them, such as the monoaminergic and cholinergic inputs, may be viewed as largely modulatory, others, such as the input from the amygdaloid complex, might also provide

additional sources of information. The substantial input from the amygdaloid complex, which originates mainly from the lateral and basal nuclei, is presumably conveying information about the emotional state of the organism (Pikkarainen et al., 1999a). The densest termination of the amygdaloid fibers is in the ventrolateral part of the entorhinal cortex (Fig. 3–44). Efferents from the lateral amygdaloid nucleus distribute most intensely to the deep portion of layer III but end also between the cell islands of layer II and in layer I. The fibers from the basal nucleus terminate diffusely in layers III to V, whereas those from the cortical nuclei and the periamygdaloid cortex preferentially project to layers I and II. The entorhinal cortex sends feedback projections to the amygdala that terminate mainly in the basal nucleus. These projections originate from cells in layer V, although a few cells in more superficial layers may also contribute to the projection. Dense inputs also originate from the ventral part of the claustrum or endopiriform nucleus, but the topographical and laminar organization of these inputs is not well understood.

The entorhinal cortex projects bilaterally to the striatum, particularly to the nucleus accumbens and adjacent parts of the olfactory tubercle. These projections originate mainly from layer V and are topographically organized; medial parts of the entorhinal cortex project to the caudomedial portion of the nucleus accumbens, and more lateral portions of the entorhinal cortex project to more lateral parts of the nucleus.

#### **Basal Forebrain and Hypothalamic Connections**

The entorhinal cortex receives its cholinergic innervation mainly from the septum. This projection is topographically organized such that cells in the horizontal limb of the nucleus of the diagonal band preferentially project to the most lateral part of the entorhinal cortex, whereas the medial septal nucleus and the vertical limb of the nucleus of the diagonal band project to more medial parts of the entorhinal cortex. Septal projections terminate densely in the cell-sparse lamina dissecans and less densely in layer II.

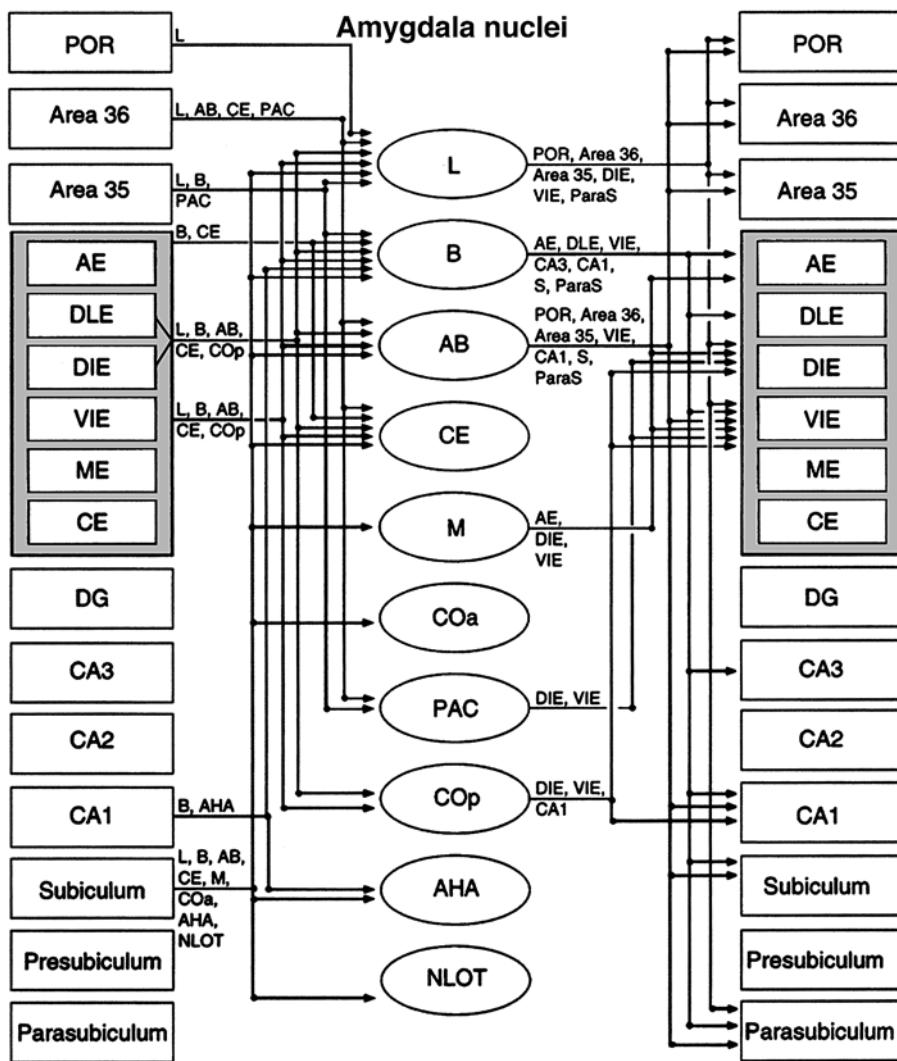

Like the hippocampus and the subiculum but unlike the pre- and parasubiculum, the entorhinal cortex projects back to the septal region. The projection originates from cells in layer Va, although some layer II cells also contribute to these projections. The fibers from the entorhinal cortex preferentially terminate in the lateral septal complex.

The entorhinal cortex receives diffuse inputs from various structures in the hypothalamus. They include inputs from the supramammillary nucleus that terminate rather diffusely with some preference for layers III to VI, from the tuberomammillary nucleus distributing diffusely throughout the entorhinal cortex, and from the lateral hypothalamic area reaching the deep layers of the entorhinal cortex.

#### **Thalamic Connections: Nucleus Reunions**

##### **and Other Midline Nuclei**

The major thalamic inputs to the entorhinal cortex originate in the nucleus reunions and the nucleus centralis medialis (Van der Werf et al., 2002). The rhomboid, paraventricular,

**Figure 3–44.** Summary of the reciprocal connections between the amygdala and the hippocampal formation and the perirhinal and parahippocampal cortices. The subdivisions of the entorhinal cortex follow the nomenclature of Insausti et al. (1997). Areas CE and ME

of the medial entorhinal cortex do not receive amygdala inputs. Areas DLE, DIE, VIE, and AE of the lateral entorhinal cortex receive inputs from the various amygdala nuclei. (Source: Pitkänen et al., 2000.)

and parataenial nuclei contribute minor projections. The nucleus reuniens fibers densely innervate the deep portion of layers I and III and give rise to a few collaterals that extend into layer II. Separate populations of nucleus reuniens cells project to the entorhinal cortex, CA1, and the subiculum. There is no evidence that the entorhinal cortex projects back to the thalamus.

#### Brain Stem Inputs

The entorhinal cortex receives dopaminergic input from cells located in the ventral tegmental area. The projection preferentially terminates in a restricted rostral-lateral part of the lateral entorhinal area, where fibers are arranged in dense, columnar patches in layers I to III. The serotonergic innervation arises from the central and dorsal raphe nuclei and terminates diffusely in all layers but with a preference for the superficial layers. The noradrenergic locus coeruleus sup-

plies the entorhinal cortex with a diffusely organized noradrenergic input that exhibits slightly more dense termination in layer I.

## 3.5 Chemical Neuroanatomy

### 3.5.1 Transmitters and Receptors

Detailed, comprehensive treatment of the chemical neuroanatomy of the hippocampal formation would demand a lengthy chapter of its own. We have already described the distribution of systems defined by their neurotransmitter content—noradrenaline (norepinephrine), serotonin, acetylcholine, GABA—and a variety of reviews are available on the chemical neuroanatomy of the hippocampus (Swanson et al.,

1987; Kobayashi and Amaral, 1998). We thus restrict ourselves here to providing an overview of the diversity of neurochemical substances in the hippocampal formation.

A variety of peptides and other chemical markers have been shown to subdivide the population of GABAergic interneurons. Among the peptides that colocalize with particular populations of GABAergic interneurons are VIP, somatostatin, NPY, corticotropin-releasing factor (CRF), substance P, cholecystokinin, galanin, and the opioid peptides dynorphin and enkephalin. It is worth commenting further on the distribution of the opioid peptides because, in addition to being localized to certain populations of interneurons, they are observed in intrinsic excitatory pathways of the hippocampal formation. The fibers of the lateral perforant path, for example, are immunoreactive for Leu-enkephalin, whereas the mossy fibers of the dentate gyrus are positive for dynorphin.

Another class of substances that appear to mark certain subsets of GABAergic neurons selectively is the family of calcium-binding proteins, including parvalbumin, calbindin, and calretinin. Whereas parvalbumin immunoreactivity appears to be exclusively confined to a subset of GABAergic interneurons, the other calcium-binding proteins can be found in both interneurons and principal neurons. Although the precise function of the various calcium-binding proteins has not been well established, their existence has provided a useful anatomical tool. Although standard immunohistochemistry of GABAergic neurons with antibodies to glutamic acid decarboxylase (GAD) or to GABA does not label dendrites very well, parvalbumin-immunoreactive neurons are fully labeled in a Golgi-like fashion. Thus, even though parvalbumin does not label all GABAergic neurons, those that are labeled can be subjected to precise analyses of their inputs.

### 3.5.2 Steroids

Neurons in the hippocampal formation have been shown to concentrate glucocorticoids and mineralcorticoids (McEwen and Wallach, 1973). Studies using uptake of  $^3\text{H}$ -corticosterone show that cells in CA2 and CA1 exhibit the greatest uptake. There is slightly less uptake in CA3 cells and cells of the polymorphic layer of the dentate gyrus; dentate granule cells also demonstrate some  $^3\text{H}$ -corticosterone uptake. The amount of uptake in other fields of the hippocampal formation has not yet been described. What is perhaps most surprising is the fact that, in the rat, the hippocampus demonstrates the highest level of uptake of any brain region. The distribution of glucocorticoid receptor mRNA has also been evaluated in the tree shrew. Here the highest density of mRNA was observed in the pyramidal cells of the subiculum and in the granule cells of the dentate gyrus. In the hippocampus, higher densities of mRNA were observed in CA1 than in CA3. Mineralcorticoid receptor mRNA is also expressed in the tree shrew hippocampus. It is expressed most strongly in CA1 and less strongly in CA3; this contrasts with the pattern in the rat, where mineralcorticoid expression is higher in CA3.

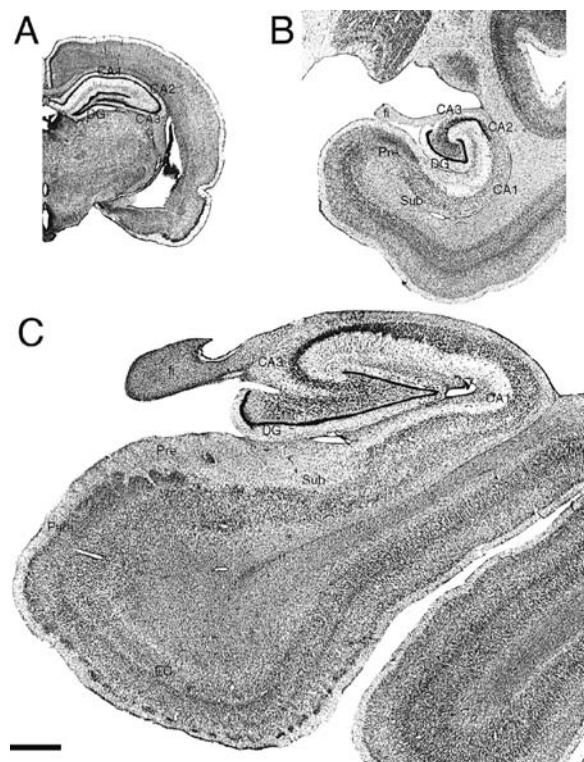

In situ hybridization has also been used in postmortem humans to study the distribution of glucocorticoid and min-

eralcorticoid receptors. Receptors for both steroids were highly expressed in cells of the dentate gyrus, CA3, and CA2. Lower levels of expression were observed in CA1. This is the opposite of the distribution observed in the rat and the tree shrew.

### 3.6 Comparative Neuroanatomy of the Rat, Monkey, and Human Hippocampal Formation

When one views Nissl-stained sections of the hippocampus from the rat, monkey, and human, it is immediately apparent that one is looking at the same brain region (Figs. 3–2 and 3–45). The densely packed granule cell layer is obvious in all three species, as is the progressively more complex lamination when one progresses from the dentate gyrus to the entorhinal cortex. On closer inspection, however, a number of differences make it clear that the hippocampal formation of the monkey or human is not simply a scaled-up version of the rat hippocampal formation. Some of the hippocampal fields, such as CA1 and the entorhinal cortex, are disproportionately larger in the primate. The entorhinal cortex has many more subdivisions in the monkey and human than in the rat; and the laminar organization is much more distinct in the primate brain. In the following sections, we review some of the similarities and differences in the organization and connections of the

**Figure 3–45.** Nissl-stained coronal sections through the hippocampal formation of the rat (A), monkey (B), and human (C) presented at the same magnification. Bar in C = 2 mm and applies to all panels.

hippocampal formation in these three species. Of course, although we can address certain issues concerning cell number and distribution in the human brain, we are unable to say anything about patterns of connectivity in the human hippocampal formation.

### 3.6.1 Neuron Numbers

The number of neurons present in the various subdivisions of the hippocampal formation have been counted by several investigators, but rarely has the same author analyzed the rat, monkey, and human hippocampal formations. Moreover, there is a lot of variability in the estimates published in the literature, and few investigators have used modern stereological techniques to carry out these assessments. We have compiled a summary of current estimates of neuron number obtained with modern stereological techniques. The data presented here are derived from published and unpublished work from three laboratories: Mark West at Aarhus University, Peter Rapp at New York University, and our own at the University of California Davis (Table 3-1).

In our initial comparison of the hippocampal formation in the rat, monkey, and human, the volume of the hippocampal complex (dentate gyrus + hippocampus) was said to be about 10 times larger in monkeys than in rats and 100 times larger in humans than in rats (rat 32 mm<sup>3</sup>, monkey 340 mm<sup>3</sup>; human 3300 mm<sup>3</sup>). If, however, we compare the total number of neurons in the various hippocampal areas, we observe that certain regions are comparatively more developed than others in the monkey and human brain. In the dentate gyrus, there are approximately 10 times more granule cells in the monkey than in the rat, a ratio that parallels the overall volume differences. However, there are only 15 times more dentate granule cells in humans compared to rats, whereas the volume of the dentate gyrus plus the hippocampus is about 100 times larger in humans than in rats. In CA1, however, there are only three times more pyramidal cells in the monkey than in the rat, whereas there are 35 times more cells in humans than in rats. We must add, however, that some of these estimates are still provisional and need to be replicated before drawing solid inferences on the relative development of the various hippocampal regions in rats, monkeys, and humans.

### 3.6.2 Comparison of Rat and Monkey Hippocampal Formation

In monkeys, the hippocampal formation lies entirely within the temporal lobe (Figs. 3-46 through 3-48) and lacks the pronounced C shape along its septotemporal axis that is so characteristic in the rat. The region equivalent to the septal pole of the rat hippocampus is located caudally in the monkey, and the equivalent of the temporal pole is located rostrally (Figs. 3-5 and 3-6). Much of the entorhinal cortex is located rostral to the remainder of the hippocampal formation. In fact, the rostral half of the entorhinal cortex lies ventral to the amygdaloid complex rather than the hippocampus.

### Cytoarchitectonic Organization

There are several cytoarchitectonic differences between the rat and monkey hippocampal formation. The polymorphic layer of the dentate gyrus is relatively smaller in the monkey, and much of the territory located enclosed within the blades of the granule cell layers is occupied by the CA3 field. This "hilar" portion of the CA3 region is so expansive that some researchers have confused it for an enlarged polymorphic layer. Cells in this region bear the gold standard of inclusion in CA3, however, as they give rise to Schaffer collaterals to CA1.

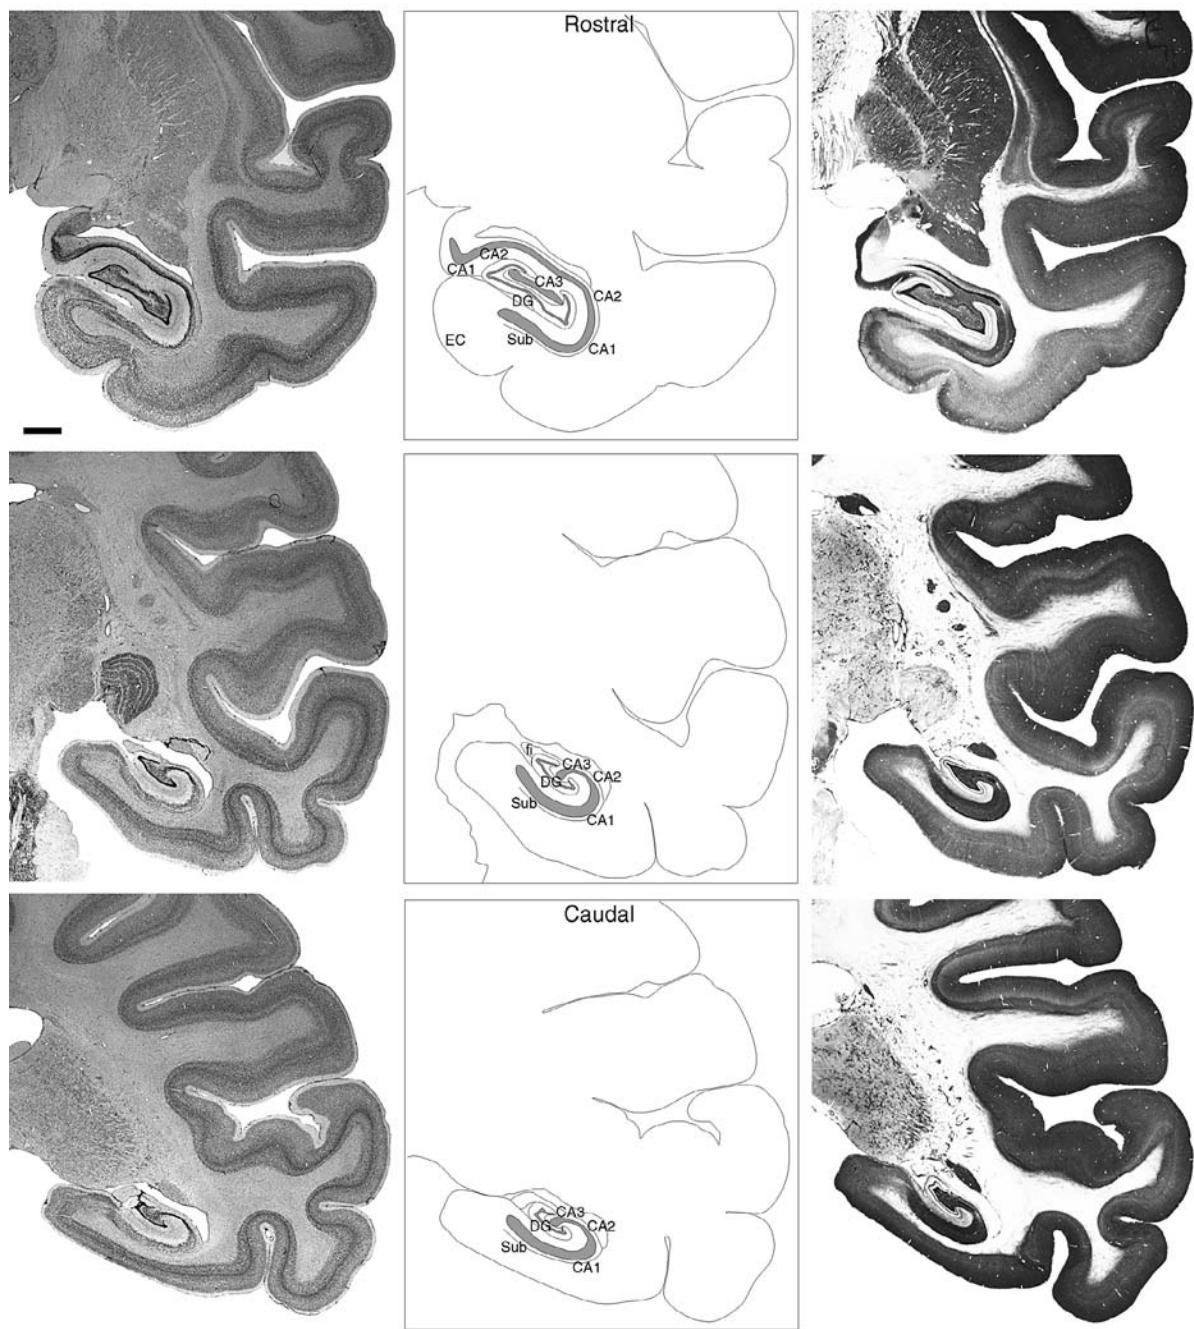

The other obvious difference between the rat and monkey hippocampal formation is the much thicker pyramidal cell layer in the monkey CA1 (Fig. 3-49). In the rat, this layer is tightly packed and is typically about 5 cells thick. In the monkey, the cell layer is much more diffusely organized and is 10 to 15 cells thick. As a result, not only is the boundary between the pyramidal cell layer and the stratum radiatum less clear, so is the boundary between CA1 and the subiculum. In the monkey, at least some of the Schaffer collaterals from CA3 terminate in the pyramidal cell layer, presumably on the apical dendrites of cells located deep in the layer or on the basal dendrites of neurons located superficially in the layer.

The entorhinal cortex exhibits major cytoarchitectonic differences between the rat and the monkey. The laminar organization of the monkey entorhinal cortex is much clearer than that in the rat. Throughout much of the entorhinal cortex, for example, there is a clear distinction between layers V and VI in the monkey, whereas these layers tend to blur together in the rat. The monkey entorhinal cortex is also much more differentiated than in the rat. As noted previously, Amaral and colleagues typically divided the rat entorhinal cortex into only lateral and medial areas, whereas they divided the monkey entorhinal cortex into seven distinct subdivisions.

### Neuron Types

Until recently, there has been little direct comparison of the morphology of similar neurons in the rat and monkey hippocampus. A few studies, using either the Golgi technique or intracellular staining techniques, have compared easily identified cell types.

The granule cells of the monkey dentate gyrus have been examined with both the Golgi technique and intracellular filling techniques in the *in vitro* slice preparation (Duffy and Rakic, 1983; Seress and Mrzljak, 1987, 1992). Depending on which aspects of these studies one wishes to emphasize, it could be concluded that granule cells are basically similar in rats and monkeys or that there have been substantial modifications of at least some granule cells. In general, dentate granule cells have the same unipolar apical dendritic tree in the monkey as in the rat. The total dendritic length of each granule cell is also relatively similar in the rat and the monkey. Seress and colleagues were the first to point out that at least some monkey granule cells have basal dendrites (Fig. 3-50),

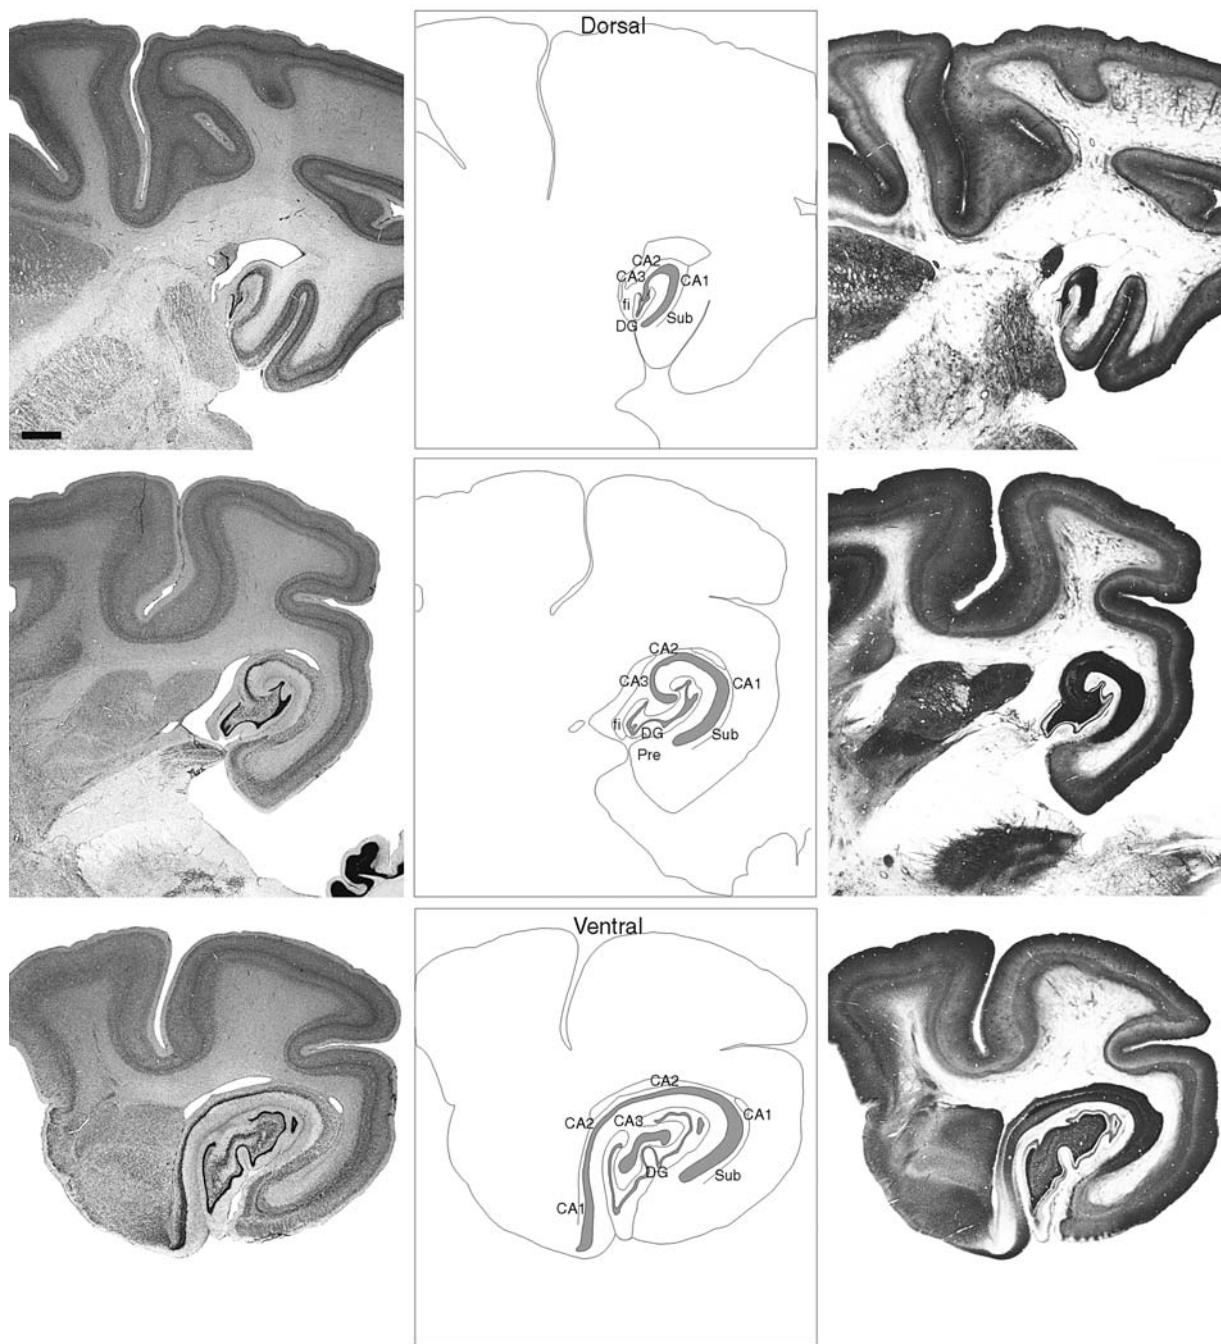

**Figure 3–46.** Coronal sections at three rostrocaudal levels through the monkey brain show the relative position of the hippocampal formation. The three panels on the left are Nissl-stained sections; the three panels on the right are adjacent sections stained with Timm's sulfide silver stain. The line drawings (middle column) highlight the regions of the monkey hippocampal formation seen in the stained sections. Bar = 2 mm.

and a similar observation has been made by Scheibel and colleagues. This feature has never been reported for normal rat granule cells. Thus, it appears that there are some species differences in dentate granule cell morphology, but the functional significance of these differences is yet unclear.

Another example of differences in an ostensibly similar cell type in the rat and the monkey has emerged from intracellular staining of mossy cells of the polymorphic region of

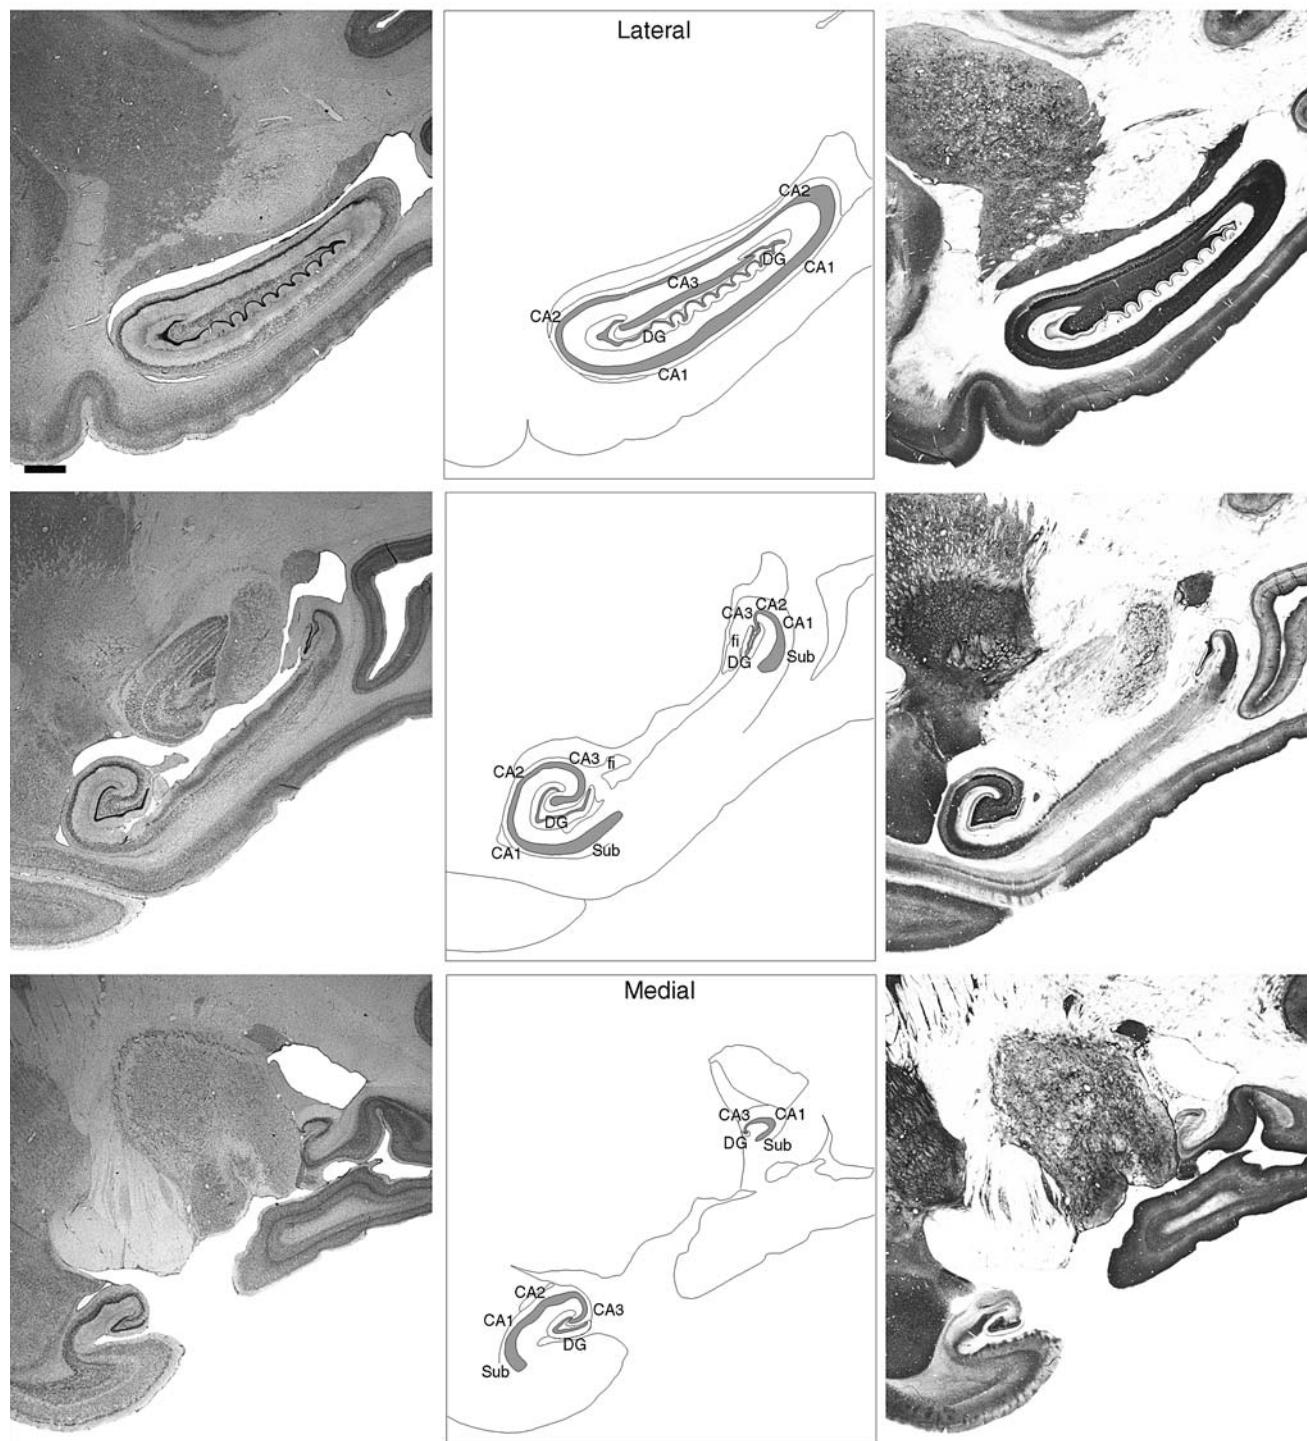

the dentate gyrus (Buckmaster et al., 1992; Buckmaster and Amaral, 2001). In the rat, these cells give rise to the associational-commissural connections to the inner portion of the molecular layer, and its dendrites are generally confined to the polymorphic area (i.e., the dendrites extend neither into the molecular layer nor into the adjacent CA3 field). The mossy cell in the monkey is quite different. First, there appear to be at least two forms. One is very much like the rat mossy cell,

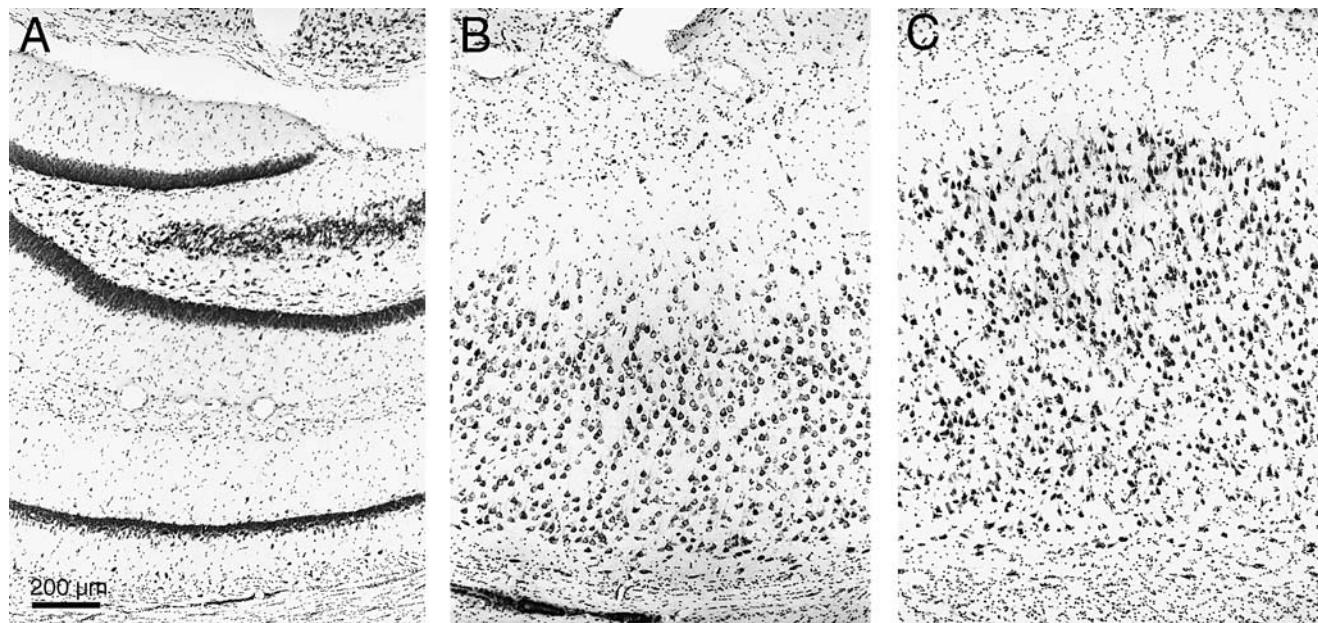

**Figure 3–47.** Horizontal sections at three dorsoventral levels through the monkey brain show the relative position of the hippocampal formation. The three panels on the left are Nissl-stained sections; the three panels on the right are adjacent sections stained with Timm's sulfide silver stain. The line drawings (middle column) highlight the regions of the monkey hippocampal formation seen in the stained sections. Bar = 2 mm.

with dendrites confined to the polymorphic cell layer and axons directed to the molecular layer. There is a second type, however, that extends much of its dendritic arbor into the molecular layer (Fig. 3–51). Moreover, many of these cells give rise to projections into the adjacent CA3 region. The implication of this altered morphology in the monkey is that these mossy cells are capable of receiving perforant path innerva-

tion in the molecular layer of the dentate gyrus, whereas standard mossy cells are not (because the perforant path does not enter the polymorphic layer). Moreover, in rats the granule cells are the only input to CA3, whereas in the monkey the mossy cells appear to contribute an additional projection. Although these structural alterations must be confirmed by functional studies, they suggest that there are fundamental

**Figure 3–48.** Sagittal sections at three mediolateral levels through the monkey brain show the relative position of the hippocampal formation. The three panels on the left are Nissl-stained sections; the three panels on the right are adjacent sections stained with Timm's sulfide silver stain. The line drawings (middle column) highlight the regions of the monkey hippocampal formation seen in the stained sections. Bar = 2 mm.

**Figure 3-49.** High magnification photomicrographs of Nissl-stained coronal sections through the CA1 field of the hippocampus in the rat (A), monkey (B), and human (C). Note that the CA1 pyramidal cell layer in the rat (which is the darkly stained layer at the bottom of panel A) is about 5 cells thick. The monkey pyrami-

dal cell layer is approximately 15 cells thick and shows some sublamination, with the top half of the layer having a slightly higher density of neurons. The pyramidal cell layer in the human CA1 is even thicker and has a more laminated structure. Bar in A = 200  $\mu\text{m}$  and applies to all panels.

differences regarding the circuit characteristics of the dentate gyrus between the rat and the monkey.

### Connections

#### **Basic Organization of the Intrinsic Hippocampal Circuitry**

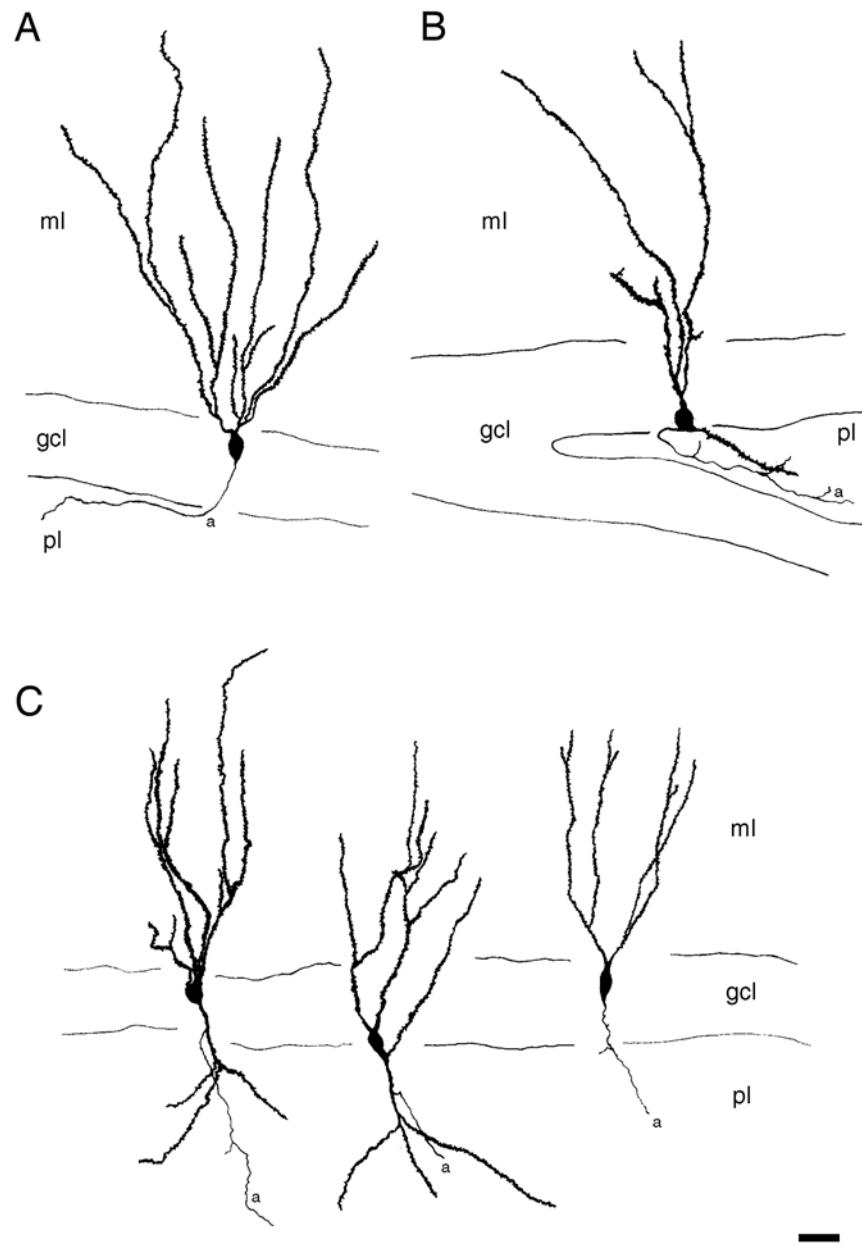

To the extent that it has been examined, the basic principles of organization of the intrinsic circuitry of the monkey hippocampal formation resemble those observed in the rat. Too

little work has been carried out in the monkey, however, to know if the topographical organization of intrinsic circuits is the same in the two species. So far, minor differences have been observed. In the monkey, for example, perforant path fibers arising from the rostral entorhinal area (the equivalent of the rat lateral entorhinal area) terminate, as in the rat, mainly in the outer third of the molecular layer of the dentate gyrus. Some terminations, however, also continue in a decreasing gradient fashion into the middle third of the molecular layer.

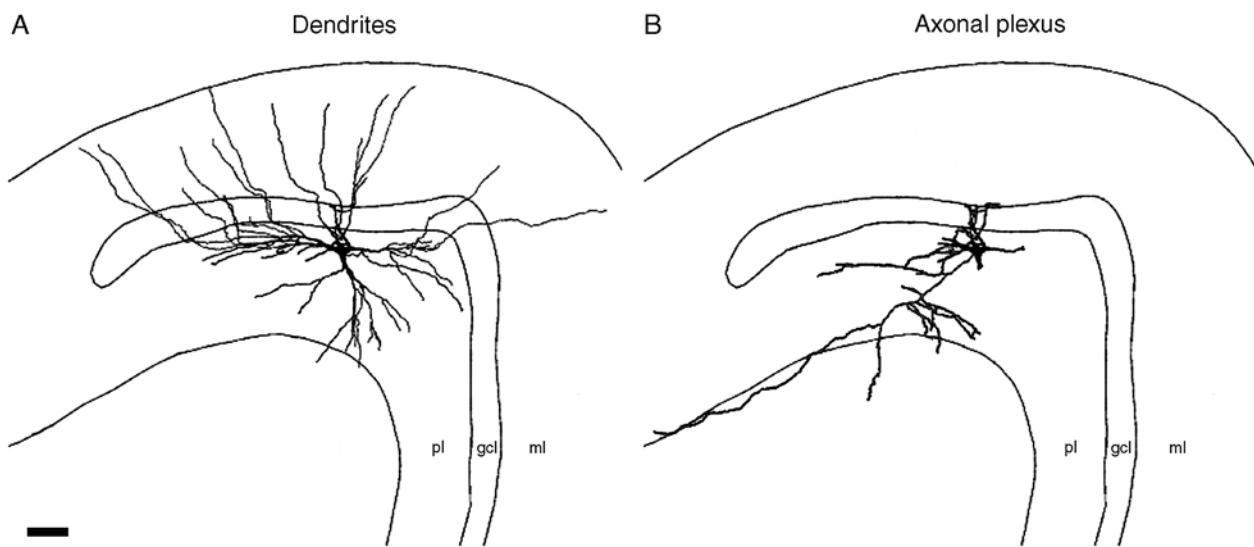

**Figure 3-50.** Camera lucida drawings of primate granule cells. *A.* Monkey granule cell in the upper part of the granule cell layer (gcl). The dendrites are cone-shaped in the molecular layer (ml); the axon (a) originates from the base of the soma and extends into the polymorphic layer (pl). *B.* Monkey granule cell in the deep part of the granule cell layer with a basal dendrite. Both apical and basal dendrites are fully covered with spines. The apical dendrites extend through the molecular layer, and the basal dendrites extend into the polymorphic layer. The axon originates from the base of the soma and extends into the polymorphic layer. *C.* Three types of human granule cell in the human dentate gyrus. The neuron on the right has dendrites in the molecular layer only, whereas the other two neurons have both apical dendrites extending into the molecular layer and basal dendrites extending into the polymorphic layer. Bar in *C* = 20  $\mu$ m and applies to all panels. (Source: Adapted from Seress and Mrzljak, 1987.)

Projections from the caudal entorhinal cortex (the region equivalent to the rat medial entorhinal area) terminate in a similar fashion: heaviest in the middle third and gradually decreasing in the outer third of the molecular layer. Thus, the border between the lateral and medial entorhinal terminations is much less distinct in the monkey than in the rat.

#### Lack of Commissural Connections in the Monkey Hippocampal Formation

One of the most striking connectional differences between the rat and the monkey relates to the organization of the commissural connections (Amaral et al., 1984; Demeter et al., 1985). In the rat, there are extensive commissural projections

from the polymorphic layer of the dentate gyrus to the contralateral molecular layer of the dentate gyrus and from the CA3 field of the hippocampus to the contralateral CA3 and CA1 fields. In the monkey, these connections are virtually absent. Only the most rostral part of the dentate gyrus and hippocampus (corresponding to the most temporal portion in the rat) demonstrates any commissural connections, and they are limited to the homotopic regions on the contralateral side. Interestingly, whereas the commissural connections of the dentate gyrus and hippocampus are largely absent, the connection originating in the presubiculum and terminating in layer III of the contralateral entorhinal cortex appears to be as robust in the monkey as in the rat.

**Figure 3-51.** Mossy cell of the polymorphic layer of the monkey dentate gyrus. A. Camera lucida drawing of the soma and dendritic arbor. Note that the dendrites extend widely in the polymorphic layer and extend into the molecular layer, in contrast to what is observed in the rat. B. Camera lucida drawing of the soma and axonal plexus. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Buckmaster and Amaral, 2001.)

#### ***Increased Cortical Interconnectivity of the Monkey Hippocampal Formation***

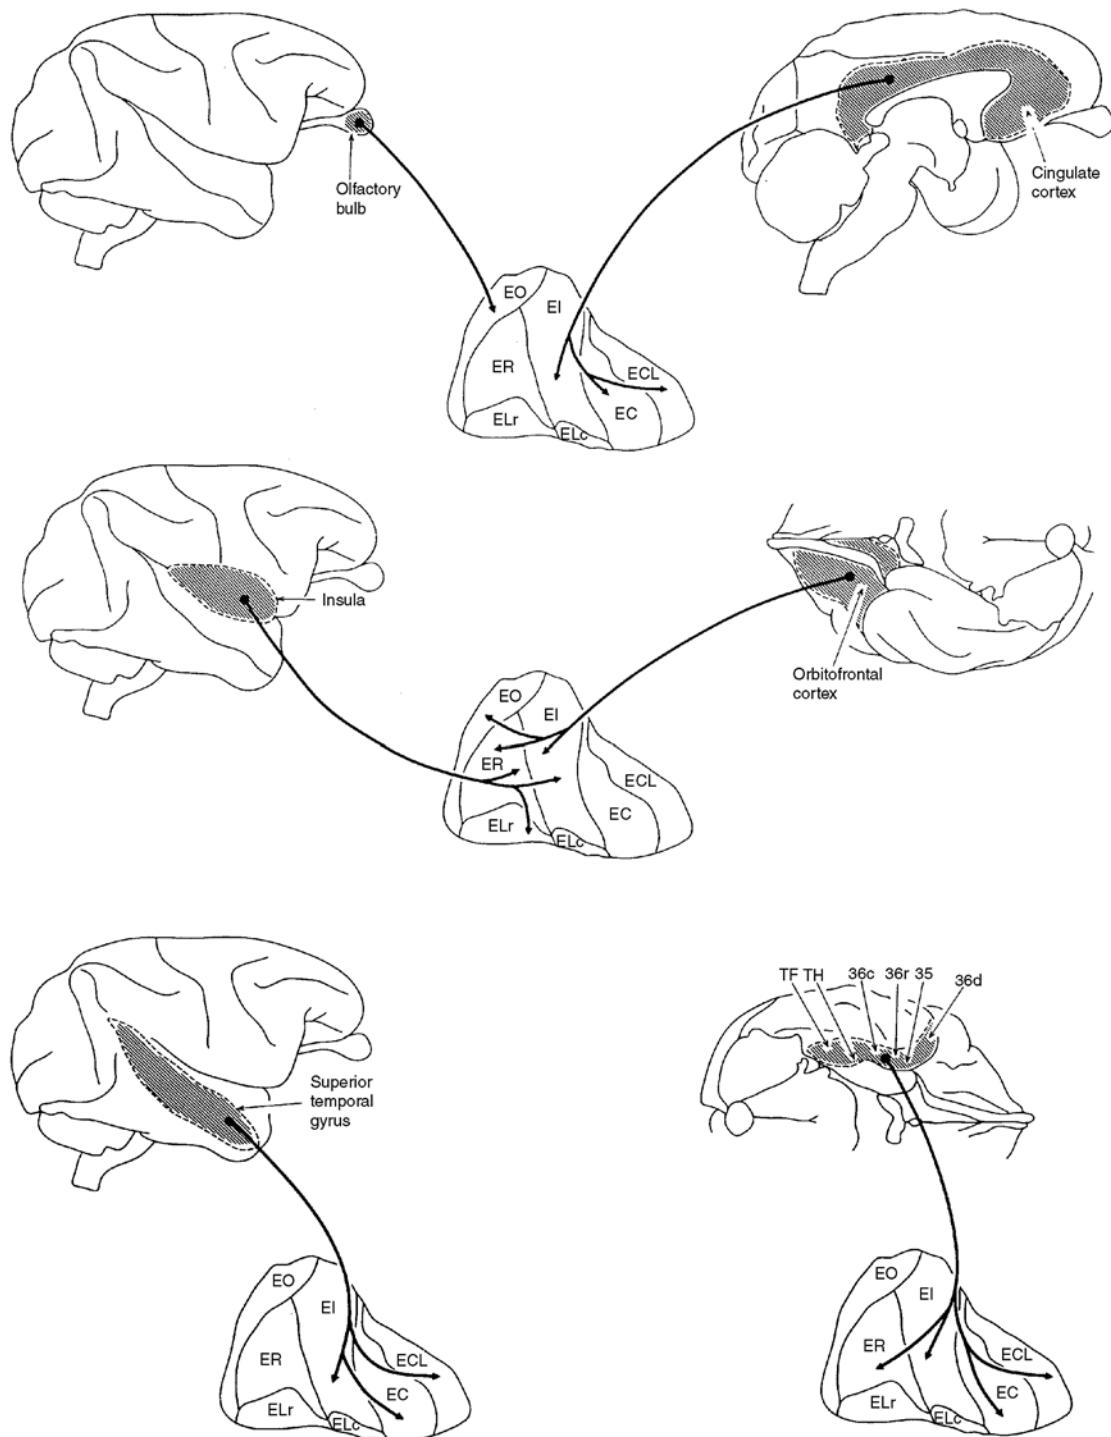

The big difference between the rat and monkey brain is the much greater amount of neocortex in the primate. Much of this neocortex is dedicated to visual processing, but there is also a substantial increase in the amount of association cortex, particularly in the frontal and temporal lobes. A substantial portion of this association cortex is polysensory, and most of the polysensory cortical regions are interconnected with the hippocampal formation via connections with the entorhinal cortex. The more robust neocortical connectivity has given rise to the suggestion that processing in the primate hippocampal formation is more highly dependent on and integrated with processing of sensory information in the neocortex.

In the monkey temporal lobe, there is massive expansion of the perirhinal and parahippocampal regions that border the hippocampal formation. Rostrally, this region includes the perirhinal cortex, which comprises areas 35 and 36 of Brodmann. The perirhinal cortex starts at a level through the rostral hippocampal formation and extends rostrally to form the medial portion of the temporal polar cortex. The caudal continuation of the perirhinal cortex is the parahippocampal cortex, which includes areas TF and TH of von Bonin and Bailey, both of which are bordered laterally by the unimodal visual areas TE or TEO. The perirhinal and parahippocampal cortices are important players in the economy of the neocortical innervation of the hippocampal formation, as they provide nearly two-thirds of the neocortical inputs to the entorhinal cortex.

The major inputs to the monkey entorhinal cortex are summarized in Figures 3-52 and 3-53. In both rats and monkeys, the entorhinal cortex provides the major interface for

communication with the neocortex (Insausti et al., 1987). For essentially all cortical regions, the return projections from the entorhinal cortex originate in layers V and VI and terminate both deeply and superficially in a manner typical of other cortical feedback projections. The laminar organization of the inputs to the entorhinal cortex varies according to the cortical area of origin. Projections from some regions, such as the perirhinal and parahippocampal cortices, terminate preferentially in layers I to III, which give rise to the perforant path projections. Projections from other cortical areas, such as the orbitofrontal and insular cortices, project to the deep layers of the entorhinal cortex, which generate the major output pathways to the neocortex and other regions. These latter connections, therefore, might preferentially be involved in modulating the output of the hippocampal formation. However, they may also contribute to the perforant pathway via some of the few layer V and VI neurons that contribute to this pathway or through intrinsic deep to superficial connections in the entorhinal cortex.

Whereas the perirhinal and parahippocampal cortices provide the major input to the hippocampal formation, other substantial inputs originate in the retrosplenial cortex (area 29 in the caudal cingulate gyrus), the polysensory region of the superior temporal gyrus (along the dorsal bank of the superior temporal gyrus), and the orbitofrontal cortex (mainly caudal area 13). The general rule is that the entorhinal cortex receives input only from cortical regions with demonstrated polysensory convergence. Thus, only olfactory input (which originates from all levels of the olfactory system including the olfactory bulb in the primate) has direct access to the hippocampal formation. The olfactory connection, however, provides another example of a difference between the rat and

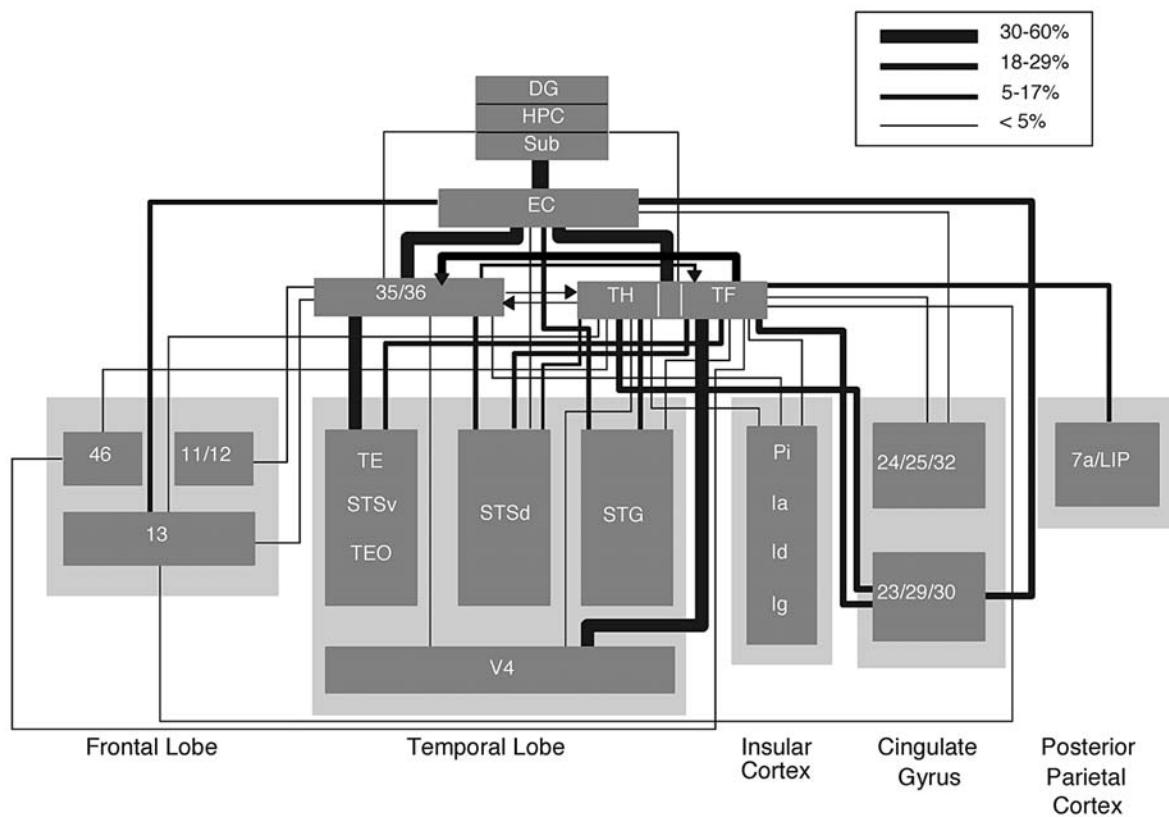

**Figure 3-52.** Summary of the major entorhinal cortical afferents in the macaque monkey.  
(Source: Adapted from Insausti et al., 1987.)

monkey hippocampal formations. Whereas in the rat almost the entire entorhinal cortex receives direct input from the olfactory bulb, in the monkey this is restricted to about 10% of the surface area of the entorhinal cortex.

Given this pattern of neocortical inputs to the monkey entorhinal cortex, the hippocampal formation can be viewed as the final stage in a cascade of neocortical sensory process-

ing. From the unimodal association cortices, information converges on a few polysensory cortical regions, which in turn project in a convergent fashion on the entorhinal cortex (Lavenex and Amaral, 2000). The entorhinal cortex relays this information to the other hippocampal fields via the perforant path projection. Once the information processed by the hippocampal formation is returned to the deep layers of the

**Figure 3-53.** Summary of the organization and strength of cortical inputs to the monkey entorhinal, perirhinal (areas 35 and 36), and parahippocampal (areas TF and TH) cortices. (Source: Adapted from Suzuki and Amaral, 1994.)

entorhinal cortex, they return this highly processed information to many of the polysensory cortical regions that provide feedback projections to the unimodal sensory regions.

There are a number of implications of this cascade of projections into the entorhinal cortex and the organization of the entorhinal projections to the other hippocampal fields. One is that the information the hippocampal formation is using has been highly preprocessed and integrated. Except for the olfactory input, little elemental or unimodal sensory information is directed to the hippocampal formation. A second, related implication is that it is unlikely that there is appreciable segregation of sensory information processing in the hippocampal formation (i.e., visual information is not processed separately from auditory information). In fact, the pattern of neuroanatomical connectivity predicts that the hippocampal formation carries out whatever functions it accomplishes with high level, multimodal representations of sensory experiences.

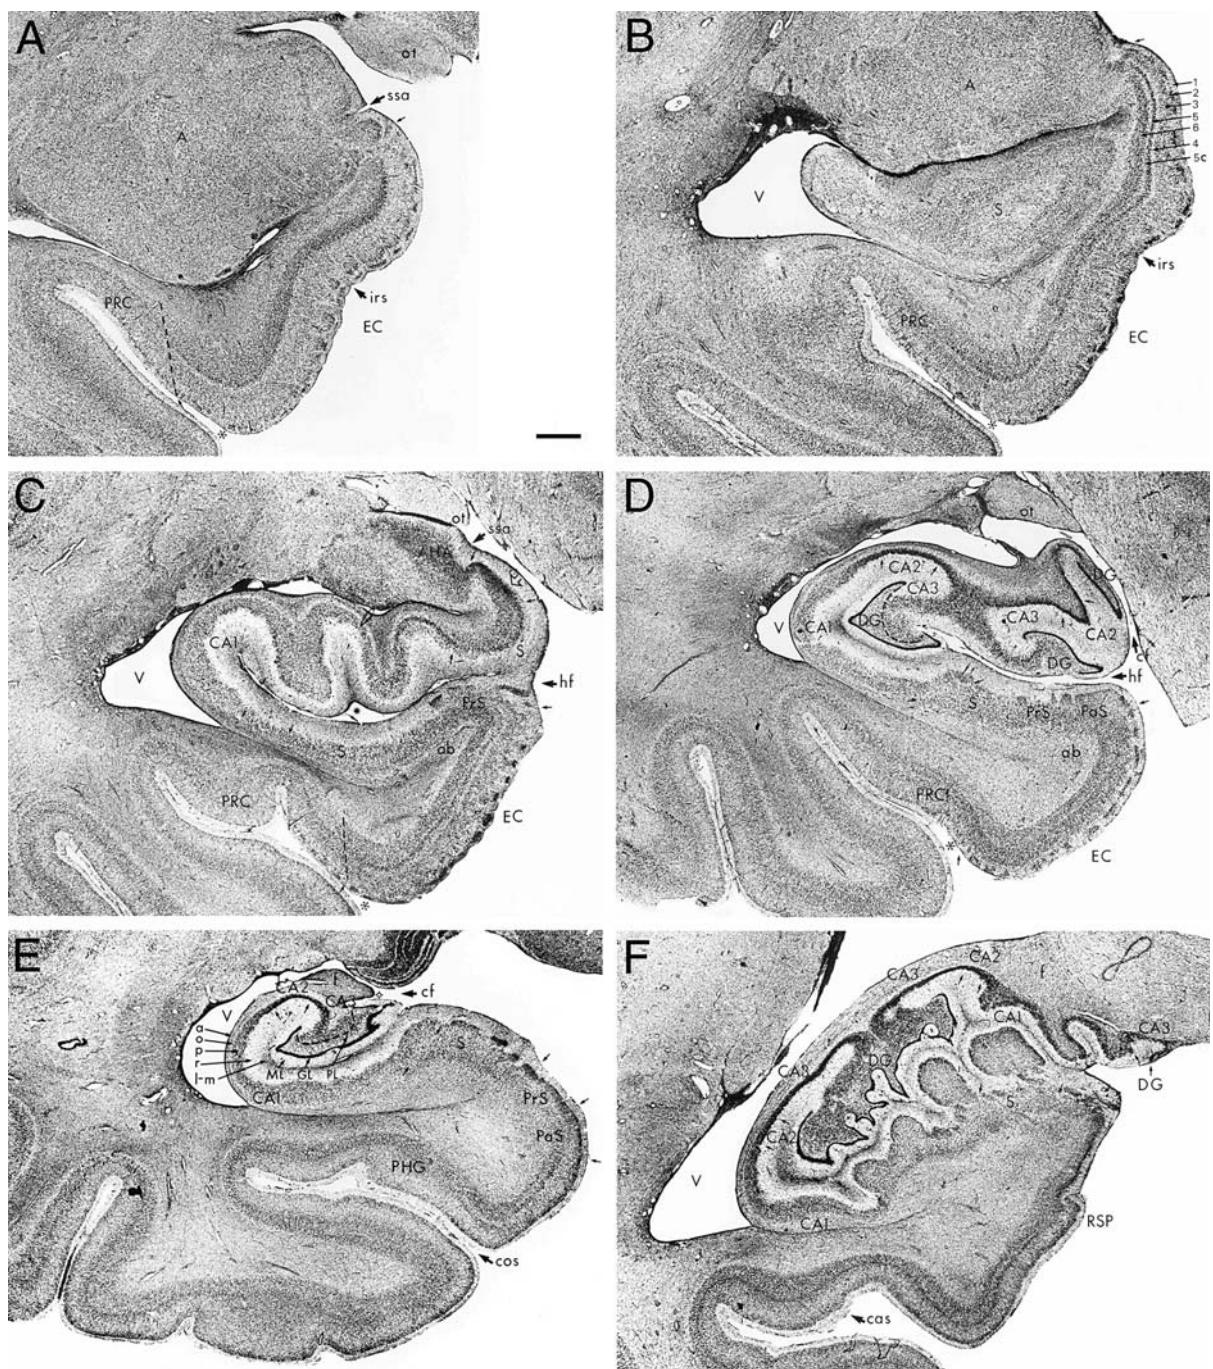

### 3.6.3 Comparison of Monkey and Human Hippocampal Formation

At the risk of making points that may seem obvious, our understanding of the human hippocampus is necessarily primitive compared to that of the rat or the monkey. Because standard experimental tract-tracing studies cannot be done, novel approaches for mapping connections in the

human brain do need to be developed. Perhaps the combination of transcranial electromagnetic stimulation during functional magnetic resonance imaging (fMRI) can provide some information on pathways in the human brain, and one can only hope that the wizardry of molecular biology will someday provide new pathway-selective markers that allow comparative studies of the rat, monkey, and human hippocampal formation. That being said, we next provide a short overview of the neuroanatomy of the human hippocampal formation.

### Cytoarchitectonic Organization

The general appearance of the human hippocampal formation is reminiscent of the monkey hippocampal formation (Figs. 3-2, 3-45, 3-54). Yet, differences are also apparent. For example, the CA1 field of the hippocampus is even thicker in humans than in monkeys (Fig. 3-49); in some regions, it is as much as 30 cells thick. In addition to being thicker, the CA1 pyramidal cell layer takes on a distinctly multilaminate appearance, with cells of different size and shape predominating at different depths of the layer. Unfortunately, there is little information concerning the exact morphological or neurochemical characteristics of these neurons; there is not even a comprehensive Golgi analysis of the neurons of the human dentate gyrus and hippocampus.

**Figure 3-54.** Nissl-stained coronal sections through the human hippocampal formation, arranged from rostral (A) to caudal (F). A, amygdaloid complex; a, alveus; ab, angular bundle; ac, anterior commissure; AHA, amygdalo-hippocampal area; CA1, CA1 field of the hippocampus; CA2, CA2 field of the hippocampus; CA3, CA3 field of the hippocampus; cas, calcarine sulcus; cf, choroidal fissure; cos, collateral sulcus; DG, dentate gyrus; EC, entorhinal cortex; f, fimbria; GL, granule cell layer of the dentate gyrus; hc, hippocampal commissure; hf, hippocampal fissure; irs, intrarhinal sulcus; LGN, lateral geniculate nucleus; l-m: stratum lacunosum-moleculare of

the hippocampus; ML, molecular layer of the dentate gyrus; o, stratum oriens of the hippocampus; ot, optic tract; p, pyramidal cell layer of the hippocampus; PaS, parasubiculum; PHG, parahippocampal gyrus (areas TF and TH); pl, polymorphic layer of the dentate gyrus; PRC, perirhinal cortex (areas 35 and 36); PrS, presubiculum; r, stratum radiatum of the hippocampus; RSP, retrosplenial cortex; S, subiculum; ssa, sulcus semianularis; V, temporal horn of the lateral ventricle. The numbers in B indicate the layers of the entorhinal cortex. Bar in A = 2 mm and applies to all panels.

Another obvious difference is the cellular composition of the region enclosed within the limbs of the granule cell layer. There are obviously far more cells in this region, and most appear to be cells of the CA3 field. The polymorphic layer of the dentate gyrus (the hilus) forms a narrow band that lies just subjacent to the granule cell layer. Little is known about the morphology of cells in the human dentate gyrus. As indicated in the comparison between the rat and the monkey, however, there are clear differences in the morphology of certain cell types. As many as 30% of granule cells in the human dentate gyrus have basal dendrites (Fig. 3–50); this number may be even larger than in the monkey.

Even less is known about the human subiculum, presubiculum, and parasubiculum. Although the distribution of various neurochemicals or receptors has been incidentally illustrated during the course of large survey studies, almost nothing has been written on the cellular morphology of these regions. The human entorhinal cortex has attracted considerably more attention because of its vulnerability in Alzheimer's disease. Although the same general regions identified in the monkey can be identified in the human, there is evidence for additional fields in the human entorhinal cortex. Classic cytoarchitectonicists, for example, have defined as many as 27 divisions.

### Connections

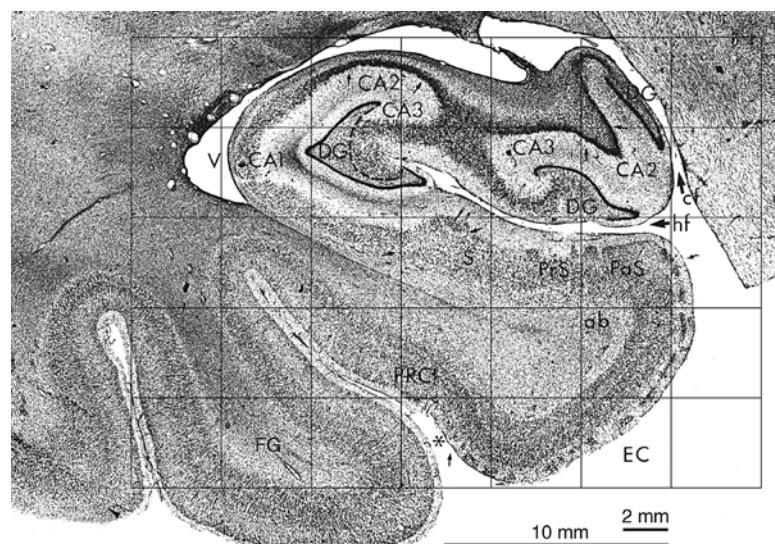

There is little information concerning the organization of connections in the human hippocampal formation owing to the fact that most neuroanatomical tracing techniques require injection of tracers into the living brain. Some investigators have relied instead on techniques such as local application of the lipophilic dye DiI to map short pathways in human postmortem material. Clifford Saper and colleagues have used this technique to study the connections of the granule cells and the projections of the enclosed portion of CA3 (Lim et al.,

1997a,b). They found that both the mossy fiber projection and the Schaffer collateral system (from CA3 to CA1) can be labeled over short distances by DiI and that these projections resemble those observed in the monkey. As important as these limited observations are, they highlight the fact that we do not currently know whether the neuroanatomical connections that have been described for the rat and the monkey are applicable to the human brain.

### Magnetic Resonance Imaging of the Human Hippocampal Formation

With the emergence of MRI studies of the human brain, there have been numerous structural (Jack et al., 2003) and functional (Maguire et al., 2003) studies of the human hippocampal formation. Studies have used both manual tracing techniques as well as algorithms for automated segmentation. Of course, without the benefit of cytoarchitectonic guidance, it has generally proven difficult if not impossible to differentiate the component parts of the hippocampal formation. It has even been complicated to define accurately the boundaries of regions, such as the entorhinal cortex (Insausti et al., 1998).

Figure 3–55 presents a coronal section stained by the Nissl method. To get a sense of the dimensions of this region and what can be distinguished during a standard functional imaging study, we have placed a grid of 4-mm square boxes over the medial temporal lobe. With resolution at this level (which might be typical for a standard functional imaging study), one might expect to have one voxel focused over the subiculum or perhaps two voxels over the entorhinal cortex. Other voxels, however, would clearly overlap adjacent fields, such as the dentate gyrus and CA3. Positron emission tomography studies have even poorer spatial resolution. Thus, given current functional imaging technologies, it is difficult to define specific activations for defined subfields of the hippocampal formation.

**Figure 3–55.** Nissl-stained coronal sections through the human hippocampal formation at the caudal aspect of the uncus. The grid overlay consists of squares that are 4 mm on edge. For abbreviations, see Figure 3–11. (Source: Adapted from Amaral, 1999.)

### **Critical Comparison of Neuroanatomy of Rat, Monkey, and Human Hippocampal Formation Must Await Comparable Quantitative Data for Each Species**

This chapter has dealt primarily with the rat hippocampal formation because, as we pointed out at the beginning, much of the neuroanatomical information available has been gained from studies of the rat. Furthermore, much of the electrophysiological and behavioral literature discussed throughout the rest of the book is based on studies in the rat. With the dramatic increase in the use of noninvasive imaging of the human hippocampal formation, particularly in studies of memory, the need has grown for more detailed information about the neuroanatomical organization of the human hippocampal formation. This is also important as increasingly sophisticated models of hippocampus-related pathology are introduced based primarily on rodent studies. A variety of models for temporal lobe epilepsy, for example, have been advanced based on cell degeneration and fiber sprouting in the rat hippocampus. However, if the fundamental circuit diagram of the rat hippocampal formation is different from that of humans, models based on the rat may be misleading.

Unfortunately, the extent of the similarities and differences in the hippocampal formation of the rat, monkey, and human cannot yet be accurately gauged. Based on the few examples of established species differences described previously, it would not be surprising if substantial differences exist in the cellular morphology, connectivity, and chemical neuroanatomy of the hippocampal formation across species. The relevance of these differences to the normal function and the pathology of the hippocampal function will be an interesting area of comparative neuroanatomy in the future.

## **3.7 Principles of Hippocampal Connectivity and Implications for Information Processing**

Neuroanatomy has the unfortunate characteristic of being detail-oriented, and it is easy to lose sight of the forest for the trees when absorbing and recounting information on the cells and connections of the hippocampal formation. In the following sections, we take a somewhat more integrative approach and attempt to draw implications from what we have described so far. These implications are generally quite speculative at this point, but they concern the important issue of the functional correlates of the known hippocampal neuroanatomy.

### **3.7.1 Highly Distributed Three-Dimensional Network of Intrinsic Connections**

What is the hallmark of hippocampal connectivity? Beyond the defining aspect of unidirectional connectivity between individual components, perhaps the facet that is most striking is that each of the intrinsic connections of the hippocampal

formation is both massively divergent and convergent. Cells located in a focused point in the entorhinal cortex, for example, can influence neurons in as much as 50% of the entire septotemporal axis of the dentate gyrus. Cells in the polymorphic layer of the dentate gyrus, in turn, can interconnect different levels of the dentate gyrus, providing further spread of information to as much as 75% of the septotemporal axis. Similarly, divergent projections have been described for the CA3 to CA1 connections and for the CA1 to subiculum connections. Thus, a perspective most consistent with the known neuroanatomy is that the hippocampal formation contains a series of three-dimensional networks of connections. Depending on the synaptic interactions of these connections (excitatory versus inhibitory), as well as the setting of the myriad physiological parameters described in Chapter 5 (e.g., density and efficiency of synapses, transmitter release, synaptic plasticity), they might focus information processing to a specific level, recruit neurons at distant levels into the ongoing processing, or have no effect at all. Presumably, the role of this distributed network will become better understood as increasingly massive parallel electrophysiological recording procedures are employed.

### **3.7.2 Functional Implications of the Septotemporal Topography of Connections**

Given the septotemporal topography observed throughout the hippocampal formation, there may still be some segregation of functional divisions in this system. Although the massively divergent/convergent nature of hippocampal connections is inconsistent with a high degree of spatially restricted information processing, the possibility remains that there are a few septotemporally positioned domains of relatively restricted information processing, at least at early stages, through the hippocampal circuitry. It appears that there are at least three separable domains of neurons in the entorhinal cortex: a lateral region, a mid region and a medial region. The most laterally situated domain of neurons innervates the septal half of the dentate gyrus and other innervated hippocampal fields; the mid region innervates the next quarter; and the medial domain innervates the temporal quarter of the dentate gyrus (Fig. 3–41). Because the lateral portion of the rat entorhinal cortex receives the bulk of the input from other neocortical areas, it is reasonable to assume that septal levels of the hippocampal formation are more highly involved with processing exteroceptive sensory information. Because the medial portions of the rat entorhinal cortex are preferentially innervated by structures such as the amygdaloid complex, the temporal portion of the hippocampal formation may preferentially deal with interoceptive or emotional information. Because virtually all of the *in vivo* electrophysiological analysis of the rat hippocampal formation has been carried out in the septal portion (and most of the *in vitro* work was carried out to give slices from the rostral and mid-septotemporal levels), it is of interest to determine whether fundamentally

different types of response patterns are observed when temporally situated neurons are probed. Several lines of behavioral data from lesioned animals are already consistent with this idea (see Chapter 14).

### 3.7.3 Functional Implications of the Transverse Topography of Connections

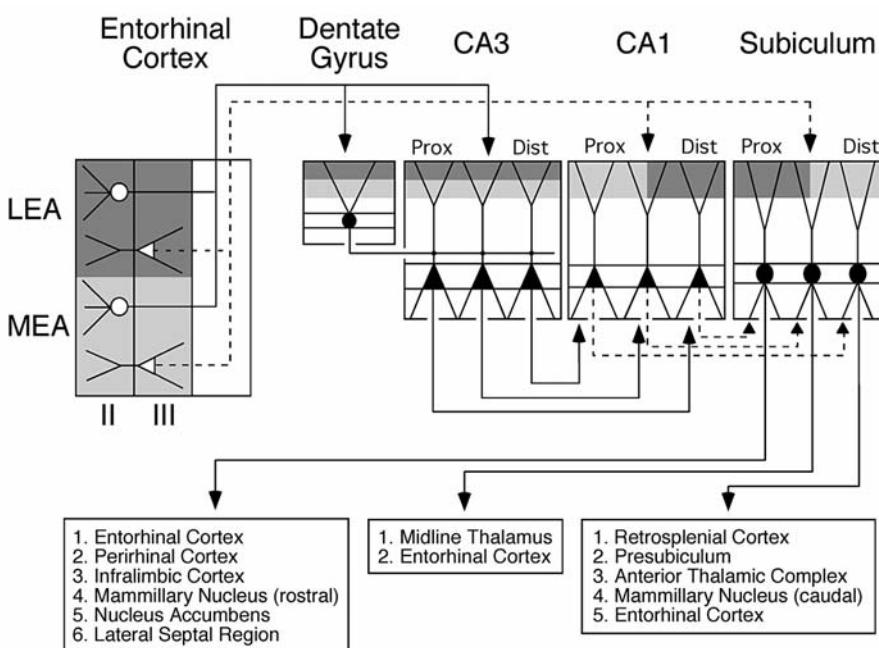

Despite the fact that intrinsic hippocampal connections have an extensive septotemporal distribution, they are not uniformly distributed along the transverse axis. This organization raises the possibility of partially independent channels of information flow through and out of the hippocampal formation (Fig. 3–56). As we mentioned previously, it is not the case that every CA1 cell has equal probability of input from every CA3 cell. The intrinsic circuitry of the hippocampal formation appears to be organized such that cells located at a particular transverse position in a field are much more likely to be connected with cells located at a particular transverse position of the innervated field. This allows the possibility, therefore, that there is some channeling of information processing through the various hippocampal fields. As described fully above, cells located proximally in CA3 tend to project to the most distal CA1 cells. Projections from the distal portion of CA3, in contrast, terminate mainly in the proximal portion of CA1. The midportion of CA3 fills in the spaces between these two projections. The CA1 projection to the subiculum demonstrates even more striking transverse topography. The proximal portion of CA1 projects discretely to the distal third of the subiculum; the distal portion of CA1 projects just across the border into the proximal third of the subiculum; and the middle portion of CA1 projects to the midregion of the subiculum.

The tripartite transverse organization in CA1 and the subiculum also appears to be respected by the entorhinal pro-

jections to these fields. The lateral entorhinal cortex projects to the border region of CA1 and the subiculum, whereas the medial entorhinal cortex projects either more proximally in CA1 or more distally in the subiculum. Layer III neurons of the medial entorhinal cortex are heavily influenced by presubiculum input and thus by the thalamus, whereas layer III neurons in the lateral entorhinal area are heavily innervated by the amygdaloid complex.

Taken together, this organization suggests that CA1 cells located close to the CA3 field receive information from a subset of CA3 cells located close to CA2 and a subset of layer III cells located in the medial entorhinal cortex. CA1 cells located closer to the subiculum, in contrast, receive preferential input from CA3 cells located close to the dentate gyrus and from layer III cells in the lateral entorhinal cortex. A prediction would be, therefore, that the response properties of CA1 cells at different transverse positions, at a particular septotemporal level, should be different.

The notion of transverse topography of hippocampal connections is made all the more compelling when it is appreciated that the subicular output is also organized in a columnar fashion, with projections to different brain regions, or different parts of the same brain region, originating from the proximal, middle, and distal thirds of the subiculum. Neurons in the proximal third of the subiculum project to the infralimbic and prelimbic cortices, the nucleus accumbens, and the lateral septal region. Projections from this portion of the ventral part of the subiculum also project to the ventromedial nucleus of the hypothalamus and to the amygdala. The midtransverse portion of the subiculum projects mainly to the midline thalamic nuclei, and neurons in the distal portion of the subiculum project to the retrosplenial portion of the cingulate cortex and the presubiculum. Although all portions of the subiculum project to the entorhinal cortex, the pattern of projections

**Figure 3–56.** Summary of the transverse organization of the connections through the hippocampal formation. This figure highlights the possibility that information is segregated, or “channeled,” through the hippocampal formation and ultimately reaches different recipients of hippocampal output.

reciprocates the topography of the perforant path projections to the subiculum. Thus, the proximal portion of the subiculum projects to the lateral entorhinal area, and more distal portions of the subiculum project to the medial entorhinal area. Thus, from CA3 on through the entorhinal cortex, there exists the potential for information that arrives at the earliest point in this chain of connections to maintain some uniqueness from information that arrives at different portions of CA3. The functional significance of this neuroanatomical pathway segregation is unknown at present.

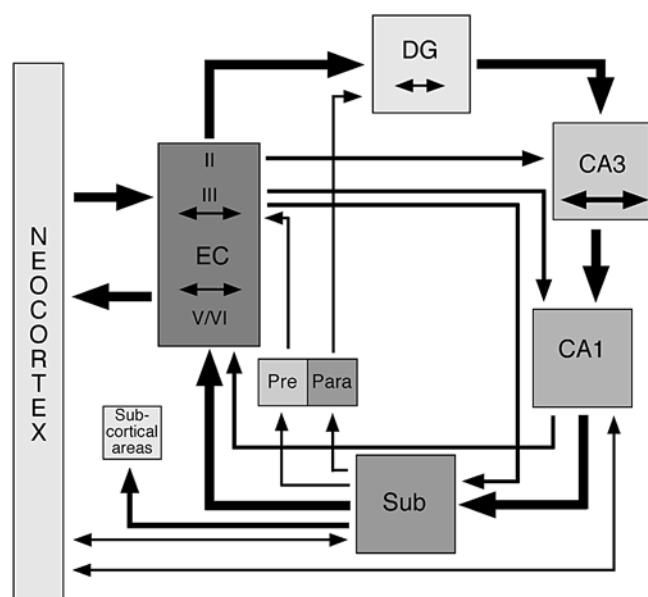

To summarize, although the intrinsic connectivity of the hippocampal formation is highly divergent, the network that is formed is not without some topography. The septotemporal and transverse components of this topography provide the increased probability of communication between certain neurons in each field and thus the possibility of some form of channeling or segregation of information processing in the hippocampal formation.

### 3.7.4 Serial and Parallel Processing in the Hippocampal Formation

A unique feature of the intrinsic hippocampal circuitry is the largely unidirectional organization of the projections that interconnect the various hippocampal regions. A popular notion is that these unidirectional projections also imply an exclusively serial or sequential flow of information—first from the entorhinal cortex to the dentate gyrus, then to the CA3 field of the hippocampus, and so on. However, the data summarized in the body of this chapter clearly indicate that the intrinsic hippocampal circuitry has both serial and parallel projections (Fig. 3–57).

The entorhinal cortex, in particular, contributes many parallel projections to several fields of the hippocampal formation. The same layer II entorhinal cells probably give rise to projections that terminate in both the dentate gyrus and the CA3 field of the hippocampus. Thus, whatever the information conveyed by layer II entorhinal cells, it arrives both monosynaptically and disynaptically (through mossy fiber intermediaries) at CA3. It is not known, of course, whether information from a single entorhinal cell reaches a particular CA3 cell both monosynaptically and disynaptically. This is an important question to resolve in future studies.

The existence of prominent associational connections in the dentate gyrus, hippocampus, and entorhinal cortex also provides the substrate for polysynaptic activation in hippocampal circuits. The functional implication of this more complex circuitry is that each hippocampal region is not entirely dependent on the preceding region for input, which raises the prospect that each region may be acting semi-independently from, as well as in concert with, other hippocampal fields. Hippocampal neuroanatomy is thus consistent with the electrophysiological findings—for example, that CA1 place fields are apparently normal even after pharmacological inactivation of the dentate gyrus.

**Figure 3–57.** Summary of the serial and parallel pathways through the hippocampal formation. Although the intrinsic hippocampal circuitry is largely unidirectional, it contains both serial and parallel projections. See text for details.

## 3.8 Conclusions

Although this chapter has presented a substantial amount of neuroanatomical information, it has only begun to scratch the surface of what is available in the primary literature. However, because we have focused on general features and principles of organization, it should be more than adequate for delving into the molecular and cellular aspects of hippocampal organization (see Chapters 5 and 7) as well as the function of the hippocampal formation in the living organism. The neuroanatomy of the hippocampal formation is unique and predicts that the behavioral functions it subserves are undoubtedly unique as well.

## ACKNOWLEDGMENTS

The authors are indebted to the many colleagues who have worked in our laboratory over the years. Much of the knowledge they have uncovered has gone into the pages of this chapter. We are grateful particularly to Dr. Menno Witter and Dr. Ricardo Insausti, who not only co-authored earlier comprehensive summaries on the neuroanatomy of the rat and human hippocampal formation, but also reviewed the current chapter to help ensure its accuracy. We also thank Dr. Lazlo Seress for additional comments on the manuscript. The original research summarized in this chapter has been supported by the National Institutes of Health and the Human Frontier Science Program. Finally, we are grateful to our families who understand that science requires some sacrifice of time with them. Their support has made this chapter possible.

# Morphological Development of the Hippocampus

## 4.1 Overview

A fundamental question in neurobiology is how the various brain structures and the enormous number of specific interneuronal connections that serve the complex functions of the mature CNS are formed during development. Work on the hippocampal formation has shed light on the principles underlying this process. With the advent of modern genetic approaches, including mutant mice lacking or overexpressing genes important for developmental processes, new insights into the development of the hippocampal formation are in the process of being obtained.

Not all aspects of hippocampal development are covered in this chapter. Traditionally, developmental processes are studied in a descriptive manner by monitoring the formation of mature structures from simpler, undifferentiated stages. Major contributions have also come from studies of the phylogenetic development of the hippocampal formation and have demonstrated that it is a form of phylogenetically old cortex, the archicortex, that develops in the medial wall of the telencephalic vesicle. Owing to the expansion of the cerebral cortex in higher vertebrates, the hippocampal formation is translocated medially and ventrally into the inferior portion of the lateral ventricle. In rodents, the primary focus of this chapter, much of the hippocampus is located dorsally, the curved structure of the hippocampus reflecting this rotation of the telencephalon (see Chapter 3). Phylogenetic development is not dealt with in detail here, although we do present some information on species other than rodents where appropriate. For a fuller treatment of phylogenetic differences, the reader is referred to the exhaustive coverage by Stephan (Stephan, 1975).

What are the fundamental issues regarding the development of the hippocampus? As in other organs, it is important to understand the signals governing cell proliferation. Once

neurons are formed, what molecules and mechanisms determine the fate of newly generated cells? For example, postmitotic neurons migrate to their final destination. How does this happen? Upon arrival in their appropriate structure or layer, the postmigratory neuroblasts start to develop their processes. Why does only one axon originate from the cell body, whereas many dendrites emerge from it? Moreover, as these processes emerge, they do so in an organized manner. For example, in the various hippocampal fields, principal neurons display a rather uniform structure. What are the molecules and mechanisms controlling this uniform differentiation? Why do the nonprincipal cells that invade the hippocampus from the ganglionic eminence (Pleasure et al., 2000) form such a heterogeneous population of neurons? Finally, what are the determinants of synapse formation? The hippocampus is a laminated structure in which all fibers originating from a particular afferent source terminate at identical dendritic segments. How is this layer-specific termination of hippocampal afferents to be explained? To what extent is neuronal activity involved in the differentiation of dendrites, dendritic spines, and synaptic contacts?

An attempt is first made to summarize our present knowledge on neuronal generation and migration in the hippocampus. We then address the development of major hippocampal connections by describing determinants of pathfinding, target layer recognition, and synapse formation of hippocampal afferents.

## 4.2 Neurogenesis and Cell Migration

Most of our knowledge about cell formation in the rodent hippocampal formation dates back to the seminal studies by Angevine (1965) and Altman and coworkers (Altman, 1966; Altman and Das, 1966; Altman and Bayer, 1975; Bayer, 1980).

These important papers provided the first descriptions of the origin, the time course of the generation, and the laminar distribution of principal neurons, pyramidal neurons, and granule cells.

#### 4.2.1 Pyramidal Neurons

Stem cells of both pyramidal neurons and granule cells originate from the ventricular germinal layers (or ventricular neuroepithelial layers) that are located below the ventricular wall along the CA1 area. In contrast to the neocortical ventricular germinal layers, there is no subventricular zone at the hippocampal germinal area. Therefore the multiplying neurons directly migrate from the ventricular zone to their final target region (Altman and Bayer, 1990b). Pyramidal neurons of the rodent hippocampus are generated between embryonic days (E) 10 and E 18 in the mouse (Angevine, 1965) and between E 16 and E 21 in the rat brain (Bayer, 1980). Pregnancy lasts 19 days in mice and 21 days in rats. CA3 pyramidal cells are generated with a peak of generation on E 17, whereas the peak of cell generation of CA1 pyramidal cells is on E 18 and E 19 (Bayer, 1980).

Except for the CA3 pyramidal cells, the route of migration is short because the hippocampus closely follows the curve of the ventricle (Fig. 4-1). Future CA1 neurons form cell rows oriented perpendicular to the ventricular area that end in the incipient CA1 pyramidal layer. From the ventricular germlinal layer, the early-generated CA3 pyramidal cells migrate 3 to 4 days longer (than the CA1 cells) along the ventricular wall in the only prenatally existing intermediate zone (Altman and Bayer, 1990b). As a consequence, the later-generated CA1 pyramidal cells establish a distinct layer earlier than the CA3 cells. It remains an open question whether the pyramidal neurons in CA1 and CA3 originate from the same segment of the hippocampal neuroepithelium. A separate ori-

gin might explain their characteristic morphological differences. On E 14.5 and E 15.5, the newly formed pyramidal cells already show field-specific genetic markers characteristic for the CA1 or CA3 area of the mouse hippocampus (Tole et al., 1997).

At birth, the pyramidal layer in the rat is thick and composed of 6 to 10 rows of neuronal somata. As the hippocampus gets larger postnatally, the pyramidal layer becomes thinner; and in adult rats it comprises two or three cell layers. This process of pyramidal cell rearrangement is unlikely to be a passive one due, for example, to the volumetric increase of the hippocampal formation. Postnatally generated glial cells might contribute to the reorganization. In fact, neonatal X-ray irradiation, which has its greatest impact on glial cells, prevents formation of the mature pyramidal cell layer (Czurkó et al., 1997). However, early-generated reelin-synthesizing Cajal-Retzius cells also appear to play a role in the formation of the pyramidal cell layer (see below).

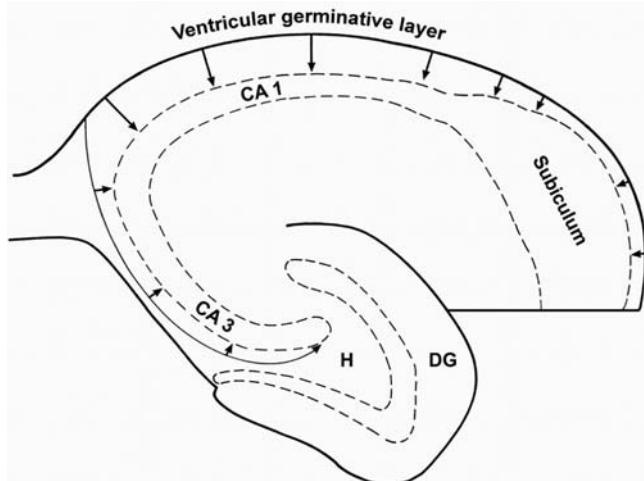

It is worth noting that the pyramidal cell layer of the hippocampus also forms quite early in the human brain. The pyramidal layer is formed during the first half of pregnancy (Arnold and Trojanowsky, 1996). In addition, the CA1 to C3 subregions of the hippocampus can be differentiated as early as during the 16th embryonic week. Regional differentiation of the hippocampal formation thus substantially precedes that of the neocortex (Kostovic et al., 1989).

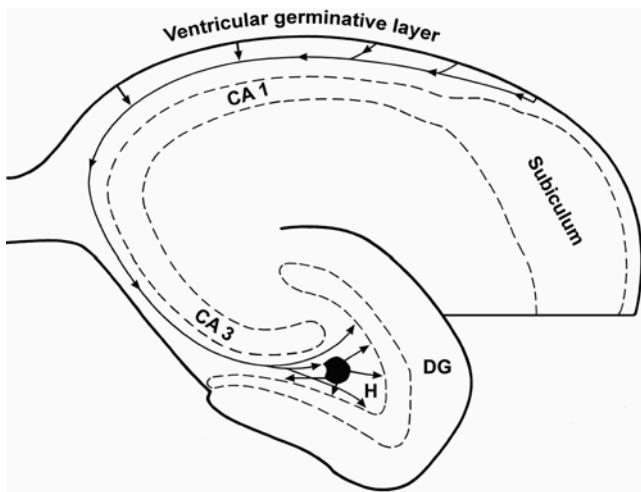

#### 4.2.2 Granule Cells

The formation of the granule cell layer of the dentate gyrus differs in many respects from that of the pyramidal cell layer of the hippocampus. The first granule cells of the mouse dentate gyrus appear at approximately the same time as the first pyramidal cells (i.e., on E 10) (Angevine, 1965). There is a suprapyramidal to infrapyramidal, or medial to lateral, gradient in the formation of the two blades of the granule cell layer; that is, granule cells at the tip of the suprapyramidal blade are the first to be generated. The generation of granule cells lasts a much longer time than that of pyramidal neurons. There is substantial evidence that it continues long into the postnatal period and, at a reduced level, into adulthood. In the rat dentate gyrus, first granule cells are generated 1 day later than the first pyramidal neurons (i.e., on E 17) (Bayer, 1980). In rats, 15% of the granule cells are generated before birth (Altman and Bayer, 1975). Therefore, the time span of granule cell generation is approximately three times longer than that of pyramidal neurons and is likely to continue for the rest of the animal's life (for adult neurogenesis, see Chapter 9). Interestingly, adult granule cell formation does not follow the suprapyramidal to infrapyramidal sequence observed during the embryonic and early postnatal period. Granule cells are generated with no obvious pattern in both blades (Kempermann et al., 1997a,b).

The prolonged postnatal formation of granule cells is not a unique feature of rodents. In humans, granule cell formation lasts more than 30 weeks, beginning at approximately the 13th

**Figure 4-1.** Route of migration (arrows) of pyramidal cells from the ventricular germinative layer to the subiculum and to areas CA1 to CA3. DG, dentate gyrus; H, hilus.

**Figure 4–2.** Route of migration of dentate granule cells. There are two possible ways for granule cells to reach the suprapyramidal or infrapyramidal blade of the dentate gyrus. 1, Granule cells formed in the germinative layer move along the pyramidal layer of Ammon's horn directly to the granule cell layer (arrows); 2, after migration from the ventricular germinative layer, stem cells form a secondary germinative layer (black spot) in the hilus (H) and, following further proliferation, move to the granule cell layer (arrows) of the dentate gyrus (DG). During the embryonic period both routes are used, whereas the latter route prevails during the postnatal period.

embryonic week (Humphrey, 1967; Seress et al., 2001). There is also evidence for adult neurogenesis in the human dentate gyrus (Eriksson et al., 1998).

The route of migration of the postmitotic granule cells is much longer than that of pyramidal neurons. Postmitotic cells must migrate from the ventricular germinative layer along the already formed hippocampus through the narrow intermediate zone between the alveus and future stratum oriens toward the hippocampus, where they form the cup-shaped dentate gyrus that surrounds the tip of CA3 (Fig. 4–2).

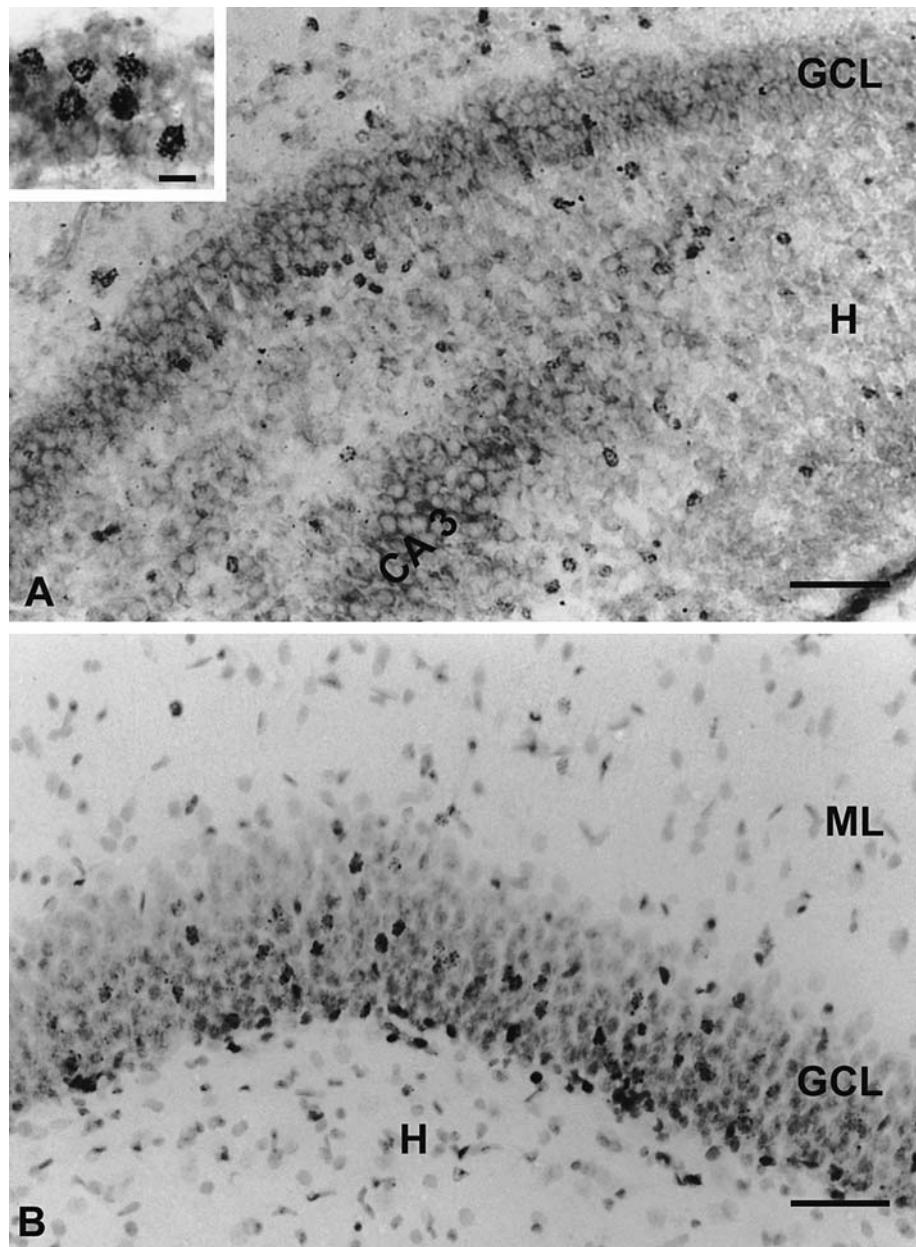

The two blades of dentate granule cells and the tip of the CA3 area border the hilus of the dentate gyrus (see Chapter 3). During postnatal ontogenesis, the hilus (Fig. 4–3A, see color insert) contains large numbers of mitotic cells (Bayer, 1980). Large hilar neurons, such as the mossy cells, are generated between E 15 and E 21 (Bayer, 1980). In addition, virtually all hilar interneurons, representing approximately half of the hilar cells (Seress and Ribak, 1983), are of subcortical origin and invade the hilus from the lateral and medial ganglionic eminence (Pleasure et al., 2000). Thus, the enduring cell proliferation in the hilar region (Fig. 4–2) mainly represents local generation of granule cells (Altman and Bayer, 1990c). In fact, the rate of postnatal cell formation in the hilus is similar to that in the periventricular germinal layer of the telencephalon (Seress, 1978). It is therefore reasonable to assume that the hilar region is a “displaced” secondary germinal layer of the dentate gyrus (Altman and Bayer, 1975; Seress, 1977). Proliferating cells persist in the hilar region during the entire

period of granule cell neurogenesis, and persisting hilar stem cells may also form new neurons during adulthood (Altman and Bayer, 1975, 1990a; Seress, 1978). In rodents, the total number of hilar cells rapidly decreases between postnatal days 10 and 25, with a parallel increase in the number of granule cells in the granule cell layer, suggesting that newly formed cells from the hilus move to the granule cell layer (Seress, 1977). During the entire period of postnatal development, labeled granule cells are always observed inside the granule cell layer as early as 1 hour following the injection of bromodeoxyuridine (BrdU) or thymidine (Fig. 4–3, see color insert). It is likely that stem cells from the hippocampal ventricular zone move to the hilar region and form a secondary germinal zone (Fig. 4–2). This possibility is supported by the fact that a single neonatal X-ray irradiation prevents further cell formation in both the ventricular zone and hilus without affecting the already formed neuronal subpopulations (Czurko et al., 1997).

To the extent that it has been studied, the developmental characteristics of the rodent hilar region are also observed in humans. In human fetuses, a large number of mitotic cells (indicated by the presence of Ki-67) are present in the hilar region from the 13th week onward (Fig. 4–4A, see color insert). These proliferating cells account for a large percentage of the total hilar cell population in 16- to 18-week-old fetuses (Seress, unpublished observations). Proliferating cells can also be found in the hilus during the late gestational period and after birth (Seress et al., 2001) (Fig. 4–4B, see color insert). Persisting stem cells have also been found in the hilus of the adult human hippocampal formation (Eriksson et al., 1998). However, proliferative activity drops off considerably during the postnatal period (Seress et al., 2001).

There is little morphological variability among granule cells even though they may be located at different places in the granule cell layer and may be born at different time points. This morphological uniformity leads one to assume that all granule cells originate from the same stem cell population. However, granule cells may originate from different germinal sources (Altman and Bayer, 1990a), and precursors of the perinatally and postnatally forming granule cells can be distinguished (Altman and Bayer, 1990c). A newly discovered gene (*Lef1*) has been found to distinguish granule cell precursors. This gene is expressed in the proliferating precursors of granule cells in the ventricular zone as well as in those of the secondary germinal zone. *Lef1*-deficient mice fail to form dentate granule cells (Galceran et al., 2000).

Most of the granule cells display similar features in the rodent and primate dentate gyrus. However, a subpopulation of granule cells in the primate dentate gyrus is characterized by the formation of basal dendrites (Seress and Mrzljak, 1987). It is likely that local environmental factors, such as available space for dendritic expansion, may play an important role in the formation of basal dendrites on granule cells (Seress and Frotscher, 1990). Basal dendrites have also been regarded as a pathological phenomenon. For example, increased activity of the granule cells may evoke the formation of basal dendrites in epileptic rats (Spigelman et al., 1998).

**Figure 4-3.** A. Photomicrograph showing  $^3\text{H}$ -thymidine-labeled cells (black) in the hilus (H) and granule cell layer (GCL) of the dentate gyrus of a 5-day-old rat that received a single injection of thymidine 1 hour before sacrifice. At this age, the infrapyramidal blade is still very short and hardly reaches the tip of the CA3 pyramidal layer. The large number of labeled cells above the granule cell layer suggests that glial cells are also formed at this age because the molecular layer contains only a few interneurons, which are born prenatally. Note the lack of labeling in the CA3 area of Ammon's horn where pyramidal cells are generated prenatally. *Inset*. Labeled cells in the granule cell layer of this animal at higher magnification. Section is 10  $\mu\text{m}$  thick and stained with toluidine blue. B. BrdU-labeled cells (brown) in the suprapyramidal blade of the dentate gyrus of a 3-month-old rat that received daily injections of BrdU from P4 to P6. Bars: A, B, 50  $\mu\text{m}$ ; *inset*, 10  $\mu\text{m}$ .

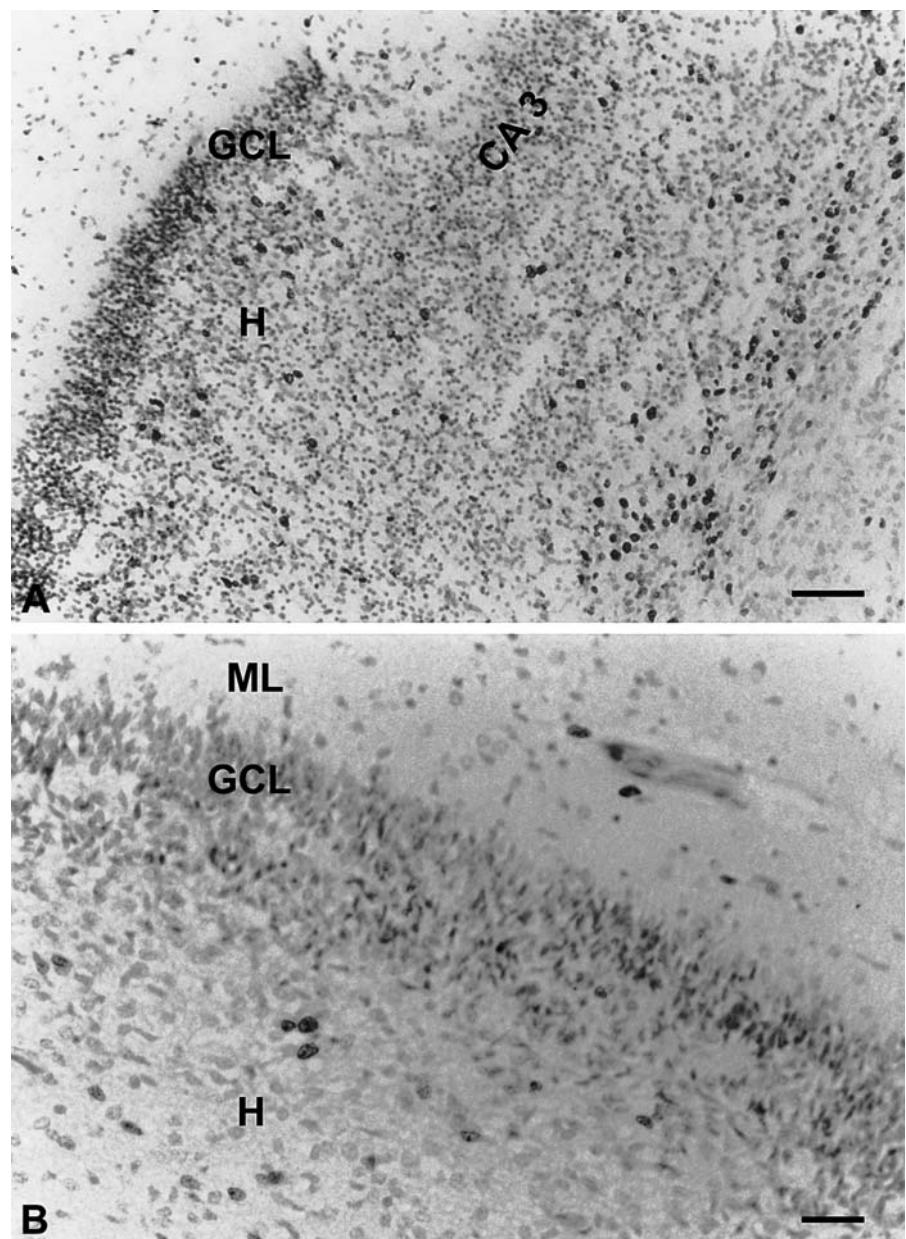

Epileptic seizures also appear to lead to an increased number of granule cells with basal dendrites in the human dentate gyrus (von Campe et al., 1997).

In summary, dentate granule cells in different mammalian species form a largely homogeneous neuronal population. Their dendritic morphology, however, may be modified to some extent depending on the local environmental or pathological factors.

#### 4.2.3 Local Circuit Neurons and Hilar Neurons

Local circuit neurons of the hippocampal formation differ from the principal cells in both their morphological and developmental features. In contrast to the morphologically

uniform granule cells and pyramidal neurons, local circuit neurons of the hippocampal formation form a heterogeneous population (Freund and Buzsáki, 1996) (see Chapters 3 and 8). Even the classic basket cell can be subdivided into five types based on differences in location and dendritic arborization (Ribak and Seress, 1983). Neurochemical studies have confirmed the existence of at least two basket cell types, which display different receptors and co-transmitters (Hájos et al., 1998; Katona et al., 1999). In addition to dendritic morphology, differences in axonal projections also distinguish subpopulations of local circuit neurons in both the dentate gyrus (Halasy and Somogyi, 1993a,b) and the hippocampus proper (Soriano and Frotscher, 1989, 1993; Halasy et al., 1996; Spruston et al., 1997; Vida et al., 1998; Vida and Frotscher, 2000).

**Figure 4-4.** A. MIB-1 (Ki-67)-labeled cells (brown) in the dentate gyrus of a 16-week-old human fetus. A large number of labeled cells are seen in the hilus (H) underneath the granule cell layer (GCL). Note the absence of labeled cells in the CA3 area of Ammon's horn. In contrast, numerous labeled cells, migrating from the ventricular germinative layer along the pyramidal layer toward the hilus, are seen in the intermediate zone. B. MIB-1 (Ki-67)-labeled cells are still frequent in the hilus (H) of a 28-week-old fetus. The granule cell layer and molecular layer (ML) contain only a few labeled cells. Sections are 10  $\mu\text{m}$  thick and are stained with cresyl violet. Bars: A, 50  $\mu\text{m}$ ; B, 20  $\mu\text{m}$ .

In contrast to the heterogeneity of the local circuit neuron phenotype, their neurogenetic profile seems much more homogeneous; that is, there are no developmental events that would allow one to predict the large diversity among  $\gamma$ -aminobutyric acid (GABA)ergic cells. GABAergic interneurons are generated early in both the dentate gyrus and the hippocampus (Bayer, 1980). This conclusion was based on the observation that neurons in the molecular layer and hilus of the dentate gyrus as well as in the strata oriens, radiatum, and lacunosum-moleculare appear earlier than the neurons in the principal cell layers (Bayer, 1980). The peak cell formation in both the hilus and the molecular layer precedes the onset of granule cell generation. Similarly, in the CA1 to C3 areas, the peak cell generation in the strata oriens and radiatum pre-

cedes formation of the first pyramidal cells by 1 day (Bayer, 1980). Cell formation of the cells destined to reside in the dendritic layers ceases relatively early. It is reasonable to suggest that this exquisite timing may play some role in pyramidal and granule cell morphogenesis, although there is no evidence for this at this time.

Double-labeling studies have confirmed that GABAergic neurons are generated earlier than the principal cells of the hippocampal formation (Amaral and Kurz, 1985; Lübbbers et al., 1985; Soriano et al., 1989a,b; Dupuy and Houser, 1997, 1999). The site of origin of hippocampal local circuit neurons is in the ventricular/subventricular zone of the medial and lateral ganglionic eminence. Available data do not allow one to correlate the site of generation with the diverse

morphological features of the local circuit neurons (Pleasure et al., 2000).

Although GABAergic neurons are generated and positioned before their target cells, some of them change their position later on in development (Dupuy and Houser, 1999). Moreover, the differentiation of axonal collaterals and the arborization of dendrites takes place relatively late in postnatal life (Seress et al., 1989; Lang and Frotscher, 1990; Seress and Ribak, 1990). This raises the possibility that the maturation of local circuit neurons is influenced by interactions with their synaptic partners.

#### **4.2.4 Determinants of Neuronal Migration in the Hippocampus**

In the neocortex, cell layers are formed in an inside-out manner; that is, early-generated neurons form deep layers, whereas superficial layers are established by cells born late in ontogenetic development. As in the neocortex, the hippocampus follows a similar inside-out migration. The dentate gyrus, in contrast, has an outside-in migration pattern; that is, early-generated granule cells populate superficial portions of the granule cell layer and later-formed granule cells are located progressively deeper.

What are the signals controlling neuronal migration that lead to such well defined cell layers of principal neurons? It has been known for some time that these migrational processes are under fairly strict genetic control. In 1951, a mouse mutant, the reeler mouse, was described (Falconer, 1951) in which neocortical lamination was reversed. Recently, the gene missing in reeler mice was discovered (d'Arcangelo et al., 1995; Hirotsune et al., 1995). The gene product, reelin, was found to be synthesized by a well known group of neurons in the marginal zone, originally described by Cajal and Retzius more than 100 years ago (Retzius, 1893, 1894; Ramón y Cajal, 1911). These Cajal-Retzius cells are remarkable neurons. They extend long dendrites horizontally in the marginal zone, parallel to the pial surface. Cajal-Retzius cells synthesize and secrete reelin, so it forms a component of the extracellular matrix in the marginal zone (d'Arcangelo et al., 1997).

Available data are compatible with the proposal that reelin acts as a stop signal for migrating neurons. Early-generated neurons are stopped as they approach the marginal zone, which has a high concentration of reelin. For later neurons to reach this same stop signal, they must migrate past the early-generated neurons and approach the reelin-containing marginal zone. In this way the characteristic inside-out lamination of the cortex is formed (Frotscher, 1997, 1998). Because the marginal zone ultimately becomes layer I of the cortex, it remains an almost cell-free layer in normally developing mice. In reeler mice, in contrast, layer I (which does not have the stop signal) is densely filled with neurons. Early-generated neurons migrate until they reach the pial surface, and later-generated neurons accumulate underneath. The normal inside-out lamination is reversed (Fig. 4-5).

Although this scenario is certainly an oversimplification, it can be employed to explain the unusual lamination in the reeler hippocampus and dentate gyrus. In the hippocampus, a double pyramidal cell layer is formed in reeler mice. As in the neocortex, the marginal zone is located directly underneath the pial surface, which in the hippocampus proper corresponds to the stratum lacunosum-moleculare. The stratum lacunosum-moleculare contains Cajal-Retzius cells, and its extracellular matrix is enriched in reelin. The absence of the stop signal reelin in reeler mutants may allow some pyramidal cells to migrate deep into the stratum radiatum, forming there a second pyramidal layer (Stanfield and Cowan, 1979; Deller et al., 1999b).

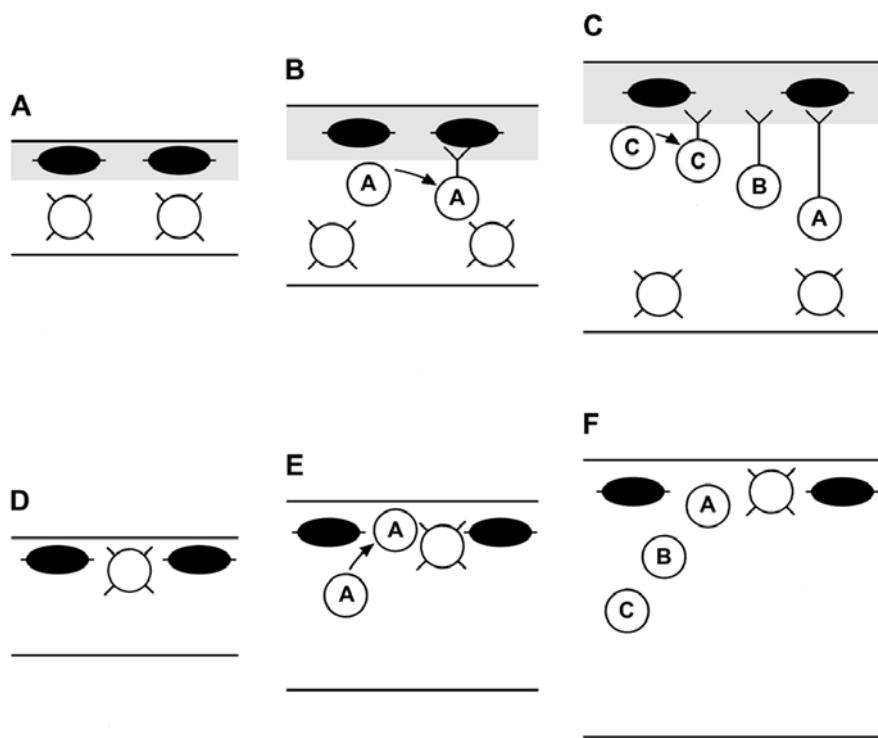

The marginal zone of the dentate gyrus corresponds to the outer portion of the molecular layer. Assuming that reelin acts as a stop signal, one would expect that many granule cells would invade the molecular layer in reeler mice because they would not be stopped earlier. However, in the reeler dentate gyrus, the granule cells do not invade the molecular layer, whereas many granule cells are found in the hilar region with their dendrites oriented in all directions (Stanfield and Cowan, 1979; Drakew et al., 2002). What might be the explanation of the hilar location of the granule cells? Förster et al. (2002) found that the radial glial fibers required for neuronal migration are dramatically altered in the dentate gyrus of reeler mice. Thus, it has been proposed that the granule cell migration defect seen in the reeler mutant is due to a malformation of the radial glial scaffold required for proper neuronal migration (Förster et al., 2002; Frotscher et al., 2003; Zhao et al., 2004).

#### **4.3 Development of Hippocampal Connections**

When describing the development of neuronal connections, it is useful to distinguish at least three processes. First, there is the way an axon navigates to the target region, called axonal pathfinding. During this process, both soluble and membrane-bound molecules and attractant and repellent signals are involved (see Tessier-Lavigne and Goodman, 1996, for review). Next, the axon must recognize the appropriate target region and target cell, called target recognition. As far as the hippocampus is concerned, the segregated fiber systems must recognize their appropriate layers. Finally, there is the process of synapse formation.

There is substantial and increasing evidence that a variety of molecules are involved in these three processes. In principle, membrane-bound molecules that attract or repel the growing tip of an axon, diffusible factors building up a gradient, and components of the extracellular matrix are likely to play a role. The involvement of various ligand/receptor families in the formation of hippocampal connections has been summarized by Skutella and Nitsch (2001). Thus, the various

**Figure 4-5.** Hypothetical function of reelin in cortical lamination. *A*. In wild-type mice, the preplate splits into the marginal zone, largely containing Cajal-Retzius cells (black cells), and the subplate (white cells). Cajal-Retzius cells synthesize and secrete reelin (stippled zone). *B*. The cortical plate develops between the marginal zone and the subplate. An early-generated cell (*A*) migrates from the ventricular zone toward the marginal zone, where its migration is stopped by reelin. *C*. With increasing cortical thickness, the reelin-containing marginal zone is moved further outward, allowing later-generated neurons (*B*, *C*) to migrate farther than their predecessors before their migration is stopped by reelin. This way the characteris-

tic inside-out pattern of cortical lamination is formed. Apical dendrites, branching in the reelin-containing marginal zone, are extended by the increase in cortical thickness. *D*. In reeler mice lacking reelin, the separation of the subplate from the marginal zone does not take place. *E*. In the absence of reelin, migrating cells (*A*) are not stopped and reach the pial surface. *F*. Later-generated neurons (*B*, *C*) accumulate underneath the early-generated neurons (*A*). As a result, the normal inside-out pattern of cortical lamination is reversed, and apical dendrites are not anchored in the marginal zone. (Source: Frotscher, 1997.)

semaphorins and their receptors neuropilin 1 and 2 and the plexins netrin 1 and its receptor DCC (deleted in colon cancer), the ephrin (Eph) family of tyrosine kinases and their ligands, the ephrins, and Slit and Robo were found to contribute to establishment of the hippocampal circuitry.

In the following paragraphs, we deal with the development of some of the main hippocampal afferent connections: those from the entorhinal cortex, the septum, and the contralateral hippocampus. Whereas the fibers from both the entorhinal cortex and the contralateral hippocampus are examples of a strictly laminated termination of hippocampal afferents, fibers from the septum have a more diffuse distribution.

#### 4.3.1 Entorhinal Connections

Neuroanatomists have been intrigued by the unique course of the entorhino-hippocampal projection, which perforates the subiculum and hippocampal fissure en route to the dentate

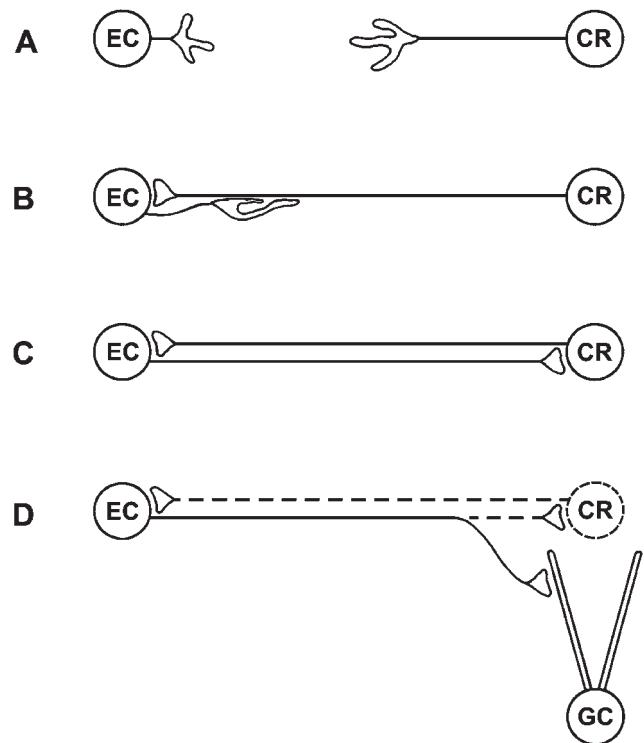

gyrus. From a developmental point of view, one would expect that the perforant path would utilize robust guidance signals for axonal pathfinding and target layer recognition. The entorhinal fibers terminating in the outer two-thirds of the dentate molecular layer and in stratum lacunosum-moleculare of the hippocampus proper form a sharp boundary toward the adjacent commissural/associational fibers in the inner molecular layer of the dentate gyrus and in the stratum radiatum of the hippocampus (see Chapter 3).

Recent studies have shed some light on the mechanisms underlying the pathfinding of entorhinal axons (del Rio et al., 1997; Chedotal et al., 1998; Förster et al., 1998; Frotscher, 1998; Ceranik et al., 1999; Deller et al., 1999a,b; Savaskan et al., 1999; Skutella et al., 1999; Steup et al., 1999). Investigators have focused on repulsive molecules expressed in the hippocampus that would prevent the entorhinal afferents from terminating in proximal layers close to the cell bodies of principal neurons. Similarly, molecules specifically expressed in the entorhinal cortex were studied for their capacity to repel

entorhinal axons, thereby directing them toward the hippocampus. In particular, repulsive effects of semaphorins (Sema3A) on entorhinal fibers have been observed (Steup et al., 1999), an effect that can be blocked by antibodies against the semaphorin receptor neuropilin 1 (Chedotal et al., 1998). As Sema3A is expressed by granule cells, it has been speculated that this expression may be involved in the termination of entorhinal fibers on distal granule cell dendrites. Neuropilin 2, the receptor for Sema3F, is strongly expressed in the hippocampus, whereas the ligand is expressed in the developing entorhinal cortex. As Sema3F is repulsive for growing axons bearing its receptor, this particular pattern may be responsible for the lack of ingrowth of hippocampal and dentate axons into the entorhinal cortex (Chedotal et al., 1998; Steup et al., 1999; Skutella and Nitsch, 2001). Similarly, Slit 1 and Slit 2, being expressed in the entorhinal cortex, can repel axons of hippocampal neurons expressing their receptors Robo 1 and Robo 2 (Nguyen-Ba-Charvet et al., 1999). Also ephrins were found to be involved in repulsive effects on entorhinal axons, restricting their termination to distal dendritic portions of hippocampal neurons (Stein et al., 1999). In addition to these repulsive effects, neurotrophic factors with an attractive *neurotropic* effect, components of the extracellular matrix, and a guiding scaffold provided by pioneer neurons have been found to navigate the axons of entorhinal neurons to their hippocampal target structures.

What could be the sequence of events underlying this complex process? Probably as a first step, a guiding scaffold supporting the directed growth of entorhinal axons toward the hippocampus is formed. In fact, Ceranik et al. (1999) have shown that early-generated Cajal-Retzius cells, located in the marginal zones of the dentate gyrus (outer molecular layer) and hippocampus proper (stratum lacunosum-moleculare), give rise to a heavy projection to the entorhinal cortex that is established before the entorhino-hippocampal projection. Thus, Cajal-Retzius cells in the outer molecular layer of the rat dentate gyrus are retrogradely labeled from the entorhinal cortex as early as on E 17, whereas the first entorhino-hippocampal fibers were found to arrive in the dentate outer molecular layer only thereafter. Moreover, with combined injections of two tracers, DiI and DiO, into the entorhinal cortex and hippocampus, respectively, entorhinal axons were found to grow along axons of Cajal-Retzius cells. These findings suggest that the early-formed projection of hippocampal Cajal-Retzius cells to the entorhinal cortex provides a template for outgrowing entorhinal axons Fig. 4–6A(C). A role of Cajal-Retzius cells in the pathfinding of entorhinal axons is strongly supported by experiments in slice cultures, in which Cajal-Retzius cells had been caused to degenerate by excitotoxic lesions (del Rio et al., 1997). In the absence of Cajal-Retzius cells, entorhinal axons were unable to find their way to the hippocampus, whereas commissural fibers invaded their termination fields as normal.

Because the entorhino-hippocampal projection develops almost normally in reeler mice, it does not appear that reelin synthesized by Cajal-Retzius cells is essential to this process. In

**Figure 4–6.** A–C. Early-generated hippocampal Cajal-Retzius (CR) cells form a template for outgrowing axons of projection neurons in the entorhinal cortex (EC). D. Later on in development when many CR cells have disappeared, the axons of projection cells in the entorhinal cortex establish definitive connections with distal dendrites of dentate granule cells (GC).

fact, Cajal-Retzius cells and their projections to the entorhinal cortex are also present in these mutants and may thus serve their normal function as a template for entorhinal axons. In normal mice, reelin affects the branching pattern of entorhinal terminals. In the absence of reelin, entorhinal axons give rise to fewer collaterals and synapses (del Rio et al., 1997; Borrell et al., 1999). The growth of entorhinal fibers along Cajal-Retzius cell axons is likely to be controlled by a variety of repulsive and attractive molecules (see above).

How do the entorhinal fibers recognize their target layer? Current evidence strongly suggests that components of the extracellular matrix play an important part in the segregation of hippocampal afferents. Förster et al. (1998), for example, demonstrated that fluorescent beads coated with entorhinal membranes precisely adhered to the correct entorhinal termination zone of the hippocampus. They then used this pattern as an assay to study the role of extracellular matrix components in this layer-specific adhesion. When slice cultures of hippocampus were treated with hyaluronidase, the membrane-coated beads no longer adhered with layer specificity, indicating that hyaluronic acid and proteoglycans bound to it may contribute to the layer-specific adhesion. Such adhesion seems also to be an important factor for target layer recognition of entorhinal fibers. When hippocampal slices were treated with hyaluronidase and then cocultured with entorhi-

nal cortex, entorhinal fibers invaded the molecular layer but were no longer restricted to its outer two-thirds (Förster et al., 2001). It appears that hyaluronic acid and proteoglycans are essential for the formation of boundaries between afferent terminal zones in the hippocampus. Interestingly enough, no similar role of extracellular matrix components was found for the laminar specificity of commissural/associational fibers (Zhao et al., 2003). In conclusion, secreted molecules such as the semaphorins, membrane-bound receptors, extracellular matrix components, and a template formed by Cajal-Retzius cell axons are likely to be involved in the directed growth and layer-specific termination of entorhinal fibers.

What is the role of the postsynaptic target cell in the layer-specific termination of entorhinal afferents? In the rodent brain, entorhinal axons innervate the hippocampus proper at E 15 and the dentate gyrus at E 18/E 19 (Super and Soriano, 1994; Ceranik et al., 1999). The entorhinal fibers arrive much earlier than the commissural fibers from the contralateral hippocampus (see below). At this early stage, pyramidal neurons and granule cells have not yet grown their distal dendritic tips to the stratum lacunosum-moleculare and the outer molecular layer of the dentate gyrus. Most of the granule cells have not even been generated yet. Interestingly, the entorhinal fibers recognize their appropriate target layers from the very beginning despite the absence of their appropriate target dendrites at the stage of fiber ingrowth. Evidently, the target cells are unlikely to be involved in pathfinding of entorhinal axons and target layer recognition. The early-generated Cajal-Retzius cells, located in the termination zones of entorhinal fibers, may serve as primary targets. In fact, entorhinal fibers were found to establish synaptic contacts with cell bodies and dendrites of Cajal-Retzius cells (del Rio et al., 1997; Frotscher et al., 2001). A role of Cajal-Retzius cells as primary target neurons of entorhinal fibers is supported by X-irradiation experiments. Irradiation of newborn rats, which eliminates most of the postnatally generated granule cells but not the early-born Cajal-Retzius cells, does not alter the layer-specific termination of entorhinal fibers (Laurberg and Hjorth-Simonsen, 1977; Frotscher et al., 2001). Conversely, ablation of Cajal-Retzius cells prevented layer-specific ingrowth (del Rio et al., 1997).

Many Cajal-Retzius cells degenerate later during postnatal development (i.e., after the entorhino-hippocampal projection has been formed and pyramidal cells and granule cells have grown their distal dendrites into the entorhinal termination fields). At that time, the contacts of entorhinal fibers are reorganized, and definitive synapses with distal dendritic portions of pyramidal cells and granule cells are made (Fig. 4–6D). Although pathfinding and target recognition are not affected by the absence of neuronal activity, there is an effect on the maturation of synaptic structures. Drakew and colleagues (Drakew et al., 1999; Frotscher et al., 2000b) observed normal formation of the entorhino-hippocampal projection in cocultures of entorhinal cortex and hippocampus incubated in the presence of tetrodotoxin (TTX), which blocks fast sodium channels. However, they observed an increased num-

ber of long, immature spines, indicating that neuronal activity may be required for the maturation of spines.

Many questions concerning the layer-specific termination of entorhinal fibers remain open at present. As an example, the development of the fiber lamination in the infrapyramidal blade of the dentate gyrus is different from that in the suprapyramidal blade. Whereas the entorhinal fibers arrive before the commissural axons in the suprapyramidal blade, this sequence is reversed in the infrapyramidal blade (Tamamaki, 1999). Do the fibers to these different blades originate from the same cells of origin in the entorhinal cortex? If so, what causes the delay in the ingrowth into the infrapyramidal blade?

#### 4.3.2 Commissural Connections

Commissural fibers, originating from CA3 pyramidal neurons and hilar mossy cells, project via the hippocampal commissure to the contralateral hippocampus and dentate gyrus. In the mouse hippocampus, the first commissural axons arrive in the contralateral hippocampus at E 18 and in the dentate gyrus at P 2. This is considerably later than the arrival of the entorhinal axons. The sequential generation of the entorhinal neurons and commissurally projecting hippocampal cells and their sequential ingrowth into their target fields has led to a hypothesis concerning their laminated termination in both the hippocampus proper and the dentate gyrus: The later the fibers invade their target zones, the more proximally do they terminate on their target cell dendrites (Bayer and Altman, 1987). Entorhinal axons, arriving early in development, contact distal dendrites of pyramidal cells and granule cells, whereas later-arriving commissural fibers establish synapses in the stratum radiatum of the hippocampus proper and in the inner molecular layer of the dentate gyrus. One of the last projections to be formed, the ipsilateral mossy fiber projection, accordingly terminates on the most proximal dendritic segments of CA3 pyramidal neurons.

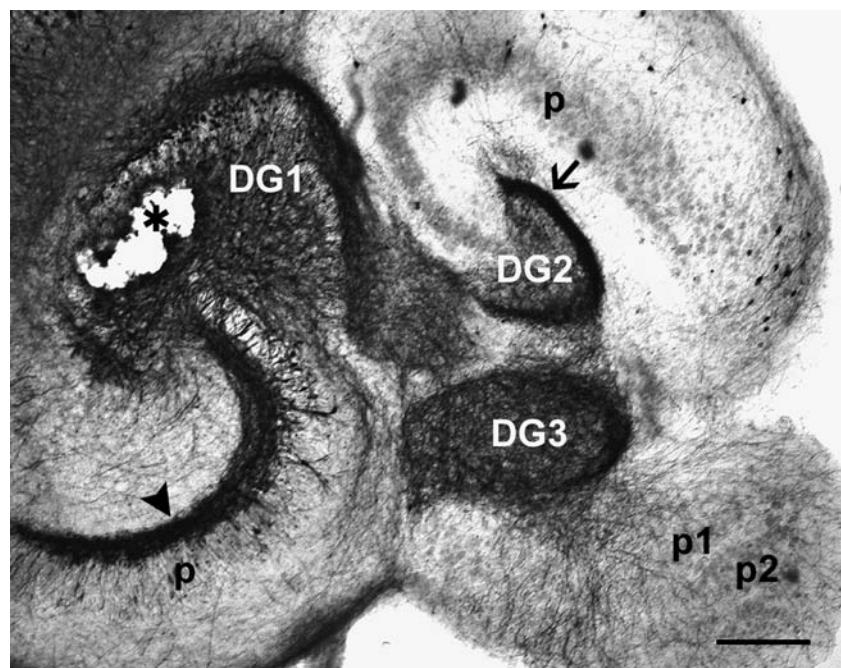

This hypothesis is not easy to test *in vivo*. However, it can be addressed in slice culture experiments in which the time of arrival of growing axons can be brought under precise experimental control. Frotscher and Heimrich (1993) cocultured a hippocampal target culture first with an entorhinal culture and then with a second hippocampal culture, thus imitating the normal developmental sequence in this sequential culture system. They then traced the entorhinal and “commissural” connections to the hippocampal target culture and observed, as one would expect, that the entorhinal fibers terminated on the distal dendritic segments of their target neurons, as normal. Next, they reversed this sequence: First, the two hippocampal cultures were cocultivated; then, with a delay of a couple of days, an entorhinal slice culture was added. Despite the reversal of the sequence of fiber ingrowth, the commissural and entorhinal fibers still terminated in their appropriate layers, indicating that the sequence of fiber arrival in the target region is not responsible for the laminated, proximo-distal termination of these two afferents.

As the time of arrival is not the factor governing lamination, the question arises as to potential cellular and molecular factors determining the layer specificity of commissural fibers. Soriano and colleagues (Super et al., 1998) have suggested that there are pioneer neurons, early-generated GABAergic cells, that serve as primary targets for the commissural fibers. Their role is comparable to that of the Cajal-Retzius cells as primary targets of the entorhinal afferents. This idea became testable with the possibility of depleting the hippocampus of GABAergic neurons during development (Pleasure et al., 2000). Contrary to Soriano's idea, commissural fibers still innervated their proper target areas in the absence of GABAergic neurons.

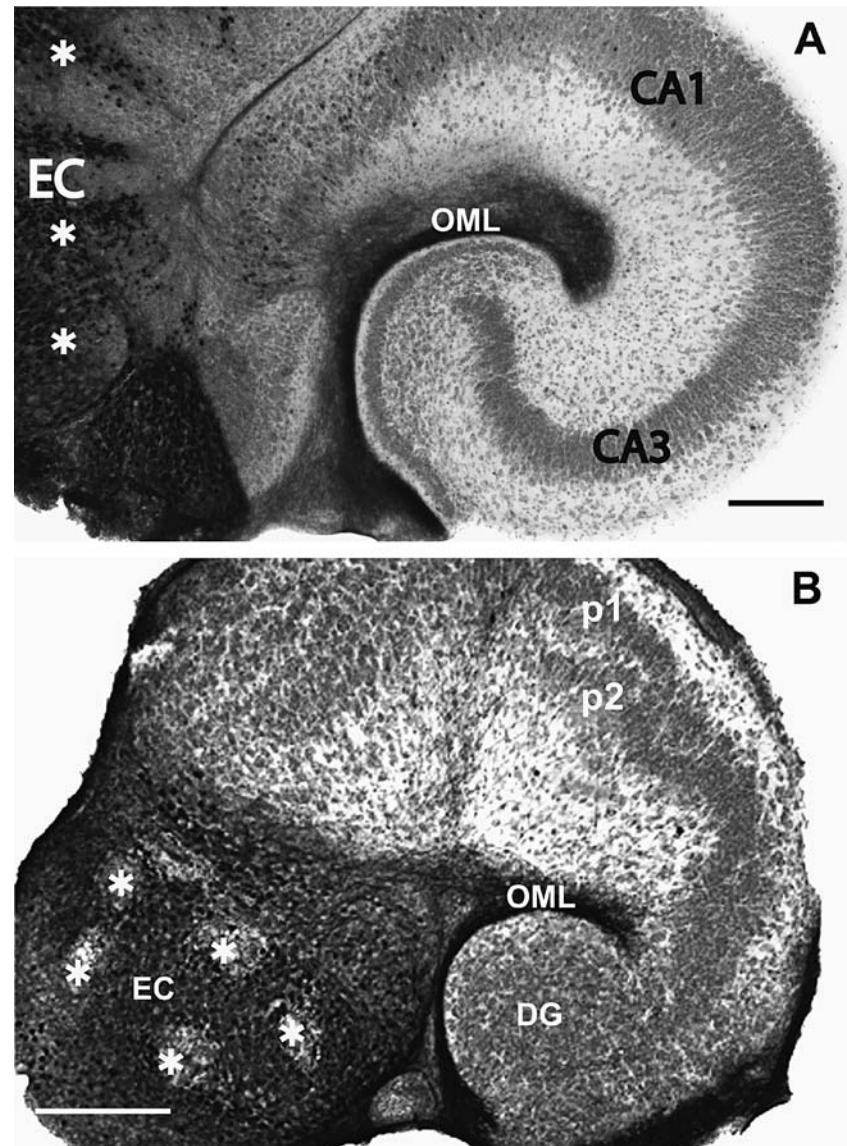

As the commissural fibers arrive relatively late in the hippocampus and dentate gyrus, an alternative proposal was that pioneer neurons are not required. This is because the target cells, the principal neurons, are already present at that time and have already grown a dendritic arbor (Deller et al., 1999a). Evidence relevant to this idea has come from studies in reeler mice. In this mutant, the granule cells are loosely distributed throughout the hilar region (Stanfield and Cowan, 1979; Deller et al., 1999a; Drakew et al., 2002) and the commissural fibers do not form a compact layer but are, instead, distributed all over the hilar region (Deller et al., 1999a). This target-dependent termination of commissural fibers is nicely seen when commissural axons from a wild-type culture are traced to both a second wild-type culture and a reeler culture: Whereas the commissural axons terminating in the wild-type culture form their normal compact projection to the inner molecular layer of the dentate, the commissural fibers that innervate the reeler culture terminate diffusely, corresponding to the scattered distribution of their target granule cells (Fig. 4–7, see color

insert). This is in striking contrast to the entorhino-dentate projection, which forms a compact termination zone with sharp borders in the outer molecular layer of the reeler mutant (Deller et al., 1999a); moreover, this characteristic layer-specific projection is nicely preserved in slice cultures from wild-type animals and reeler mutants (Zhao et al., 2003) (Fig. 4–8, see color insert). Together, these findings support the hypothesis that entorhinal fibers, because of their early arrival in the dentate gyrus at a time when their definitive target cells, the granule cells, have not yet been generated, do require pioneer target neurons. These neurons are likely to be the Cajal-Retzius cells, which are, as normal, located in the outer molecular layer of reeler mice (see above). One is tempted to speculate that whereas the entorhinal fibers require pioneer neurons the commissural afferents establish contacts directly with principal cell dendrites, which is reflected in reeler mice by the irregular, loose distribution of both commissural fibers and granule cells (Fig. 4–9). In fact, when commissural fibers from a reeler culture are traced to a wild-type culture, they are found to form a normal, compact projection to the inner molecular layer, precluding a cell-autonomous effect of the reeler mutation on commissural neurons (Zhao et al., 2003).

Little is known about the molecules involved in pathfinding and target recognition of commissural fibers. As with other commissures, Netrin 1 and its receptor DCC are important for formation of the hippocampal commissure. Thus, a hippocampal commissure does not form in Netrin 1-deficient animals. Along this line, neurites of hippocampal neurons are attracted by Netrin 1 in the stripe choice assay (Steup et al., 2000). The molecules governing the laminar specificity of the commissural fibers in their target zones remain to be determined.

**Figure 4–7.** Triplet cocultures of two wild-type slices of hippocampus together with a reeler hippocampal slice. The biocytin injection site into the dentate gyrus of one of the wild-type cultures (DG1) is marked with an asterisk. Labeled commissural fibers invade the two other cultures, but only in the dentate gyrus of the second wild-type culture (DG2) do they show their characteristic compact termination in the inner molecular layer (arrow). In the reeler hippocampal culture, the commissural fibers arising from the same cells of origin have lost their laminar specificity and terminate throughout the hilar region of the dentate gyrus (DG3). Arrowhead points to the mossy fiber projection in the wild-type culture that was also labeled by the tracer injection into the hilus. p, pyramidal layer; p1, p2 two pyramidal layers in the reeler culture. Bar = 100 µm. (Source: Zhao et al., 2003, © 2003 by the Society for Neuroscience.)

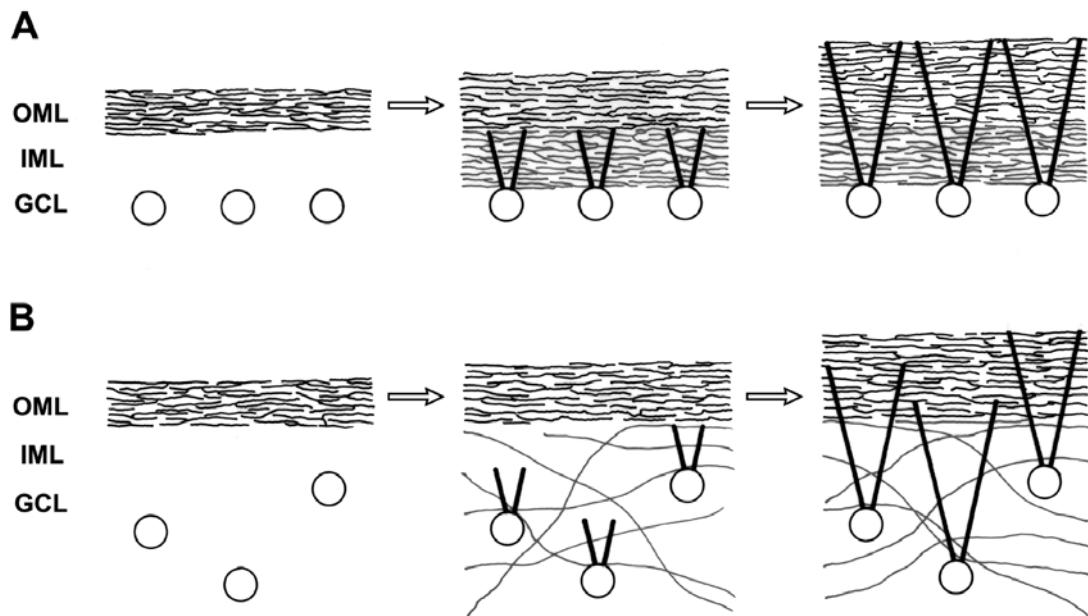

**Figure 4-8.** A. Entorhino-hippocampal projection in a complex culture of entorhinal cortex (EC) and hippocampus. Biocytin injection sites are labeled by asterisks. Note the layer-specific termination of the entorhinal fibers in the outer molecular layer (OML) of the dentate gyrus. B. In a slice culture of reeler hippocampus and entorhinal cortex, entorhinal fibers labeled by biocytin injection into the entorhinal cortex (asterisks) form a sharply segregated projection to the outer portion of the molecular layer of the dentate gyrus (DG) despite the malpositioned granule cells, demonstrating that the trajectory of entorhinal fibers is not influenced by the position of their target neurons. p1, p2, two pyramidal layers in the reeler hippocampus. Bar = 100  $\mu$ m. (Source: Zhao et al., 2003; © 2003 by the Society for Neuroscience.)

### 4.3.3 Septal Connections

The septohippocampal projection consists of two parts: a cholinergic one and a GABAergic one. The cells of origin for both parts are located in the medial septal nucleus/diagonal band complex (MSDB) (see Chapter 3). The development of the septohippocampal projection can be understood only by taking into account the hippocampo-septal projection. The latter develops relatively early and surprisingly terminates in the medial septum during development as early as on E 15. In adults, hippocampo-septal fibers project to the lateral septum (Linke and Frotscher, 1993; Super and Soriano, 1994; Linke et al., 1995). This early termination in the medial septal nucleus has led to the hypothesis that the early formed hippocampo-septal projection serves as a template by which septohip-

pocampal fibers can find their way to the hippocampus. It has in fact been shown that growth cones of septohippocampal fibers grow along hippocampo-septal axons (Linke and Frotscher, 1993). The molecular mechanisms underlying the change of hippocampo-septal fibers from the medial to the lateral septum remain to be elucidated.

Unlike the entorhino-hippocampal and commissural projections to the hippocampus, septohippocampal cholinergic fibers do not terminate in clearly demarcated layers. They are found in all layers of the hippocampal formation but are certainly more concentrated in the cell body layers. In contrast, the septohippocampal GABAergic projection cells display a high target cell specificity terminating almost exclusively on GABAergic interneurons in the hippocampus. Inhibitory neurons afferent to inhibitory neurons serve a disinhibitory role

**Figure 4-9.** Different signals control the laminar specificity of entorhinal fibers (black) and commissural fibers (gray) to the dentate gyrus. *A*. In wild-type mice, entorhinal fibers, guided by Cajal-Retzius cell axons, reach the outer molecular layer (OML) of the dentate gyrus before the granule cells in the granule cell layer (GCL) have grown their distal dendritic tips to the OML. Molecules of the extracellular matrix control the laminar specificity of entorhinal axons. In contrast, later-arriving commissural fibers, terminating in the inner molecular layer (IML), meet the

outgrowing granule cell dendrites. *B*. Findings in the *reeler* mutant, where the granule cells are not aligned but scattered over the dentate gyrus, confirm that the entorhinal axons are not guided by their target granule cells. As for the wild-type fibers, entorhinal fibers terminate with laminar specificity in the OML. In contrast, commissural fibers are loosely distributed over the dentate gyrus, thus following their scattered target cells. (Source: Adapted from Frotscher, 1998).

with respect to the principal neurons (Freund and Antal, 1988). The septal cholinergic fibers establish contacts with both principal neurons and interneurons, and their contacts are on cell bodies, dendritic shafts, and spines. Two types of contact are established: symmetrical and asymmetrical (Frotscher and Leranth, 1985, 1986). It remains to be established whether one of these types derives from the few intrahippocampal cholinergic cells (Frotscher et al., 1986, 2000a) that are found in the rat hippocampus but not in the monkey hippocampus.

The first septohippocampal fibers arrive in the hippocampus at E 17 (i.e., 2 days after the hippocampo-septal projection is established) (Linke and Frotscher, 1993; Super and Soriano, 1994). Little is known about the molecules involved in pathfinding and target recognition of septohippocampal fibers. Cholinergic fibers are known to bear the p75 neurotrophin receptor ( $p75^{\text{NTR}}$ ), suggesting that neurotrophins play a role. Nerve growth factor (NGF), one of the ligands for the p75 receptor, is synthesized by GABAergic hippocampal neurons, which are distributed over all hippocampal layers, compatible with the diffuse termination of septohippocampal fibers. Moreover, NGF-synthesizing hippocampal nonprincipal neurons project to the septum (Acsady et al., 2000), thus providing both a neurotrophic source and a template

for axonal orientation (see above). A *neurotropic* effect of NGF was demonstrated some time ago (Gundersen and Barrett, 1979; see Tessier-Lavigne and Goodman, 1996, for review), but it needs to be confirmed that the ingrowth of septohippocampal fibers is controlled by neurotrophins. One of the semaphorins, Sema3C, was found to repel septal fibers (Steup et al., 2000); and neuropilin 2, its receptor, is present along the pathway of septal fibers (Chedotal et al., 1998; Steup et al., 2000), suggesting involvement of this ligand–receptor system in the formation of the septohippocampal projection.

#### 4.3.4 General Principles Underlying the Formation of Synaptic Connections in the Hippocampus

We are now beginning to understand at least some of the principles underlying pathway formation in the hippocampus. Different cellular and molecular factors, probably being effective only during certain developmental time windows, are involved in the formation of the different projections to the hippocampus. When describing the formation of a pathway, we found it useful to distinguish between *axonal pathfinding*, *target recognition*, and *synapse formation*. For pathfinding and

target recognition, pioneer neurons provide a template by an early-formed projection. Membrane-bound and soluble molecules and components of the extracellular matrix also seem to play a role at different times of development. A variety of ligand–receptor interactions has been elucidated that, by their repulsive or attractive effects, may guide the growth cone of a growing axon to the target region. Undoubtedly, new molecules or families of molecules of this kind will be discovered in the future. Extracellular matrix molecules, proteoglycans such as neurocan, may be essential for the segregation of fiber systems in the hippocampus (Förster et al., 2001; Zhao et al., 2003).

*Synapse formation* is dealt with only briefly here, and the reader is referred to quantitative electron microscopic analyses and Golgi studies on the development of synapses and dendritic spines (e.g., Crain et al., 1973; Minkwitz 1976; Frotscher et al., 1977). This is a rapidly developing field, and more recent studies have provided evidence that the mechanisms leading to new contacts or changes in the shape of synapses or spines may not only be effective during development but may also underlie plastic processes in the adult organism. A striking example is Engert and Bonhoeffer's (1999) *in vitro* observation of new spines formed during the development of long-term potentiation (LTP). Similarly, Woolley and McEwen (1993) have shown that estrogen application to ovariectomized adult rats induces new spines on CA1 pyramidal cell dendrites, an effect likely caused by estrogen acting primarily on CA3 pyramidal cells and inducing the sprouting of their Schaffer collaterals to CA1 pyramidal neurons (Rune et al., 2002). Interestingly, recent studies have shown that estrogens synthesized in the hippocampus are important for hippocampal synaptic plasticity (Kretz et al., 2004). Future studies will help us establish whether these plastic changes at spine synapses are specific for hippocampal neurons or are a more general phenomenon occurring at many synapses in the central nervous system.

#### 4.4 Development of the Primate Hippocampal Formation

As in the previous chapter (see Chapter 3), one may raise the question of how hippocampal development varies across phylogenetically distant species such as rats, monkeys, and humans. What is similar and what is different? Do the steps of hippocampal development change proportionally with an extended life-span, or are there some fundamental differences in the mechanisms and the timing of cell formation, cell migration, dendritic development, and formation of neuronal connectivity? We provide a short comparative analysis of hippocampal development in primates. For details the reader should consult a review on monkey and human hippocampal development (Seress, 2001).

##### 4.4.1 Neurogenesis

The duration of embryonic development is 19 to 21 days in mice and rats (life-span 1.5–3.0 years), 165 days in rhesus monkeys (life span 25–30 years), and 280 days in humans. As we have already noted, cell formation is a relatively late event in rodents: Pyramidal cells are generated during the second half of the embryonic period, and granule cell formation starts only a few days before birth. Furthermore, 85% of the dentate granule cells are formed postnatally. In contrast, neurogenesis in the primate hippocampal formation takes place relatively early. In rhesus monkeys, the first neurons appear almost simultaneously in the various subregions of the hippocampal formation, from the entorhinal cortex to the dentate gyrus, between E 36 and E 38 (Rakic and Nowakowski, 1981). Except for the dentate gyrus, cell formation ceases during the first half of pregnancy, between E 62 and E 65. Granule cell formation lasts until the end of the first postnatal month, with only 15% of the granule cells forming postnatally (Rakic and Nowakowski, 1981). Granule cell formation has also been found in the dentate gyrus of adult monkeys (Kornack and Rakic, 1999).

In humans, the time of pyramidal cell neurogenesis is not known and must be extrapolated from the time of the appearance of the cytoarchitectonic layers. Subfields of the hippocampal formation, such as the entorhinal cortex, subiculum, and hippocampus, are discernible between E 70 and E 80, whereas the dentate granular layer appears around E 90 (Humphrey, 1967). Between E 160 and E 170, the cytoarchitectonic characteristics of all of the divisions of the hippocampal formation are similar to what is observed in adults (Humphrey, 1967; Arnold and Trojanowski, 1996). With the aid of the mitotic marker MIB-1 (Ki-67), we have directly shown that the ventricular zone and hilus contain a large number of proliferating cells at E 100 (Fig. 4–4). The number of labeled cells decreases rapidly from E 170 onward (24th week), but MIB-1 (Ki-67)-positive cells are still observed in the hilus and granule cell layer during the first 6 months postnatally (Seress et al., 2001).

##### 4.4.2 Neuronal Differentiation

Differentiation of pyramidal neurons and granule cells continues for a relatively long period in rodents and primates. Spine density increases until the time of sexual maturation, and total dendritic length is not reached before P 90 in the rat CA1 area (Pokorny and Yamamoto, 1981). In the monkey, the spine density of CA3 and CA1 pyramidal cells does not reach adult levels before sexual maturation (i.e., during the fourth year in rhesus monkeys) (Seress and Ribak, 1995b, unpublished observation). In humans, spine density and total dendritic length of CA1 pyramidal neurons increase until at least the third postnatal year (Simic et al., 2001). In contrast to the long-term differentiation of principal cells, local circuit neurons in the primate hippocampal formation mature fast, as

indicated by the early fetal appearance of neurochemical markers of these neurons (Del Fiacco and Quartu, 1989; Berger et al., 1993, 1999).

Arrival of afferents at the rat hippocampal formation coincides with the development of their target cells. Thus, it takes place during the perinatal and early postnatal period, as previously noted. In both the monkey and human, however, afferent projections from the hypothalamus as well as from the entorhinal cortex arrive early during the fetal period (Kostovic et al., 1989; Hevner and Kinney, 1996; Berger et al., 2001). In contrast to extrinsic afferents, intrinsic associational connections of the rodent hippocampus develop relatively late, partly owing to the late formation of granule cells. Connections between dentate granule cells and CA3 pyramidal neurons as well as between dentate granule cells and hilar mossy cells develop postnatally (Ribak et al., 1985). This late development coincides with the prolonged postnatal development of hippocampal functions (Nadel and Willner, 1989). In contrast, the development of associational connections is relatively fast in rhesus monkeys, and the mainly prenatally formed granule cells establish a well developed synaptic network by the fifth to seventh postnatal month (Seress and Ribak, 1995a,b). Surprisingly, this is not the case in humans, where the prenatally formed granule cells appear to form the first connections with hilar mossy cells and CA3 pyramidal neurons as late as during the 33rd gestational week, as indicated by the late appearance of excrescences on hilar mossy cells and CA3 pyramidal neurons (Purpura, 1975). In fact, there are almost no light microscopic signs of such connections at birth (Seress and Mrzljak, 1992; Seress, 2001).

Taken together, developmental events of the hippocampal formation are different in rodents and primates. However, there are also common traits. In both rodents and humans the late development of intrahippocampal associational connections may influence the maturation of the entire hippocampal network. The factors contributing to this late development are likely to be different in rodents and primates. In rodents, the late formation of granule cells may play a role. It remains to be elucidated why the early-formed granule cells in humans do not immediately form synapses with their target cells as is the case in nonhuman primates.

# Structural and Functional Properties of Hippocampal Neurons

## 5.1 Overview

One of the most striking qualities of Cajal's drawings is the great diversity of form exhibited by neurons in the central nervous system (CNS). Looking at these drawings, it is difficult to escape the conclusion that neurons with different morphologies are likely to function differently. Indeed a plethora of anatomical, histological, and physiological studies support the view that diversity in form is mirrored by diversity of function. The hippocampus presents, in many ways, a microcosm of the cellular diversity exhibited on a larger scale throughout the CNS. An important step on the path to understanding the function of the hippocampus is to reveal the unique morphological and physiological properties of the great variety of neurons it comprises.

Much can be learned by examining neuronal structure. The dendritic tree defines which inputs can be received, and the axonal arborization indicates the targets of the output (although dendro-dendritic and axo-axonal communication should not be forgotten). Electron microscopy provides details about the nature of each neuron's inputs and output. It allows us to infer which synapses are inhibitory (symmetrical) and which are excitatory (asymmetrical) and where modulatory machinery resides (e.g., endoplasmic reticulum for calcium release, ribosomes for protein synthesis, vesicles for neurotransmitter release or insertion of membrane proteins). Histological studies (antibody or cDNA binding, histochemical assays) provide further information, ranging from which neurotransmitters are used to which voltage-gated channels are present and where. Physiological studies, using electrodes and imaging both *in vitro* and *in vivo*, reveal the dynamic function of each neuron.

A detailed picture of the function of each neuron can only emerge by bringing together information from this variety of techniques. Ultimately, complete understanding of the function of each type of neuron may be encapsulated by detailed

models that can reproduce or explain virtually any aspect of neuronal function. The purpose of such models, of course, is to offer insight into the neuron's function within a network and provide experimentally testable predictions.

In this chapter, our aim is to summarize the wealth of structural, histological, and physiological information that is available for hippocampal neurons. Most of the available data on this topic come from studies of the rat hippocampal formation. Accordingly, we mention species primarily when referring to data from species other than rat. We begin with the CA1 pyramidal neuron because it is arguably the most studied class of neuron in the brain and probably better understood from both structural and functional points of view than any other type of neuron in the hippocampus. From there we proceed by comparing the function of the other pyramidal neurons in the hippocampus: those in CA3 and the subiculum. We next cover two nonpyramidal excitatory neurons in the hippocampus: granule cells of the dentate gyrus and mossy cells of the hilus. Finally, we conclude by describing the properties of a variety of neurons in other regions comprising the hippocampal formation: the entorhinal cortex, presubiculum, and parasubiculum. In the final section, we consider the many types of interneurons found in the hippocampus.

## 5.2 CA1 Pyramidal Neurons

The vastness of the literature on CA1 pyramidal neurons is largely attributable to a combination of structural considerations, cell viability, and historical accidents. Although long-term potentiation was first described in the dentate gyrus, most of the studies in the decades that followed its original description have focused on the CA1 region. This is because of the relative ease of obtaining field potential recordings and intracellular recordings in this region. Also, the Schaffer col-

lateral axons from CA3 form a homogeneous pathway that is easily activated to study synaptic transmission and plasticity. Studies of CA1 are more numerous than adjacent CA3 because it is generally easier to keep cells in this region alive and healthy in slice preparations. Recently, CA1 pyramidal neurons have been the focus of several studies of dendritic integration because of the large primary apical dendrite, from which dendritic patch-clamp recordings can be obtained routinely. These factors have contributed to tremendous advances in understanding synaptic transmission, integration, and plasticity in the CNS.

### 5.2.1 Dendritic Morphology

Two elaborately branching dendritic trees emerge from the pyramid-shaped soma of CA1 neurons (Fig. 5–1A). The basal dendrites occupy the stratum oriens, and the apical dendrites occupy the stratum radiatum (proximal apical) and stratum lacunosum-moleculare (distal apical). [Note: in this context the terms “proximal” and “distal” refer to the relative distance from the soma and should not be confused with the “proximo-distal” axis of the hippocampal circuit (dentate-CA3-CA1-subiculum-entorhinal cortex) introduced in Chapter 3.] Both the apical and basal dendritic trees occupy a roughly conical (sometimes ovoid) volume (Pyapali et al., 1998). The size of the CA1 dendritic tree depends on species and age, but the best available data are from adult rats. The distance from the stratum pyramidale to the hippocampal fissure is about 600 μm, and the distance from the stratum pyramidale to the alveus is about 300 μm, yielding a distance of just under 1 mm from the tips of the basal dendrites to the tips of the apical dendrites. The combined length of all CA1 dendritic branches is 12.0 to 13.5 mm: basal dendrites contribute about 36% of the total length, apical dendrites in the stratum radiatum contribute about 40%, and apical dendrites in the stratum lacunosum-moleculare contribute the remaining 24% (Bannister and Larkman, 1995a; Ishizuka et al., 1995; Trommald et al., 1995; Megias et al., 2001). CA1 dendrites are studded with spines (Fig. 5–1B), the sites of most excitatory synaptic contacts throughout the dendritic tree (Ramon y Cajal, 1904; Lorente de Nò, 1934; Bannister and Larkman, 1995b; Megias et al., 2001).

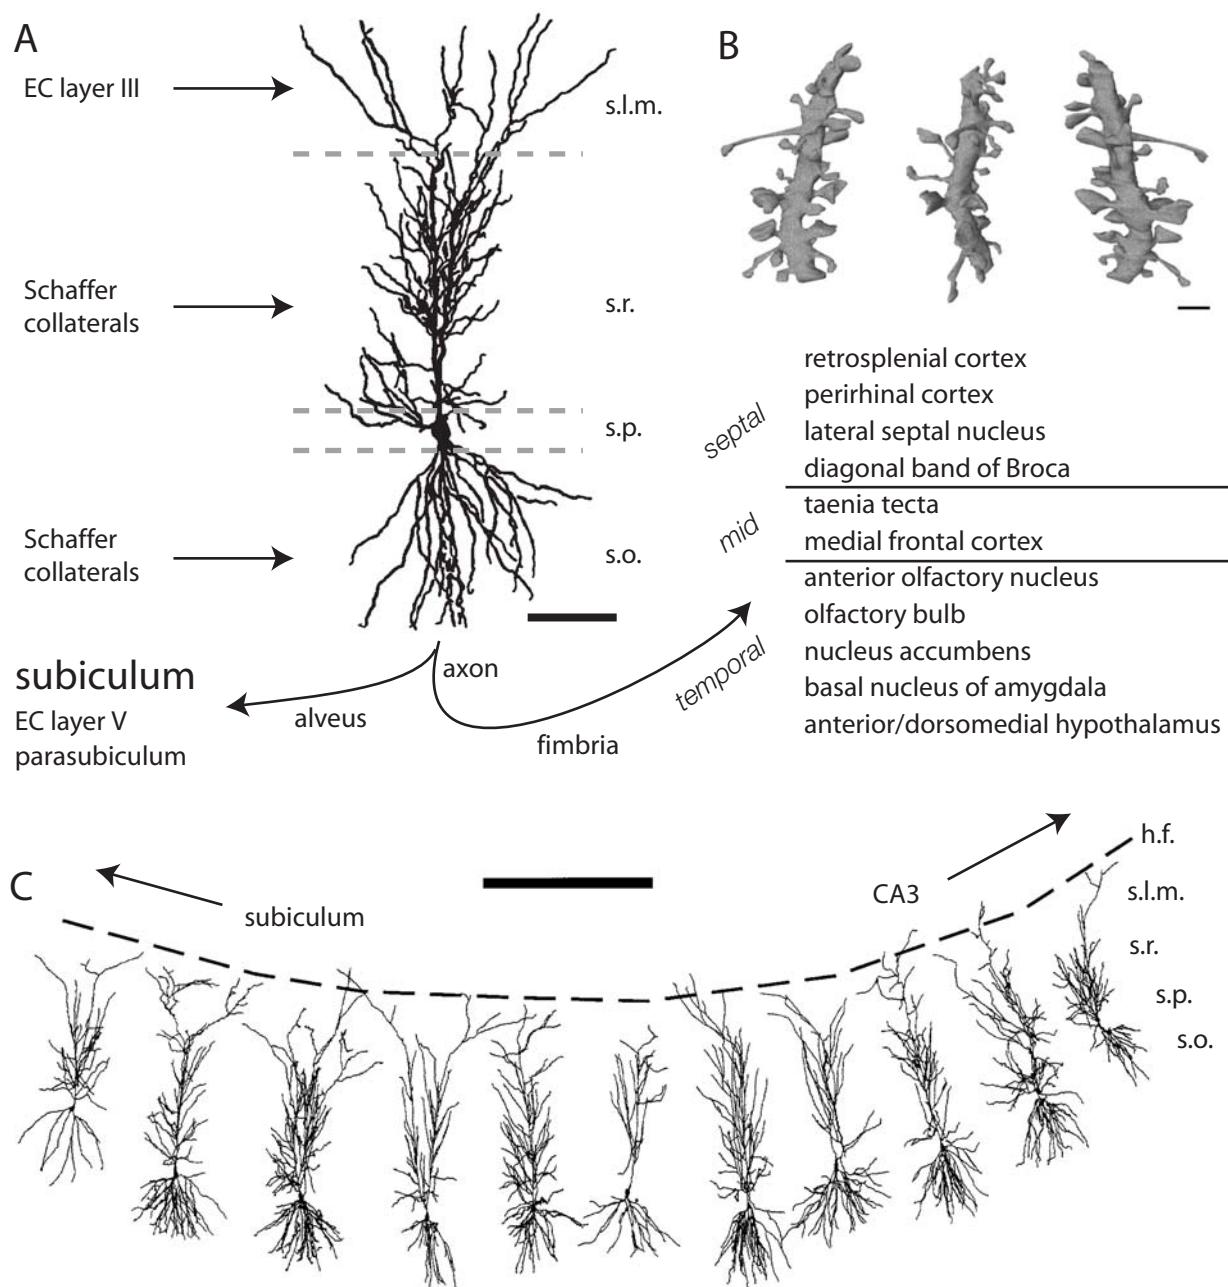

Studies of dendritic morphology in adult rats suggest that CA1 pyramidal neurons can be broadly classified into two groups on the basis of dendritic morphology. In one group of neurons, the primary apical dendrite extends all the way through the stratum radiatum before bifurcating in the stratum lacunosum-moleculare. The other group of CA1 neurons has apical dendrites that bifurcate in the stratum radiatum (Bannister and Larkman, 1995a). Most other features of these two classes of CA1 neurons are similar, so most structural studies consider CA1 pyramidal neurons as a single morphological class (Fig. 5–1C).

Along the length of the primary apical dendrite, several dendritic branches emerge obliquely in the stratum radiatum.

The number of these oblique branches varies from 9 to 30, with a mean of 17 (Bannister and Larkman, 1995a; Pyapali et al., 1998) (Fig. 5–1C). Oblique dendrites branch no more than a few times, with a typical branch bifurcating just once at a location close to its origin from the apical trunk. Despite their limited branching, however, oblique dendrites constitute most of the dendritic length in the stratum radiatum (Bannister and Larkman, 1995a; Megias et al., 2001). After the primary apical trunk enters the stratum lacunosum-moleculare the apical dendrites continue to branch, forming a structure referred to as the apical tuft, which has an average of about 15 terminal branches (Bannister and Larkman, 1995a; Trommald et al., 1995).

Emerging from the base of the pyramidal soma are two to eight dendrites (a mean of five). Most of these dendrites branch several times (maximum 15 branch points), forming a basal dendritic tree with about 40 terminal segments (Bannister and Larkman, 1995; Pyapali et al., 1998). Most branches in the basal dendrites occur rather close to the soma, so the terminal segments are quite long, constituting about 80% of the total dendritic length (Bannister and Larkman, 1995a; Trommald et al., 1995). CA1 neurons differ considerably in the position of the cell body, with some cells located in the stratum oriens as far as 100 μm from the border between the stratum pyramidale and the stratum radiatum. Cells with somata farther from this border tend to have more terminal dendrites in the stratum oriens (basal dendrites) and fewer terminal dendrites in the stratum radiatum (apical oblique dendrites) (Bannister and Larkman, 1995a).

Many of the organelles found in the cell body extend into the proximal apical dendrites of CA1 neurons (Harris and Stevens, 1989; Spacek and Harris, 1997). These include structures such as the smooth endoplasmic reticulum (SER) and the Golgi apparatus. At greater distances from the soma, however, a more limited set of organelles is found in dendrites. Microtubules, neurofilaments, and actin are prominent and serve transport and motility functions, and they are likely to be important in synaptic plasticity. A network of SER is also present in dendrites, where it is likely to serve important functions in calcium buffering and release. The SER forms a continuous reticulum, which can extend into dendritic spines (Spacek and Harris, 1997). Mitochondria are also numerous in dendrites and are often associated with the SER, but glycogen granules are largely absent, except in sliced tissue, where they probably represent a response to stress (Fiala et al., 2003). Dendritic mitochondria likely contribute to calcium handling in addition to serving as the primary energy source. In apical dendrites of CA1 pyramidal neurons, mitochondria fill about 2% of the area of the main apical dendrite but 13% of smaller-diameter branches (Nafstad and Blackstad, 1966). Sorting endosomes and multivesicular bodies form the endosomal pathway, which is responsible for sorting and recycling proteins in dendrites as well as packaging them for transport to the soma for degradation. This endosomal compartment forms a network that spans as many as 20 spines in CA1 den-

**Figure 5-1.** CA1 dendritic morphology, spines, and synaptic inputs and outputs. *A.* Camera lucida drawing of a CA1 pyramidal neuron from an adult rat, showing the cell body in the stratum pyramidale (s.p.), basal dendrites in the stratum oriens (s.o.), and apical dendrites in the stratum radiatum (s.r.) and stratum lacunosum-moleculare (s.l.m.). The major excitatory inputs in each layer and the major outputs are also indicated. For the fimbrial projection, the septo-temporal positions noted indicate the source of CA1 cells projecting to different target regions. For the alveus projection, the subiculum is the major target. drites (Cooney et al., 2002). Clathrin-coated pits and vesicles are also present in CA1 dendrites, often near the ends of tubular endosomal compartments. Ribosomes are present in CA1 dendrites, where they are usually clustered in the form of polyribosomes (Steward et al., 1996; Steward and Worley, 2002).

### 5.2.2 Dendritic Spines and Synapses

CA1 pyramidal neurons are covered with about 30,000 dendritic spines. Electron microscopic, immunocytochemical, and physiological analyses have all converged on the conclusion that most dendritic spines receive excitatory synaptic inputs, indicating that spine density can be used as a reasonable measure of excitatory synapse density (Gray, 1959; Andersen et al., 1966; Megias et al., 2001). The distribution of spines on different dendritic domains has been carefully quantified (Andersen et al., 1980; Bannister and Larkman, 1995b; Megias et al., 2001). The density of dendritic spines and synapses on CA1 pyramidal neurons is highest in the stratum radiatum and stratum oriens but lower in the stratum lacunosum-moleculare. The soma and the first 100  $\mu\text{m}$  of the main apical dendrite (1.8–2.5  $\mu\text{m}$  diameter) are almost completely devoid of spines. The next 150  $\mu\text{m}$  of the apical dendrite (1.6–2.2  $\mu\text{m}$  diameter) has a very low spine density, but the final 150  $\mu\text{m}$  of the main apical dendrite (1.0–1.5  $\mu\text{m}$  diameter) has a high spine density (about seven spines per linear micrometer). Spine density is lower in the oblique apical branches (0.5–0.6  $\mu\text{m}$  diameter; about three spines per micrometer); but because these dendrites constitute a large fraction of the total dendritic length, about 47% of all CA1 spines are located on these branches. Together with the spines on the main apical dendrite, about 54% of all excitatory synapses contact spines in the apical dendrites in the stratum radiatum. Spine density is considerably lower in the apical tuft (0.2–1.2  $\mu\text{m}$  diameter). Although these dendrites contribute about 20% of the total dendritic length, they contain only about 6% of the dendritic spines. Asymmetrical synapses, however, are also found on dendritic shafts in this region. If these synapses are excitatory, as is usually presumed, about 10% of all excitatory synapses are located in the apical tuft. The first 30 to 50  $\mu\text{m}$  of the basal dendrites (0.5–0.9  $\mu\text{m}$  diameter) have a low spine density, whereas the distal basal dendrites (0.3–0.5  $\mu\text{m}$  diameter) have a spine density comparable to that of the apical oblique dendrites. Accordingly, about 36% of all excitatory synapses on CA1 neurons contact spines in the basal dendrites.

The distribution of symmetrical, GABA-positive synapses has also been quantified in CA1 neurons (Megias et al., 2001). About 24% of these synapses contact the soma and spine-free proximal dendrites (apical and basal). Somewhat surprisingly, the sparsely spiny and densely spiny regions of the main apical dendrite (in the stratum radiatum) receive similar numbers of inhibitory synapses, at about 3% of the total each. About 26% of the inhibitory synapses contact oblique apical branches. About 20% of all inhibitory synapses contact dendrites of the apical tuft. These dendrites therefore

receive roughly twice as many inhibitory synapses as excitatory synapses. The remaining 24% of inhibitory synapses contact the distal basal dendrites. These dendrites are therefore similar to the apical obliques in terms of diameter, spine density, and numbers of excitatory versus inhibitory synapses.

The dendritic spines studding the surface of CA1 dendrites exhibit a broad range of size and morphological complexity (Fig. 5–1B). Although quantitative analysis of spine shapes does not indicate clear groups of spines (Trommald and Hulleberg, 1997), several investigators have used a variety of names to describe spines of different shapes (Laatsch and Cowan, 1966; Peters and Kaiserman-Abramof, 1970; Harris and Kater, 1994; Sorra and Harris, 2000). Thin spines are long, narrow protrusions terminating in a small, bulbous head. Sessile spines are long, narrow protrusions that do not terminate in a head. Stubby spines are small protrusions lacking a clearly distinguishable neck and a head. Mushroom spines have a narrow neck and a large, bulbous head. Branched spines consist of a neck that branches and terminates in two bulbous heads, each of which receives synaptic input from different axons. These five types of spines are not specifically localized to any particular region of the CA1 dendritic tree but can be found in close apposition on virtually any dendritic branch.

Spine structure is not static but may change in response to neurotransmitter receptor activation or environmental and hormonal signals (Hering and Sheng 2001; Bonhoeffer and Yuste, 2002; Nikonenko et al., 2002; Nimchinsky et al., 2002). Growth of new spines and changes in the structure of existing spines are possible substrates of synaptic plasticity in the hippocampus (Geinisman, 2000; Popov et al., 2004). Although the plasticity of spine structure *in vivo* is a matter of some controversy (Grutzendler et al., 2002; Trachtenberg et al., 2002), imaging studies of hippocampal neurons *in vitro* have revealed a rather dynamic picture of spine morphology (Hosokawa et al., 1995; Dailey and Smith, 1996; Engert and Bonhoeffer, 1999; Maletic-Savatic et al., 1999; Matsuzaki et al., 2004). One particularly noticeable feature of time-lapse movies of hippocampal dendrites is the continuous extension and retraction of filopodia. Occasionally, these filopodia extend without retracting fully, leading to the hypothesis that they form the precursors for mature, stable spines, which eventually establish functional synaptic connections with presynaptic boutons (Dailey and Smith, 1996; Fiala et al. 1998; Parnass et al., 2000). The motility of dendritic filopodia and spines, which notably lack microtubules and neurofilaments, is facilitated by a network of filamentous actin (Sorra and Harris, 2000).

CA1 neurons have been the target of numerous studies of the mechanisms of calcium entry, buffering, and extrusion in dendritic spines (Yuste and Denk, 1995; Yuste et al., 1999; Majewska et al., 2000). Such studies have contributed to important advances in our understanding not only of calcium handling in spines but the mechanisms of synaptic transmission at single synapses and a variety of forms of morphological and functional plasticity (Emptage et al., 1999; Matsuzaki

et al., 2001; Nimchinsky et al., 2002; Oertner et al., 2002; Sabatini et al., 2002; Yasuda et al., 2003; Matsuzaki et al., 2004; Nimchinsky et al., 2004).

Spines also contain numerous organelles, including smooth endoplasmic reticulum (SER). SER is found in about half of the spines in CA1 but is present in most of the largest, morphologically complex spines (Spacek and Harris, 1997; Cooney et al. 2002). SER is occasionally associated with a spine apparatus, which consists of stacks of SER associated with other electron-dense material including polyribosomes. CA1 spines also contain free polyribosomes and mRNA, leading to the hypothesis that proteins can be synthesized on demand in individual dendritic spines (Steward et al., 1996). Endosomal organelles and coated vesicles are found in about one-third of CA1 spines (Cooney et al., 2002). Interestingly, mitochondria are absent from most spines (Sorra and Harris, 2000). The presence of a large number of molecules and organelles in spines, together with the separation that the spine neck provides from the dendritic shaft and other spines, has led to the hypothesis that spines function as isolated molecular compartments (Wickens, 1988; Koch and Zador, 1993; Harris and Kater, 1994; Sorra and Harris, 2000) and that such compartmentalization is necessary for synapse-specific changes in synaptic strength (Wickens, 1988; Harris and Kater, 1994).

A prominent feature of almost all CA1 spines (and spines throughout the nervous system) is a postsynaptic density (PSD), an electron-dense thickening of the postsynaptic membrane. The PSD is located adjacent to the presynaptic bouton(s) associated with the spine. Structurally, the size and shape of the PSD defines two classes of axo-spinous synapses: perforated synapses, which have large PSDs with complex shapes, and nonperforated synapses, which have smaller, disk-like PSDs (Harris et al., 1992). Functionally, the PSD is a biochemical specialization that allows numerous molecules (e.g., receptors, kinases, cytoskeletal elements) to be associated in a structured array at the synapse (Sheng, 2001). Perforated PSDs on CA1 pyramidal neurons have more  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and N-methyl-D-aspartate (NMDA) receptors than their nonperforated counterparts, suggesting that they may constitute a population of relatively powerful synapses (Ganeshina et al., 2004a,b).

A picture is now emerging concerning the organization of the glutamate receptors in the PSD found in excitatory synapses on CA1 spines (see Chapters 6 and 7). These synapses contain three types of glutamate receptors: NMDA, AMPA, and metabotropic glutamate (mGluR). NMDA receptors, which mediate a slow synaptic current blocked in a voltage-dependent manner by  $Mg^{2+}$  (see Chapter 6), occupy a disk-like space near the center of the PSD. AMPA receptors, which mediate a fast synaptic current, are distributed more evenly throughout the PSD (Lujan et al., 1996; Racca et al., 2000). The presence of the edited form of the GluR2 subunit, which is expressed abundantly in CA1 neurons under normal conditions, renders most of these AMPA receptors impermeable to  $Ca^{2+}$ , whereas NMDA receptors have a considerable  $Ca^{2+}$  per-

meability (Verdoorn et al., 1991; Burnashev et al., 1992; Vissavajjhala et al., 1996; Wenthold et al., 1996). mGluRs are located predominantly on the periphery of the PSD (Lujan et al., 1996). These receptors are coupled directly to the SER via a molecule called Homer, which may be coupled to mechanisms for releasing calcium from the SER (Xiao et al., 2000).

Individual excitatory synapses on CA1 neurons vary considerably in their expression of AMPA and NMDA receptors, even within particular dendritic domains. Indeed, silent synapses, which are thought to contain NMDA receptors but few or no functional AMPA receptors, were first discovered and most extensively studied at SC synapses on CA1 neurons (Isaac et al., 1995; Liao et al., 1995; Isaac, 2003). Immunocytochemical analysis suggests that whereas the number of NMDA receptors is relatively invariant, a tremendous range exists in the number of AMPA receptors at individual synapses (Nusser et al., 1998; Racca et al., 2000). Quantitative immunogold data suggest a correlation between synapse size and AMPA receptor number (Nusser et al., 1998; Takumi et al., 1999; Ganeshina et al., 2004a,b) and recent physiological data indicate that there are correlations between spine morphology and glutamate receptor distribution, with mushroom-shaped spines containing the most AMPA receptors and thinner spines and filopodia containing only NMDA receptors (Matsuzaki et al., 2001).

### 5.2.3 Excitatory and Inhibitory Synaptic Inputs

Like most neurons in the CNS, CA1 neurons receive input from both excitatory and inhibitory presynaptic neurons. The principle excitatory inputs arrive from the entorhinal cortex (EC) and CA3 pyramidal neurons. Direct inputs from layer III pyramidal neurons in the EC project to CA1 neurons via the perforant path (PP), so named because the fibers leaving the angular bundle perforate the subiculum (Cajal, 1911). The PP input from the EC to CA1 (also referred to as the temporo-ammonic path) selectively innervates the distal apical dendrites in the stratum lacunosum-moleculare (Blackstad, 1958). Some of the PP fibers forming synapses on CA1 pyramidal neurons reach their targets in the stratum lacunosum-moleculare via the temporo-alvear pathway (Deller et al., 1996a). Additional inputs from the nucleus reuniens of the thalamus and the basolateral nucleus of the amygdala also innervate CA1 neurons via synapses on the distal apical dendrites (Krettek and Price, 1977; Amaral and Witter, 1995; Dolleman-Van der Weel and Witter, 1996, 1997; Kempainen et al., 2002). Inputs from CA3 pyramidal neurons on both sides of the brain form the Schaffer collateral/commissural system (SC), which form synapses on the apical dendrites in the stratum radiatum and on the basal dendrites in the stratum oriens (Schaffer, 1892; Blackstad, 1956; Storm-Mathisen and Fonnum, 1972; Hjort-Simonsen, 1973).

A few notable differences between PP and SC synaptic inputs have been identified. First, the PP synapses are located farther from the soma. Without a mechanism for compensating for this dendritic disadvantage, these synapses would be expected to have a weaker influence on action-potential initi-

ation in the axon than the SC synapses (see Sections 5.2.8 and 5.2.9). A second difference is that, relative to the stratum radiatum, a greater proportion of synapses in the stratum lacunosum-moleculare are formed on dendritic shafts, rather than spines (Megias et al., 2001). Thus, any functions normally attributed to spines (e.g., biochemical compartmentalization) must be absent at many of these synapses (but see Goldberg et al., 2003a). The functional significance of the shaft synapses in the stratum lacunosum-moleculare is not known, but approximately equal numbers of these synapses are formed by the perforant path and thalamic nucleus reuniens projections (Wouterlood et al., 1990). Another possible difference between PP and SC synapses is that there appears to be more NMDA receptor activation at stratum lacunosum-moleculare synapses (Otmakhova and Lisman, 1999), although immunogold EM studies do not reveal increased NMDA receptor density in the stratum lacunosum-moleculare (Nicholson et al., 2006). Finally, PP synapses are inhibited by dopamine, serotonin, and noradrenaline (norepinephrine) to a much greater degree than SC synapses (Otmakhova and Lisman, 2000).

Numerous inhibitory neurons also target CA1 pyramidal neurons. Some of these interneurons target the soma and axon, and others target the dendrites. This selective targeting suggests that the PP and SC synapses are under differential control of different populations of interneurons. For example, the oriens-alveus/lacunosum-moleculare (O-LM) interneurons project a single axon to the stratum lacunosum-moleculare region of CA1, where the axon collateralizes extensively and forms synapses on the same dendritic branches as the PP synapses from entorhinal cortex. (For more details on interneuron targeting, see Section 5.9 and Chapter 8.) Despite the differential targeting of the various interneurons in CA1, a common feature is that they all use  $\gamma$ -aminobutyric acid (GABA) as the principal neurotransmitter. GABA activates  $GABA_A$  (ionotropic  $Cl^-$  channels) and  $GABA_B$  receptors (G protein receptors coupled to  $K^+$  channel activation).  $GABA_A$  receptor function, however, is inhomogeneous, with more rapid kinetics associated with proximal  $GABA_A$  receptors and slower kinetics associated with more distal  $GABA_A$  receptors (Pearce, 1993).

CA1 pyramidal neurons also receive neuromodulatory inputs from a number of subcortical nuclei. A large input arriving from the septum contains cholinergic afferents (Swanson et al., 1987). Projections from the locus coeruleus contain noradrenergic inputs; the raphe nuclei projections contain serotonergic inputs; and the ventral tegmental area sends dopaminergic afferents to the hippocampus (Storm-Mathisen, 1977). CA1 pyramidal neurons express numerous receptor subtypes for each of these neuromodulators, but their distribution is not always uniform throughout various subcellular domains. For example, dopamine receptors are localized preferentially in the stratum lacunosum-moleculare (Swanson et al., 1987; Goldsmith and Joyce, 1994), suggesting that neuromodulation via this pathway is selectively positioned to influence PP synapses to a greater extent than SC

synapses (Otmakhova and Lisman, 1999). Similarly, the noreadrenergic fibers from the locus coeruleus project preferentially to the stratum lacunosum-moleculare region of CA1 (Pasquier and Reinoso-Suarez, 1978).

#### 5.2.4 Axon Morphology and Synaptic Targets

A single axon emanates from the pyramidal soma of CA1 pyramidal neurons and projects through the stratum oriens and into the alveus. CA1 axons branch extensively, forming collaterals with several targets, both within and beyond the hippocampus. In the CA1 subfield, CA1 axons form a limited arbor restricted primarily to the stratum oriens; very few collaterals enter the stratum radiatum (Amaral et al., 1991). Anatomical and physiological analyses indicate that CA1 neurons show a remarkably low connection probability of about 1% (Knowles and Schwartzkroin, 1981; Deuchars and Thomson, 1996). Thus, unlike CA3 pyramidal neurons, CA1 cells do not make many connections among themselves, except in the developing hippocampus (Tamamaki et al., 1987; Amaral et al., 1991; Aniksztejn et al., 2001). By contrast, CA1-interneuron connectivity is much higher, and the strength of excitatory postsynaptic potentials (EPSPs) on interneurons is powerful (Gulyás et al., 1993a; Ali et al., 1998; Csicsvari et al., 1998; Marshall et al., 2002). Because the CA1 axon does not enter the stratum radiatum, local synaptic connections onto other CA1 neurons occur on basal dendrites. Interneurons outside the stratum oriens are not significantly contacted by CA1 axons.

The most significant intrahippocampal connection of CA1 neurons is to pyramidal neurons in the subiculum (Tamamaki et al., 1987; Tamamaki and Nojyo, 1990; Amaral et al., 1991). This connection is likely to be especially important because the subiculum forms a powerful output of the hippocampus (see Section 5.4). CA1 axons collateralize extensively in the subiculum but form a topographical projection. CA1 neurons closest to the subiculum contact their nearest neighbors in the proximal subiculum, whereas CA1 neurons farther from the subiculum project to the most distal regions of the subiculum (see Chapter 3). Collaterals from individual CA1 axons form a column extending the full height of the subiculum (500  $\mu$ m in the rat) occupying about one-third the width of the subiculum (250–300  $\mu$ m) and extending about 2 mm along the septo-temporal length of the hippocampus (Tamamaki et al., 1987; Tamamaki and Nojyo, 1990).

The extrahippocampal projections of CA1 neurons via the fimbria depend on their position along the septo-temporal axis (Fig. 5–1A). Septal CA1 neurons project to retrosplenial and perirhinal cortex as well as to the lateral septal nucleus and the diagonal band of Broca. Midsepto-temporal CA1 neurons project to the taenia tecta and medial frontal cortex. Temporal CA1 neurons project to the taenia tecta, medial frontal cortex, anterior olfactory nucleus, olfactory bulb, nucleus accumbens, basal nucleus of the amygdala, and anterior and dorsomedial hypothalamus (Jay et al., 1989; van Groen and Wyss, 1990; Amaral and Witter, 1995). Importantly, however, not all CA1

neurons project to each of these regions. For example, only a subset of CA1 pyramidal neurons, along with a population of giant, nonpyramidal principal neurons, project to the olfactory bulb (van Groen and Wyss, 1990; Gulyás et al., 1998).

No studies have explicitly quantified the total axonal length or number of synapses formed by CA1 axon collaterals. More extensive data are available for the CA3 axon, which is discussed in Section 5.3.4. Light microscopic studies indicate, however, that the CA1 axon, which has a diameter of less than 1  $\mu\text{m}$ , has numerous en passant and terminal synaptic specializations along its length (Tamamaki and Nojyo, 1990). The total number of synaptic connections is likely on the order of several thousand.

### 5.2.5 Resting Potential and Action Potential Firing Properties

CA1 pyramidal neurons have resting potentials, recorded in slice preparations, in the range of  $-60$  to  $-70$  mV. Similar values have been recorded using either sharp microelectrodes or patch pipettes (e.g., Storm, 1987; Spruston and Johnston, 1992; Staff et al., 2000). At birth, resting potentials are 5 to 10 mV depolarized from this value but gradually hyperpolarize to their adult value by 2 to 3 weeks of age (Spiegelman et al., 1992). In response to depolarizing current injections, action potentials typically have a threshold in the range of  $-40$  to  $-50$  mV (Spruston and Johnston, 1992; Staff et al., 2000; but see Fricker et al., 1999). Thus, CA1 neurons must be depolarized by about 20 mV before action potentials are triggered *in vitro*. The resulting action potentials have amplitudes of about 100 mV.

The data discussed above are from recordings made in hippocampal slices. Such measurements provide good estimates of the intrinsic properties of CA1 neurons, but the values may be slightly different in an active network. *In vivo* the ongoing synaptic activity causes action potentials at a rate of 1 to 10 Hz, and the average membrane potential between spikes is sometimes as much as 10 mV depolarized from the *in vitro* measurements (Henze and Buzsáki, 2001). During locomotion through a place field, action potential firing transiently increases to rates of around 8 Hz (theta frequency), with occasional bursts of high-frequency action potential firing ( $> 100$  Hz) (Frank et al. 2001) (see Chapter 11).

Action potential firing patterns *in vivo* are determined in part by the timing of synaptic inputs and in part by the intrinsic firing properties of CA1 neurons. The intrinsic firing properties of CA1 neurons have been studied extensively in the slice preparation, in which it is relatively easy to obtain recordings and to isolate the effects of intrinsic properties on spike firing due to the low rate of spontaneous background synaptic input. Under these conditions, brief depolarizing current injections typically elicit a single action potential followed by four after-potentials (Storm, 1987, 1990): (1) a fast after-hyperpolarization (AHP); (2) an after-depolarization (ADP); (3) a medium AHP; and (4) a slow AHP (Fig. 5–2A). A fast K<sup>+</sup> conductance gated by voltage and Ca<sup>2+</sup> (named I<sub>C</sub> or BK)

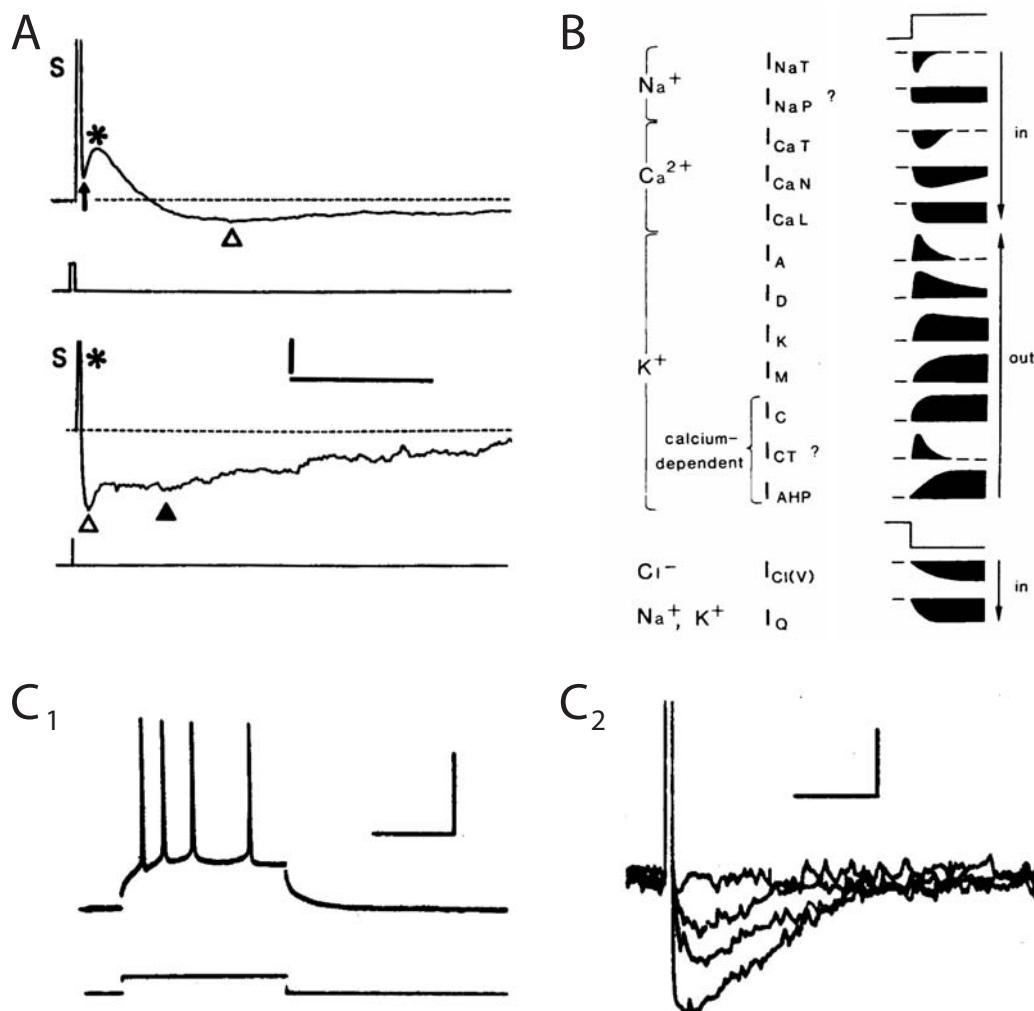

contributes to the fast AHP, whereas a slow, Ca<sup>2+</sup>-activated K<sup>+</sup> conductance contributes to the slow AHP (I<sub>AHP</sub>, mediated by SK channels). A K<sup>+</sup> conductance reduced by muscarinic receptor activation (I<sub>M</sub>) and I<sub>C</sub> contribute to the medium AHP (Storm, 1990) (Fig. 5–2B). The ADP is mediated in part by a Ca<sup>2+</sup> tail current mediated by R-type Ca<sup>2+</sup> channels (Metz et al., 2005) and may also have a contribution from persistent Na<sup>+</sup> current (Yue et al., 2005).

Action potentials in CA1 pyramidal neurons typically have a half-width of about 1 ms (Staff et al., 2000). In mature rats, repolarization is slowed by application of either tetraethylammonium (TEA) or 4-aminopyridine (4-AP) at concentrations that block the delayed rectifier K<sup>+</sup> current, the inactivating A-type and D-type K<sup>+</sup> currents, and fast voltage- and Ca<sup>2+</sup>-gated K<sup>+</sup> currents (Storm, 1987; Golding et al., 1999). Such results suggest that a variety of voltage-gated and Ca<sup>2+</sup>-sensitive K<sup>+</sup> currents contribute to action-potential repolarization as well as the various phases of the AHP (Storm, 1990) (Fig. 5–2B).

Longer depolarizing current injections via somatic recording electrodes typically elicit continuous action potential firing at a rate that is roughly proportional to the amount of current injected. These spike trains usually exhibit spike-frequency accommodation: a high frequency of action potentials at the beginning of a step current injection followed by a gradual reduction in spike frequency later in the current injection (Madison and Nicoll, 1984) (Fig. 5–2C<sub>1</sub>). Spike-frequency accommodation is caused by gradual activation of K<sup>+</sup> conductances such as I<sub>M</sub> and I<sub>AHP</sub> (Lancaster and Adams, 1986; Lancaster and Nicoll, 1987). These K<sup>+</sup> currents increase cumulatively during the action potential train because they do not inactivate and also deactivate slowly, resulting in a larger AHP and longer times to repolarize back to threshold for the next spike. Trains of action potentials are followed by an after-hyperpolarization (AHP) lasting more than a second (Fig. 5–2C<sub>2</sub>); and the amplitude of each of these AHPs increases with the number of action potentials in the preceding train (Hotson and Prince, 1980; Madison and Nicoll, 1984) owing to increased Ca<sup>2+</sup> entry and activation of SK-type Ca<sup>2+</sup>-activated K<sup>+</sup> channels (Marrion and Tavalin, 1998; Bowden et al., 2001).

K<sup>+</sup> currents that are activated below threshold for action potentials can also affect spike-firing patterns. The best example of this is the delay to firing of the first action potential observed with current injections just above threshold. K<sup>+</sup> conductances, such as A-type and D-type K<sup>+</sup> currents, can be activated by subthreshold depolarizations, thus keeping the membrane potential from reaching the action potential threshold. As these conductances inactivate, however, their hyperpolarizing influence is removed, allowing the membrane to reach threshold. The delay to first spike is partly determined, therefore, by the activation and inactivation rates of subthreshold K<sup>+</sup> currents (Storm, 1990).

A common feature of action-potential firing patterns *in vivo* is bursting (Kandel and Spencer, 1961; Ranck, 1973; Fox and Ranck, 1975; Suzuki and Smith, 1985; Frank et al., 2001),

**Figure 5-2.** CA1 spike frequency adaptation and slow after-hyperpolarization (AHP). *A*. Four after-potentials following single spikes (S) in CA1 pyramidal neurons: (1) fast AHP ( $\uparrow$ ); (2) after-depolarization (ADP) (\*); (3) medium AHP ( $\Delta$ ); and (4) slow AHP ( $\blacktriangle$ ). The lower trace is on a slower time scale. Bar = 5 mV, 50 ms (top) or 5 mV, 500 ms (bottom). Spikes are truncated. (Source: Adapted from Storm, 1987.) *B*. Overview of a variety of voltage- and  $\text{Ca}^{2+}$ -dependent currents in hippocampal pyramidal neurons: transient  $\text{Na}^+$  current ( $I_{\text{NaT}}$ ); persistent  $\text{Na}^+$  current ( $I_{\text{NaP}}$ ); T-type  $\text{Ca}^{2+}$  current ( $I_{\text{CaT}}$ ); N-type  $\text{Ca}^{2+}$  current ( $I_{\text{CaN}}$ ); L-type  $\text{Ca}^{2+}$  current ( $I_{\text{CaL}}$ ); fast transient  $\text{K}^+$  current ( $I_A$ ); delay  $\text{K}^+$  current ( $I_D$ );

delayed rectifier  $\text{K}^+$  current ( $I_K$ ); M current ( $I_M$ ); fast  $\text{Ca}^{2+}$ -dependent  $\text{K}^+$  current ( $I_C$ ); transient  $\text{Ca}^{2+}$ -dependent  $\text{K}^+$  current ( $I_{\text{CT}}$ ); slow  $\text{Ca}^{2+}$ -dependent  $\text{K}^+$  current ( $I_{\text{AHP}}$ ); voltage-dependent  $\text{Cl}^-$  current ( $I_{\text{Cl(V)}}$ ); hyperpolarization-activated mixed cation current ( $I_Q = I_H$ ). (Source: Adapted from Storm, 1990.) *C*. Spike-frequency adaptation and the slow AHP in CA1 pyramidal neurons.  $C_1$  shows a train of adapting action potentials in response to a step current injection. Bar = 40 mV and 2 nA vertical and 40 ms horizontal.  $C_2$  shows the slow AHP corresponding to 1, 4, 5, and 7 action potentials. Bar = 5 mV, 1 second. (Source: Adapted from Madison and Nicoll, 1984.)

defined broadly as a brief period of high-frequency spiking ( $> 100$  Hz) followed by a longer period of inactivity. The relative contributions of synaptic drive and intrinsic membrane properties to the burst firing of CA1 neurons *in vivo* are unclear. Although CA1 cells exhibit some intrinsic bursting under normal *in vitro* conditions (Wong and Prince, 1981; Masukawa et al., 1982), it is modest compared to other neurons, such as pyramidal neurons of subiculum, which burst much more robustly (see Section 5.4.4). In the absence of a strong intrinsic burst mechanism, bursting may occur as a consequence of large synaptic inputs, which could transiently

increase the action potential firing rate. The intrinsic properties of CA1 neurons may, however, provide an additional contribution to bursting *in vivo*.

*In vitro* studies have identified two types of intrinsic bursting in CA1 neurons: Low-threshold bursting occurs in response to somatic current injections just above action potential threshold; they are generated when the ADP that follows an action potential is large enough to trigger additional action potentials (Jensen et al., 1994; Metz et al., 2005; Yue et al., 2005). High-threshold bursting occurs in response to strong dendritic current injection or synaptic activation and is

caused by the generation of  $\text{Ca}^{2+}$  spikes in CA1 dendrites (Wong and Prince, 1978; Golding et al., 1999; Magee and Carruth, 1999) (see Section 5.2.11).

A variety of factors influence the spike-firing mode of CA1 pyramidal neurons. Increasing extracellular  $\text{K}^+$ , decreasing extracellular  $\text{Ca}^{2+}$ , and decreasing osmolarity all enhance bursting through different mechanisms (Jensen et al., 1994; Azouz et al., 1997; Su et al., 2002). Bursting is also likely to be a target of modulation by neurotransmitters. For example, cholinergic activation facilitates the induction of plateau potentials, which may be associated with some kinds of burst firing in vivo (Fraser and MacVicar, 1996). Because so many factors influence bursting, it is important to determine the mechanism of bursting under conditions mimicking in vivo states as closely as possible. Intrinsic burst-firing mechanisms have also been implicated as targets of epileptogenesis in the hippocampus (Wong et al., 1986), so understanding the pathophysiology of bursting may lead to new treatments of epilepsy.

A number of aspects of pyramidal cell physiology are also under modulatory control. Activation of muscarinic receptors causes depolarization and a reduction in spike-frequency accommodation due to inhibition of  $I_{\text{M}}$ ,  $I_{\text{AHP}}$ , and voltage-insensitive  $\text{K}^+$  conductances (Benardo and Prince, 1982a,b,c; Madison et al., 1987; Benson et al., 1988). Norepinephrine also reduces spike-frequency accommodation due to inhibition of  $I_{\text{AHP}}$  (Madison and Nicoll, 1982; Pedarzani and Storm, 1996). Dopamine causes hyperpolarization and elevated action-potential threshold owing in part to activation of  $\text{Ca}^{2+}$ -sensitive  $\text{K}^+$  conductances; it also raises the action-potential threshold in CA1 neurons (Benardo and Prince, 1982d,e; Stanzione et al., 1984). Serotonin has biphasic effects on CA1 neurons, initially causing hyperpolarization owing to activation of a  $\text{K}^+$  current, but later causing depolarization

and inhibition of the AHP (Andrade and Nicoll, 1987; Ropert, 1988). Numerous other modulatory effects have been reported in CA1 neurons, indicating that the resting and active properties of these neurons *in vivo* are likely to depend on behavioral states.

### 5.2.6 Resting Membrane Properties

One key to understanding neurons at the cellular level is to be able to predict action potential output in response to a given spatiotemporal pattern of synaptic inputs. In addition to the properties of the synapses themselves, a neuron's response to a synaptic input depends on three things: its dendritic geometry and the location of the synapse(s), its passive membrane properties, and its active membrane properties. Passive membrane properties are those that do not depend on membrane potential (i.e., they are linear). Active membrane properties, by contrast, do depend on membrane potential (e.g., the voltage-gated  $\text{Na}^+$  and  $\text{K}^+$  channels that mediate the action potential, which are highly nonlinear). These properties are very much interdependent, but physiologists attempt to treat them separately, as we do in our discussion here. One justification for doing this is that detailed neuronal simulations require a description of the passive membrane properties, which constitute a foundation on which active membrane properties are superimposed.

CA1 pyramidal neurons, like most neurons in the brain, have long and extensively branching dendrites. A quantitative understanding of how membrane potential changes (such as EPSPs) spread through these structures requires a theoretical treatment of dendrites combined with experimental measurements. Wilfrid Rall provided the theoretical framework with his seminal work on the “cable theory” (Box 5–1). Hippocam-

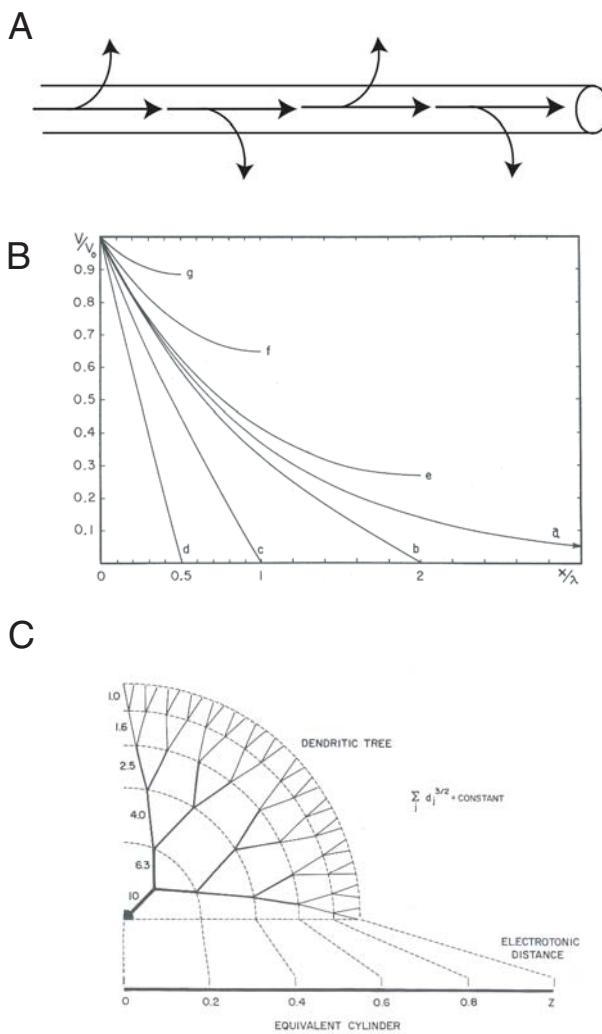

#### Box 5–1 Cable Theory

During the 1950s and 60s, Wilfrid Rall developed a theory for treating the flow of current in passive dendrites. The seminal articles comprising this theory have been compiled and republished in book form (Segev et al., 1995). Because the theory was based on a theory similar to that for trans-Atlantic telegraph cables, it is referred to as the “cable theory.” With this mathematical treatment, neurons are considered to be long, leaky cables immersed in a conductive medium (cerebrospinal fluid). A synaptic current propagating along a passive dendrite is influenced by three factors: membrane resistance, membrane capacitance, and axial (or intracellular) resistance. These properties depend in part on geometry (narrower dendrites have higher membrane resistance, smaller capacitance, and higher axial resistance) and in part on the composition of the membrane and cytoplasm. In his theory, Rall defined three geometry-independent variables: membrane resistivity ( $R_m$ ), specific membrane capacitance ( $C_m$ ), and intracellular resistivity ( $R_i$ ). He also used two useful measures. The first is called the “space constant” ( $\lambda$ ), which is equal to the length, in an infinitely long cable, over which the membrane potential decays to  $1/e$  of its original value. The second is the “electrotonic length” ( $L = l/\lambda$ ), which is the ratio of the physical length to the space constant, a measure of the total electrical length of a finite cable.

(Continued)

**Box 5-1****Cable Theory** (Continued)

Rall also showed that a class of branching dendritic trees with certain characteristics could be collapsed to an “equivalent cylinder” with a characteristic  $L$ . He also described methods for estimating  $L$  experimentally. Because most neurons deviate from the assumptions necessary to collapse them to a single cable, however, the lasting impact of Rall’s cable theory is that it provides the foundation for modern computational analysis of neurons. Properties such as dendritic structure and  $R_m$  (and possibly  $R_p$ , but less so  $C_m$ ) differ across different types of neurons and influence their integrative properties, which can be predicted using computer models.

**Box Fig. 5-1.** A. Current flowing along a dendrite may flow longitudinally (e.g., toward the soma), or it may leak out across the dendritic membrane. B. Voltage attenuates with distance along a dendritic cable in a way that depends on  $R_m$ ,  $R_p$ , and dendritic geometry. Curve a shows the decay of voltage in a semi-infinite cylinder. Curves b-d show attenuation in finite, open-ended cylinders of decreasing length. Curves e-g show attenuation in finite, closed-end cylinders of decreasing length. All curves are for dendritic cylinders with  $R_m$ ,  $R_i$  and diameter yielding a space constant of 1. (Source: Adapted from Rall, 1959.) C. Dendritic trees with particular geometries can be collapsed to an equivalent cylinder representation. Two criteria must be met: At each branch point, the diameter of the parent dendrite, raised to the  $3/2$  power, must equal the sum of the daughter-dendrite diameters, each raised to the  $3/2$  power. In addition, each dendritic branch must terminate at the same electrotonic length. (Source: Adapted from Rall, 1964.)

pal neurons were among the first to have their cable properties determined experimentally. Initially, microelectrode recordings were used to estimate the electrotonic length ( $L$ ) of CA1 pyramidal neurons (Brown et al., 1981; Johnston, 1981). These estimates proved to be of limited value, however, because CA1 dendrites clearly violate the conditions required to collapse them to a single cylinder (Mainen et al., 1996). For example, basal, apical, and oblique dendritic branches terminate at different electrotonic distances (Turner, 1984; Pyapali et al., 1998). Furthermore, there are indications that the membrane properties that contribute to  $L$  are not uniform over the surface of the dendritic tree (Golding et al., 2005). For these reasons, a more accurate picture of the passive behavior of the CA1 dendritic tree is best achieved by computer simulation methods, which facilitate the characterization based on the measured geometry and membrane properties of CA1 pyramidal neurons.

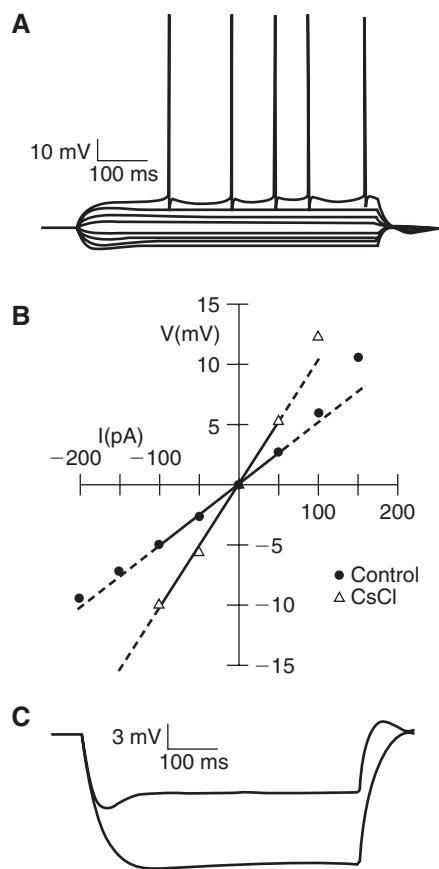

The most reliable measures of the parameters affecting cable properties— $R_m$ ,  $C_m$ ,  $R_i$ —come from patch-clamp recordings made in hippocampal slices. Earlier estimates of these parameters using microelectrodes were affected by the leak that is introduced by microelectrode penetration (Spruston and Johnston, 1992; Staley et al., 1992). Patch-clamp recordings are not without their own problems, namely the possible complications introduced by dialysis of the cytoplasm. There is good evidence, however, that this problem does not affect passive membrane properties substantially (Spruston and Johnston, 1992; Staff et al., 2000). More serious problems are posed by the voltage-gated channels that are active near the resting potential, as well as differences between *in vitro* and *in vivo* conditions (see below).

Passive membrane properties are typically estimated by measuring the response of a neuron to a step current injection. Two features define the response: the steady-state amplitude and the time course of the voltage change. Theoretically, this time course can be described by the sum of several exponentials, with the slowest component having a time constant equal to the membrane time constant ( $\tau_m$ ), given by the product  $R_m C_m$ . The steady-state voltage response ( $\Delta V$ ) is determined by the neuron's input resistance ( $R_N$ ) in a way that depends on  $R_m$  and geometry (large neurons with many dendrites and low  $R_m$  have the lowest  $R_N$ ). Input resistance can be measured directly using Ohm's law ( $R_N = \Delta V / \Delta I$ ), but determination of  $R_m$  (from  $\tau_m$ ) requires a value of  $C_m$ . Because  $C_m$  is largely dependent on the lipid composition of the membrane, its value has long been assumed to be nearly constant at  $1 \mu\text{F}/\text{cm}^2$ , an assumption that was validated by experimental measurements of capacitance in cells with simple geometry (Gentet et al., 2000). Estimates of  $C_m$  from neurons with more complex geometry are often close to this value; in instances where substantial deviations are reported, however, it is difficult to know if these reflect real variability in  $C_m$  or the extreme difficulty of accurately reconstructing the surface area of neurons with branching dendrites studded with spines. Most estimates of  $R_m$  have therefore been derived by measuring  $\tau_m$  and assuming a value for  $C_m$  of  $1 \mu\text{F}/\text{cm}^2$ .

Another complication when determining  $R_m$  is the presence of voltage-gated channels that are open at the resting membrane potential. Investigators typically seek to minimize the contribution from activation or deactivation of these channels by making the evoked voltage change small (e.g., 1–5 mV). In CA1 pyramidal neurons, however, this problem cannot be avoided entirely because of the presence of a powerful hyperpolarization-activated, nonspecific-cation current ( $I_h$ ) that is active at rest (Halliwell and Adams, 1982; Spruston and Johnston, 1992). This conductance introduces a noticeable “sag” in the voltage response. Hyperpolarizing voltage responses activate  $I_h$ , resulting in a gradual return of  $V_m$  toward the resting potential during the current injection (hyperpolarizing “sag”). Depolarizing voltage responses deactivate  $I_h$ , similarly resulting in a gradual return of  $V_m$  toward the resting potential (depolarizing “sag”). The presence of  $I_h$ -mediated sag makes it difficult or impossible to determine  $\tau_m$ . To solve this problem,  $\tau_m$  is usually measured with  $I_h$  blocked by bath application of 2 to 5 mM CsCl or 50 to 100  $\mu\text{M}$  ZD7288. Under these conditions, CA1 pyramidal neurons from adult rats and guinea pigs have an  $R_N$  of about 120 to 150  $\text{M}\Omega$  and  $\tau_m$  of about 35 to 40 ms (Spruston and Johnston, 1992; Staff et al., 2000; Golding et al., 2005) (Fig. 5–3). Assuming a  $C_m$  of  $1 \mu\text{F}/\text{cm}^2$ , this corresponds to an  $R_m$  of about  $40,000 \Omega\text{cm}^2$  (to understand the units of  $R_m$ , it may help to understand that the units of its inverse are conductance per unit area). It is important to realize, however, that these values are strongly affected by blocking  $I_h$ . In the absence of its blockers,  $R_N$  is 38% to 54% lower, and the membrane potential changes decay accordingly faster (Spruston and Johnston, 1992; Staff et al., 2000; Golding et al., 2005).

In guinea pig CA1 neurons, hyperpolarizations or depolarizations of about 5 mV from rest result in about a 20% decrease and increase in  $R_N$ , respectively (Hotson et al., 1979; Spruston and Johnston, 1992). Even after block of  $I_h$ , estimates of  $R_m$  and  $R_N$  are sensitive to small changes in the resting membrane potential, but in the opposite direction of the voltage dependence caused by  $I_h$ . These findings indicate that the experimental estimates of these parameters are influenced by multiple voltage-gated conductances; therefore, these parameters may never be truly passive. Thus, it may be more appropriate to refer to the “resting membrane properties” of CA1 neurons, which should be regarded as approximations of the theoretical “passive” membrane properties.

Despite the voltage dependence of these parameters, estimates of their values near rest are essential because they provide important parameters for computer models of neurons. One of the purposes of constructing such models, using methods originally developed by Rall (Segev et al., 1995) and currently incorporated into user-friendly programs such as NEURON (<http://www.yale.edu>) and GENESIS (<http://www.genesis-sim.org/GENESIS/>), is to estimate how synaptic potentials attenuate between the dendrites and the soma. Such estimates, however, are highly dependent on the intracellular resistivity,  $R_i$ . This parameter is best estimated using computer models of carefully reconstructed neurons along with a meas-

ure of voltage attenuation. Modeling of neurons from which attenuation was measured with simultaneous somatic and dendritic patch-clamp electrodes yielded a value for  $R_i$  of about  $180 \Omega\text{cm}$  for CA1 pyramidal neurons (Golding et al., 2005). This study also revealed that the membrane resistivity of CA1 neurons is nonuniform, with the dendritic membrane increasingly leaky at greater distances from the soma. Similarly,  $I_h$ , which is activated at rest and therefore increases voltage attenuation in dendrites, also increases with distance from the soma (Magee, 1998; Golding et al., 2005) (see Section 5.2.13).

### 5.2.7 Implications for Voltage-Clamp Experiments in CA1 Neurons

Knowledge of the structure and membrane properties of CA1 neurons allows predictions regarding the functional coupling of the soma and dendrites. Detailed compartmental modeling of CA1 neurons suggests that functional coupling between the

soma and distal dendrites is limited. One of the interesting consequences of this is that it makes it extremely difficult to study synaptic or voltage-gated conductances in dendrites using electrodes placed at the soma. Space-clamp errors are likely to be enormous for distal conductances and substantial even for relatively proximal conductances (Spruston et al., 1993, 1994; Major et al., 1994; Mainen et al., 1996). These errors are greatest for transient conductance changes; and even when measures of steady-state voltage control (such as reversal potential measurements) indicate reasonable voltage control, errors can be very large for the transient case. The presence of voltage-gated conductances in dendrites, though presumably advantageous for the normal function of the neuron, makes it still more difficult to control dendritic membrane potential using somatic electrodes. Thus, other methods are needed to complement somatic recordings to determine the functional properties of dendrites. Fortunately, several such methods are now available (see Sections 5.2.11 through 5.2.13).

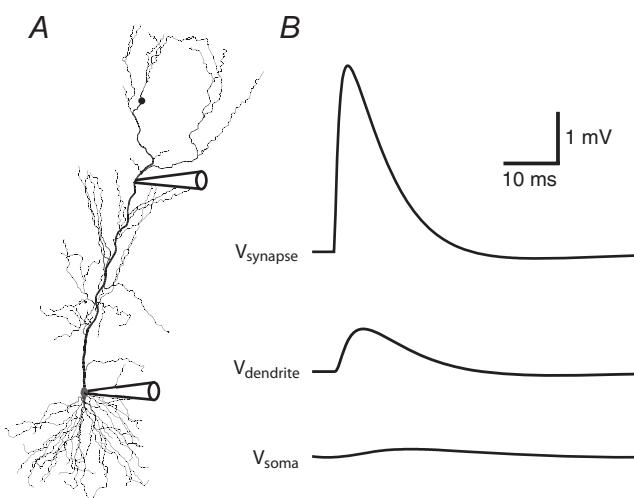

### 5.2.8 Attenuation of Synaptic Potentials in CA1 Dendrites

The functional significance of the dendritic tree, with these nonuniform membrane properties and high  $R_i$ , is perhaps best understood by considering the extent to which synaptic potentials attenuate as they propagate from the dendrite to the soma. Compartmental models constrained by simultaneous recordings have been used to predict synaptic attenuation, and the results are striking. Distal synaptic inputs are expected to attenuate many times 10-fold from the most distal sites to the soma (Mainen et al., 1996; Andreasen and Lambert, 1998; Golding et al., 2005) (Fig. 5-4). Most of this enormous attenuation occurs between the synapse and the primary apical dendrite, but direct dendritic recordings indicate an additional three- to fourfold attenuation between dendritic sites at about  $300 \mu\text{m}$  and the soma. The structure of the CA1 dendritic tree appears to maximize synaptic attenuation (Jaffe and Carnevale, 1999), a point that is considered in more detail below by way of comparison to dentate granule cells (see Section 5.5.5).

The severe synaptic attenuation predicted on the basis of *in vitro* studies and modeling might even be an underestimate of the attenuation that could occur in passive dendrites *in vivo*. Because dendrites are constantly receiving synaptic inputs, attenuation may be enhanced by the increased conductance produced at active synapses (Destexhe and Pare, 1999). The magnitude of this effect, however, has not been directly determined in the hippocampus.

### 5.2.9 Mechanisms of Compensation for Synaptic Attenuation in CA1 Dendrites

Faced with this much attenuation, it seems almost pointless for a CA1 neuron to have synapses on its distal dendrites. Yet a large number of axons (primarily the perforant path input from the entorhinal cortex) do synapse on distal apical

**Figure 5-4.** CA1 dendritic attenuation of synaptic potentials. Simulations of excitatory postsynaptic potential (EPSP) attenuation from the apical tuft to the soma. A model with nonuniform  $R_m$  and  $G_h$  was used in the simulation. The synaptic conductance was 1 nS with a rise time constant of 0.5 ms and a decay time constant of 5 ms. *A*, The synapse location is indicated by the black dot in the apical dendrite, 583  $\mu\text{m}$  from the soma. The somatic and dendritic recording sites are indicated by the electrode cartoons (dendritic recording electrode at 365  $\mu\text{m}$ ). *B*, Example of simulated EPSPs in response to activation of the distal apical synapse (black dot in *A*) and measured at the synapse, the dendritic recording site, and the soma. In this example the EPSP attenuates 26-fold between the synapse and the soma. (Source: Adapted from Golding et al., 2005.)

dendrites. Even Schaffer collaterals, the excitatory axons from CA3, form many synapses on relatively distal dendritic regions. Two mechanisms are likely to overcome this problem of “dendritic disadvantage.” First, there is now evidence that the average synaptic conductance in the stratum radiatum increases as a function of distance from the soma (Magee and Cook, 2000). The synapses at distal sites may have larger conductances as a result of an increased abundance of large, perforated synapses and a higher density of AMPA-type glutamate receptors (Andrasfalvy and Magee, 2001; Smith et al., 2003; Nicholson et al., 2006). However, both computer simulations and electron microscopy indicate that this principle of “synaptic scaling” to compensate for dendritic distance does not extend into the most distal apical dendrites, where the perforant-path fibers form synapses (Kali and Freund, 2005; Nicholson et al., 2006).

The perforant-path input to CA1 pyramidal neurons thus appears to be disadvantaged because EPSPs from this input attenuate so much on their way to the soma, and they apparently lack a conductance scaling mechanism to compensate. Exacerbating the problem is feedforward inhibition, which is so powerful, the excitatory nature of the perforant path inputs to CA1 was once in question (Buzsáki et al., 1995; Empson and Heinemann, 1995a,b; Soltesz, 1995; Andreasen and Lambert, 1998). It is now clear, however, that this input is excitatory (Doller and Weight, 1982; Yeckel and Berger, 1990,

1995) and that it is capable of discharging CA1 cells *in vivo*, even after lesions that reduce or eliminate input from Schaffer collaterals (McNaughton et al., 1989; Brun et al., 2002).

For perforant path synapses to have a significant impact on CA1 output, some mechanism must compensate for dendritic attenuation. One possibility is that distal synapses may result in significant somatic depolarization through amplification by voltage-gated channels in dendrites. Although this may occur in a graded fashion in the dendrites or the soma (Lipowsky et al., 1996; Cook and Johnston, 1997, 1999; Andreasen and Lambert, 1999), amplification may also occur through the generation of dendritic spikes (see Sections 5.2.11 through 5.5.13). Another possibility is that distal synapses normally do not exert a strong influence over action-potential initiation on their own but may interact effectively with more proximal synaptic activation to trigger action potentials (Remondes and Schuman, 2002). Such interactions may occur in two ways. First, the distal, perforant path EPSP may sum with more proximal, Schaffer collateral EPSPs to reach threshold for an action potential in the soma or the apical dendrite (Levy et al., 1995; Jarsky et al., 2005; Kali and Freund, 2005). Second, strong activation of perforant-path synapses can lead to dendritic spikes, which only propagate effectively to the soma when facilitated by coincident activation of the Schaffer collateral synapses (Jarsky et al., 2005).

## 5.2.10 Pyramidal Neuron Function: Passive Versus Active Dendrites

Even without much information about membrane properties, many neuroscientists predicted that synaptic potentials would attenuate severely as they propagate toward the soma if dendrites were truly passive. To counter the unlikely proposition that distal dendritic synapses are irrelevant, some investigators proposed that dendrites might contain voltage-gated conductances; others, however, took the view that voltage-gated channels were a unique property of the axon (reviewed in Llinás, 1988; Adams, 1992). Although the debate over passive versus active dendrites got started with studies of spinal motoneurons, the hippocampus soon took center stage, as its laminar structure and densely packed, uniformly oriented dendrites facilitated studies of dendritic function using extracellular electrodes. Field potential recordings in the CA1 region of the anesthetized rabbit indicated that spikes could be generated in the proximal dendrites of CA1 neurons and subsequently propagated actively away from this site (Cragg and Hamlyn, 1955; Andersen, 1960; Fujita and Sakata, 1962; Andersen and Lomo, 1966; Andersen et al., 1966). These conclusions were later confirmed and elaborated on by more detailed analyses using field potentials, both *in vitro* and *in vivo* (Turner et al., 1989, 1991; Herreras, 1990). Another important study was performed by Spencer and Kandel, who made intracellular recordings from CA1 neurons in the anesthetized cat (Spencer and Kandel, 1961). They observed fast, spike-like events that were smaller than action potentials and often preceded full-sized spikes. Based on the absence of such events following antidromic stimulation of the axon, Spencer

and Kandel concluded that these “fast prepotentials” originated in dendrites. This view has received some support (Schwartzkroin, 1977; Wong and Stewart, 1992; Turner et al., 1993) but has remained controversial, as action potentials from CA1 neurons coupled by gap junctions have also been implicated (MacVicar and Dudek, 1981; Schmitz et al., 2001). Nevertheless, these studies collectively indicated that the dendrites of CA1 pyramidal neurons are capable of generating active responses owing to the presence of voltage-gated channels.

The view that CA1 dendrites are active received considerable support from studies using microelectrodes to record from CA1 dendrites in slices. These recordings indicated that action potentials could be observed in dendritic recordings, even when dendrites were physically or pharmacologically isolated from the soma (Wong et al., 1979; Benardo et al., 1982; Poolos and Kocsis, 1990; Turner et al., 1991, 1993; Wong and Stewart, 1992; Colling and Wheal, 1994; Andreasen and Lambert, 1995a). Calcium imaging studies also indicated that dendrites could generate active responses capable of activating voltage-gated  $\text{Ca}^{2+}$  channels and mediating significant  $\text{Ca}^{2+}$  entry into dendrites (Regehr et al., 1989; Jaffe et al., 1992; Regehr and Tank, 1992; Yuste and Denk, 1995; Yuste et al., 1999). By the late 1980s and early 1990s, such a wealth of data had been accumulated that it was undeniable that CA1 dendrites were active. Attention then shifted to answering more detailed questions about dendritic excitability, including what types of channels are present, what properties they possess, how they are distributed, and how they contribute to the integrative properties of CA1 neurons.

### **5.2.11 Dendritic Excitability and Voltage-Gated Channels in CA1 Neurons**

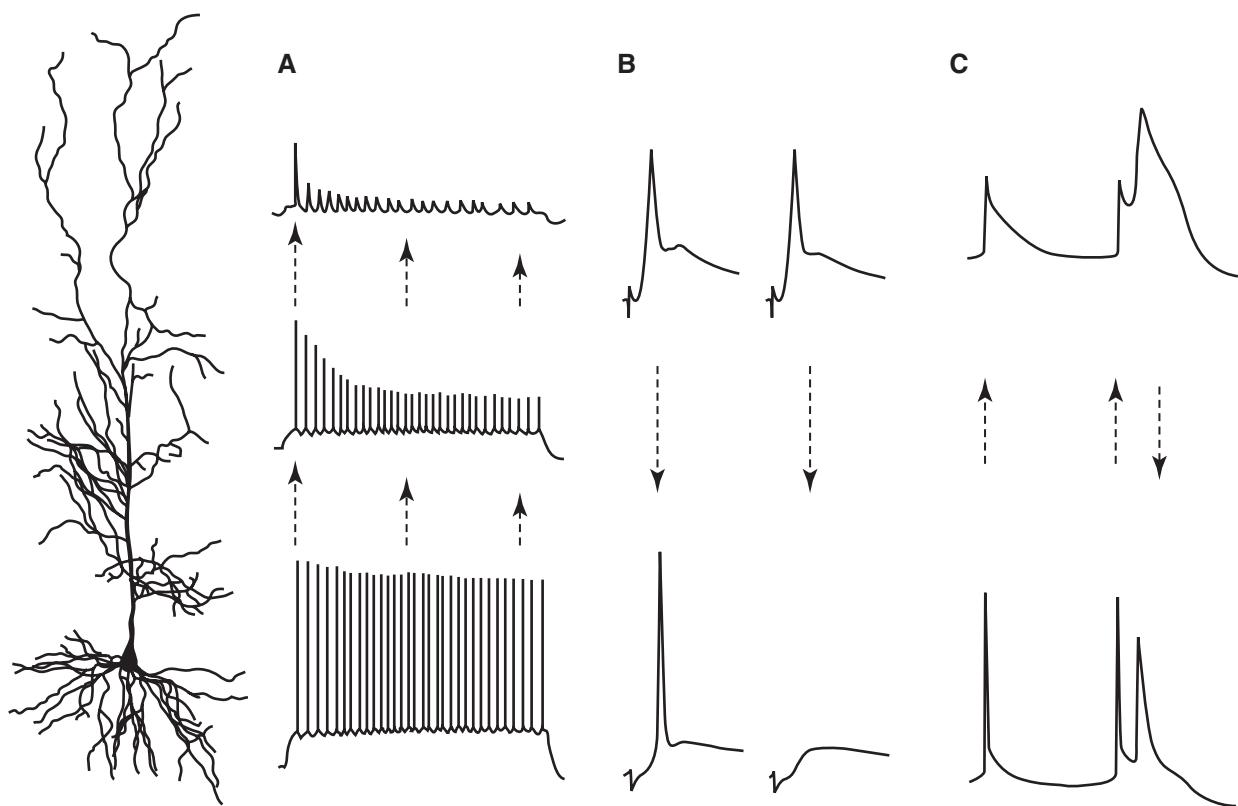

Studies of dendritic excitability in the hippocampus and elsewhere have been greatly facilitated by the development of methods to routinely record from dendrites in brain slices using patch pipettes (Stuart et al., 1993). The ability to record simultaneously from the soma and the primary apical dendrite (up to about 400  $\mu\text{m}$  from the soma) has been particularly useful. One of the first applications of this method was to address the question of where action potentials are initiated. The classic view was that action potentials are initiated in the axon, but several of the studies discussed above had led to the hypothesis that action potentials might actually be initiated in dendrites. Simultaneous somatic and dendritic recordings in CA1 neurons have indicated that fast, all-or-none action potentials begin near the soma (Spruston et al., 1995; Hoffman et al., 1997; Golding et al., 2001). Based on the sensitivity of the action potential threshold to local application to tetrodotoxin (TTX), the site of action potential initiation has been further narrowed to a region near the first node of Ranvier in the axon (Colbert et al., 1996). Similar results have been obtained in several other types of neurons, suggesting that the axon may have a low threshold for action potential initiation in most

neurons (Stuart et al., 1997). The reasons for this are not clear but are likely related to the density and/or properties of  $\text{Na}^+$  channels in the axon (Colbert and Pan, 2002).

Following their initiation in the axon, action potentials invade the dendritic tree of CA1 neurons (Spruston et al., 1995; Golding et al., 2001) (Fig. 5–5A). Application of TTX to the dendrites dramatically reduces the amplitude of these back-propagating action potentials, indicating that  $\text{Na}^+$  channels actively enhance action potential propagation in CA1 dendrites (Spruston et al., 1995; Magee and Johnston, 1997; Golding et al., 2002). In keeping with this,  $\text{Na}^+$  channels have been recorded directly in cell-attached patches in CA1 dendrites (Magee and Johnston, 1995a,b; Colbert et al., 1997; Jung et al., 1997; Mickus et al., 1999). The amplitude of the back-propagating action potential, however, decreases with distance from the soma, indicating that back-propagation is not fully regenerative. At 300  $\mu\text{m}$ , the back-propagating action potential amplitude is about half of its somatic amplitude (Golding et al., 2001). Attenuation of back-propagating action potentials in the distal half of the apical dendrites is variable. Within a given cell, back-propagation is controlled by the membrane potential and the availability of  $\text{Na}^+$  and  $\text{K}^+$  channels (Bernard and Johnston, 2003). Between cells, two populations of CA1 neurons have been identified (Golding et al., 2001). In about half of the CA1 neurons, attenuation of the backpropagating action potential from 300 to 400  $\mu\text{m}$  continues at about the same rate as in more proximal dendrites. In the other half of the CA1 neurons, attenuation in this distal region is more pronounced. The relatively strong back-propagation may be promoted by somatic depolarization, as it is not observed with antidromic stimulation (Bernard and Johnston, 2003). The dichotomy of action potential back-propagation observed during somatic current injection suggests that there may be considerable cell-to-cell variability in the densities of ion channels that control action potential back-propagation (Golding et al., 2001).

Although patch-clamp recordings from the basal dendrites of CA1 neurons have not yet been obtained, models based on  $\text{Na}^+$  and  $\text{K}^+$  channel densities in the apical dendrites predict that action potential propagation into the shorter, basal dendrites is much more reliable (Golding et al., 2001). This finding is in keeping with imaging studies of the basal dendrites in neocortical pyramidal cells, which indicate reliable back-propagation in the basal dendrites (Schiller et al., 1995). Similarly, direct recordings from oblique branches of the apical dendrites have not been obtained, but  $\text{Ca}^{2+}$  imaging experiments suggest that action potentials actively invade these branches (Frick et al., 2003).

Attenuation of the back-propagating action potential amplitude is even more severe during repetitive spiking (Fig. 5–5A). Even at modest firing frequencies such as 20 Hz, the action potential amplitude, measured about 300  $\mu\text{m}$  from the soma, attenuates to less than half of its amplitude at lower frequencies, equivalent to less than one-fourth of the somatic action potential amplitude (Andreasen and Lambert, 1995a; Callaway and Ross, 1995; Spruston et al., 1995; Golding et al.,

**Figure 5-5.** CA1 dendritic excitability. *Left.* Camera lucida drawing of a CA1 pyramidal neuron. Three types of dendritic excitability are indicated. (*Source:* Adapted from Golding et al., 1999.) *A.* Trains of back-propagating action potentials are initiated in the soma in response to step current injections and recorded in the dendrites with a second patch-clamp electrode. The somatic and mid-proximal recordings were obtained simultaneously from the same neuron. The more distal dendritic recording was obtained from a different cell. (*Source:* Adapted from Golding et al., 2001.) *B.* Dendritic Na<sup>+</sup> spikes were elicited by strong synaptic stimulation in

the s.l.m. On one trial the dendritic spike is associated with a somatic action potential, whereas on the other trial only an EPSP is recorded at the soma (i.e., propagation failure). (*Source:* Adapted from Golding and Spruston, 1998.) *C.* Dendritic Ca<sup>2+</sup> spikes were elicited by a step current injection via a dendritic patch-clamp electrode 160  $\mu$ m from the soma. The second back-propagating action potential shown is followed by a large, broad dendritic Ca<sup>2+</sup> spike. Simultaneous somatic recording shows that the dendritic Ca<sup>2+</sup> spike caused an action potential burst in the soma. (*Source:* Adapted from Golding et al., 1999.)

2001). This activity-dependent back-propagation is mediated by a form of Na<sup>+</sup> channel inactivation that recovers very slowly (Colbert et al., 1997; Jung et al., 1997; Mickus et al., 1999). Patch-clamp recordings from CA1 somata and dendrites have revealed that repetitive depolarizations lead to cumulative Na<sup>+</sup> channel inactivation. Each brief depolarization forces a fraction of the available Na<sup>+</sup> channels into the prolonged inactivated state. Recovery from this state back to the closed (available) state has a time constant of about 1 second at the resting potential (Mickus et al., 1999). This kind of inactivation, which is especially pronounced in the dendrites, results in fewer and fewer dendritic Na<sup>+</sup> channels available to support action potential back-propagation during repetitive firing, resulting in progressive reduction in the amplitude of back-propagating action potentials.

Although simultaneous somatic and dendritic patch-clamp recordings indicated that the threshold for action potential initiation was lowest in the axon, these studies did not address the question of whether spikes could, under some

conditions, be generated in the dendrites, as earlier studies had suggested (Spencer and Kandel, 1961; Schwartzkroin, 1977; Schwartzkroin and Slawsky 1977; Wong et al., 1979; Benardo et al., 1982; Masukawa and Prince, 1984; Andreasen and Lambert, 1995a). Direct evidence for dendritically generated spikes soon followed from simultaneous somatic and dendritic patch-clamp recordings. When the synaptic stimulus intensity was increased well above the threshold for action potential initiation in the axon, spikes were observed in apical dendritic recordings before the action potential was recorded in the soma (Golding and Spruston, 1998). With GABA<sub>A</sub> receptors blocked to increase the excitatory drive to dendrites, two kinds of dendritic spike could be elicited by synaptic stimulation: fast spikes mediated primarily by Na<sup>+</sup> channels and slower spikes mediated primarily by Ca<sup>2+</sup> channels (Golding and Spruston, 1998; Golding et al., 1999) (Fig. 5-5B,C). Intriguingly, these two types of dendritic spike do not propagate reliably to the soma. Dendritic Na<sup>+</sup> spikes were often observed in dendritic recordings when no action potential

reached the soma, suggesting that these events could be entirely restricted to the dendrites (Golding and Spruston, 1998). As is the case for back-propagation, forward propagation of dendritic  $\text{Na}^+$  spikes is sensitive to both distance and membrane potential. Spikes initiated more distally are less likely to propagate to the soma successfully, and membrane depolarization enhances the forward propagation of distally generated spikes (Gasparini et al., 2004). Dendritic  $\text{Ca}^{2+}$  spikes often trigger multiple fast action potentials in the axon and soma but are also isolated to the dendrites in some circumstances (Golding et al., 1999; Wei et al., 2001; Golding et al., 2002). These findings indicate that dendritic  $\text{Ca}^{2+}$  spikes may function locally or may serve as a mechanism for producing bursts of action potentials in the soma and axon of CA1 neurons. Experiments combining imaging and electrophysiology suggest that spikes can also be generated locally in the basal dendrites of CA1 pyramidal neurons (Ariav et al., 2003).

An important question is whether the dendritic excitability observed in slice experiments also occurs under natural conditions *in vivo*. Only one study to date has addressed this question directly. Microelectrode recordings from the dendrites of CA1 neurons in anesthetized rats revealed a pattern of dendritic excitability similar to that seen *in vitro*. Three types of excitability were observed in the *in vivo* recordings that were putatively attributed to back-propagating action potentials, dendritically generated  $\text{Na}^+$  spikes, and dendritically generated  $\text{Ca}^{2+}$  spikes (Kamondi et al., 1998). Putative back-propagating action potentials were identified by their rapid time course and decline in amplitude as a function of distance of the recording from the soma. These events also decayed in amplitude during repetitive firing in a manner similar to back-propagating action potentials *in vitro* (Kamondi et al., 1998; Golding et al., 2001). In addition to these events, which occurred both spontaneously and in response to current injection through the recording electrode, putative dendritically generated spikes were observed during hippocampal population discharges (sharp waves). These events were either small in amplitude and rapid in time course (putative dendritic  $\text{Na}^+$  spikes) or large in amplitude and slow in time course (putative dendritic  $\text{Ca}^{2+}$  spikes).

The dendritic excitability of CA1 pyramidal neurons is not likely to be static but probably changes depending on the behavioral state of the animal. The best direct evidence for this is that dendritic spikes are primarily observed *in vivo* during sharp waves, which occur only during awake immobility, consummatory behaviors, and slow-wave sleep in rats (Kamondi et al., 1998) (see Chapter 11). Dendritic excitability may also be heterogeneous within CA1, as is seen for action potential invasion of the distal apical dendrites, which exhibits a dichotomy of strong and weak back-propagation (Golding et al., 2001). Several factors are likely to influence dendritic excitability *in vivo*: the balance and pattern of synaptic excitation and inhibition, previous experience-dependent synaptic and nonsynaptic plasticity, and the neuromodulatory state in the hippocampus.

Inhibition has been shown to influence dendritic excitability in two ways. First, in response to synaptic stimulation in the slice, dendritic spikes occur much more frequently when inhibition is blocked (Golding and Spruston, 1998; Golding et al., 1999). This is consistent with the notion that dendritic spikes are primarily observed during sharp waves, which occur because of strong, synchronous synaptic excitation (Kamondi et al., 1998). Second, inhibition has been shown to limit action potential back-propagation (Buzsáki, 1996; Tsubokawa and Ross, 1996). Both of these observations suggest that inhibition limits dendritic excitability, but it should be noted that it could, if appropriately timed prior to an excitatory input, enhance dendritic excitability by removing inactivation from dendritic  $\text{Na}^+$  and  $\text{Ca}^{2+}$  channels.

Activation of neuromodulatory receptors and second messenger systems has also been shown to influence dendritic excitability in a variety of ways. Activation of mitogen-activated protein (MAP) kinase, protein kinase C (PKC), or protein kinase A (PKA) results in downregulation of A-type  $\text{K}^+$  current in CA1 dendrites and, accordingly, produces an increase in the amplitude of back-propagating action potentials (Hoffman and Johnston, 1998; Yuan et al., 2002). Similar results are also produced by activation of  $\beta$ -adrenergic and muscarinic acetylcholine receptors, which activate the PKA and PKC systems, respectively. Activation of dopaminergic receptors produced a similar effect in a subset of CA1 neurons, suggesting heterogeneity in the responses of CA1 neurons to neuromodulators (Hoffman and Johnston, 1998). Arachidonic acid produces a complementary effect, enhancing the amplitude of back-propagating action potentials via a reduction in dendritic A-type  $\text{K}^+$  current (Bittner and Müller, 1999; Colbert and Pan, 1999). Muscarinic receptor activation reduces the activity dependence of action potential back-propagation, presumably by reducing prolonged inactivation of  $\text{Na}^+$  channels (Tsubokawa and Ross, 1997; Colbert and Johnston, 1998). A similar effect has also been observed following rises in intracellular  $\text{Ca}^{2+}$  evoked by repeated action potential firing (Tsubokawa et al., 2000).

Repeated synaptic activity can also modulate dendritic excitability. Frick and colleagues have shown that pairing of synaptic activity and action potential firing in a theta-burst pattern not only induces synaptic plasticity but also induces long-term enhancement of dendritic excitability (Frick et al., 2004). This enhancement is caused by a leftward shift in the voltage dependence of inactivation for A-type  $\text{K}^+$  channels, which results in a reduction in the number of channels available to be activated from the resting potential and causes an increase in action potential back-propagation and dendritic  $\text{Ca}^{2+}$  entry (Frick et al., 2004).

### 5.2.12 Sources of $\text{Ca}^{2+}$ Elevation in CA1 Pyramidal Neuron Dendrites

Calcium imaging experiments have provided considerable insight into the function of CA1 dendrites. These experiments have identified three sources of  $\text{Ca}^{2+}$  entry. First, dendritic

depolarization can activate voltage-gated  $\text{Ca}^{2+}$  channels. Second, neurotransmitters can activate ligand-gated channels with significant  $\text{Ca}^{2+}$  permeability, such as the NMDA receptor. Third,  $\text{Ca}^{2+}$  can be released from intracellular stores in dendrites. Significant interactions have been identified among these mechanisms.

The large dendritic depolarizations produced by back-propagating action potentials and dendritic spikes result in activation of voltage-gated  $\text{Ca}^{2+}$  channels, which produces  $\text{Ca}^{2+}$  transients that are not uniform throughout the dendritic tree (Regehr et al., 1989; Jaffe et al., 1992; Yuste and Denk, 1995; Helmchen et al., 1996; Yuste et al., 1999; Golding et al., 2001; Frick et al., 2003). Spatial gradients in  $\text{Ca}^{2+}$  signals must be interpreted cautiously, as many factors may contribute. Larger  $\text{Ca}^{2+}$  transients may be produced by greater local depolarization, higher density of  $\text{Ca}^{2+}$  channels, larger surface-to-volume ratio (smaller dendrites), or weaker  $\text{Ca}^{2+}$  buffering and extrusion (Volfovsky et al., 1999; Majewska et al., 2000; Murthy et al., 2000). Careful interpretation of the available data suggests, however, that depolarization gradients contribute strongly to the gradients of  $\text{Ca}^{2+}$  entry observed. For example, back-propagating action potentials tend to produce smaller  $\text{Ca}^{2+}$  transients in distal dendrites than in proximal dendrites, largely due to the attenuation of the back-propagating action potential with distance from the soma (Jaffe et al., 1992; Christie et al., 1995; Golding et al., 2001). This gradient is enhanced during repetitive firing due to the activity dependence of back-propagation, which results in a steeper depolarization gradient along the dendrites (Golding et al., 2001). Neuromodulators coupled to G proteins reduce the dendritic calcium entry associated with back-propagating action potentials through membrane potential changes and a reduction in current through voltage-gated  $\text{Ca}^{2+}$  channels (Chen and Lambert, 1997; Sandler and Ross, 1999). Dendritically generated spikes produce a spatial gradient opposite to that produced by back-propagating action potentials, with the largest  $\text{Ca}^{2+}$  entry in more distal dendrites (Ariav et al., 2003).

Smaller depolarizations, such as those produced by EPSPs, tend to produce smaller  $\text{Ca}^{2+}$  transients that are even more spatially restricted (Regehr et al., 1989; Miyakawa et al., 1992; Regehr and Tank, 1992; Yuste and Denk, 1995; Yuste et al., 1999; Kovalchuk et al., 2000; Murthy et al., 2000). These  $\text{Ca}^{2+}$  transients may be produced by activation of NMDA receptors, but in some cases activation of voltage-gated  $\text{Ca}^{2+}$  channels also contributes. In fact, it can be difficult to dissect the relative contribution of these two mechanisms, as blocking either one reduces dendritic depolarization, which may reduce  $\text{Ca}^{2+}$  entry through either of these channel types.

Pairing EPSPs with back-propagating action potentials has been shown to produce  $\text{Ca}^{2+}$  entry that exceeds the sum of the two individual signals in dendritic shafts and spines (Yuste and Denk, 1995; Magee and Johnston, 1997; Yuste et al., 1999). This effect is likely to occur because EPSPs can increase the amplitude of back-propagating action potentials and because the additional depolarization provided by back-prop-

agating action potentials relieves the  $\text{Mg}^{2+}$  block of NMDA receptors.

Calcium release from intracellular stores has been observed in CA1 dendrites in response to elevation of  $\text{Ca}^{2+}$  via back-propagating action potentials and by activation of mGluRs coupled to inositol trisphosphate ( $\text{IP}_3$ ) receptors (Bianchi et al., 1999; Nakamura et al., 1999, 2000; Sandler and Barbara, 1999). Again, these two means of activating  $\text{Ca}^{2+}$  release are not independent, as pairing of action potentials with EPSPs greatly enhances release (Nakamura et al., 1999, 2000). Although intracellular  $\text{Ca}^{2+}$  release has as yet been observed only in the proximal regions of the primary apical dendrite of CA1 neurons (Nakamura et al., 2000) and spine-restricted  $\text{Ca}^{2+}$  transients are primarily coupled to activation of NMDA receptors (Yuste and Denk, 1995; Kovalchuk et al., 2000), the presence of endoplasmic reticulum organelles in other regions of the dendrites, including spines (Spacek and Harris, 1997) is consistent with observations of spatially restricted  $\text{Ca}^{2+}$  release in dendritic spines under some conditions (Emptage et al., 1999).

### 5.2.13 Distribution of Voltage-Gated Channels in the Dendrites of CA1 Neurons

The subcellular distributions of various subtypes of voltage-gated ion channels have been investigated in CA1 neurons using physiological approaches, as well as antibody binding, in some cases combined with electron microscopy. Physiological studies fall into two categories: direct measurement of ion channel function using cell-attached or cell-excised patches from the soma, axon, and dendrites and indirect assessment of ion channel distribution using whole-cell recording or calcium imaging in combination with ion-channel pharmacology. Direct approaches offer a highly detailed picture of channel distribution and properties in various subcellular compartments, whereas indirect physiological observations have provided a broader perspective and are potentially informative about regions of the dendrites inaccessible to patch-clamp recording.

Early dendritic recordings strongly suggested the presence of voltage-gated  $\text{Na}^+$  channels in CA1 apical dendrites, and the reduction of back-propagating action potentials by TTX confirmed this (see Section 5.2.11). Direct recordings of  $\text{Na}^+$  channel activity in patches up to about 300  $\mu\text{m}$  from the soma on the primary apical dendrite in CA1 neurons have revealed that  $\text{Na}^+$  channels are distributed at an approximately constant density along this region of the dendrite (Magee and Johnston, 1995a) (Fig. 5–6A). Despite the relatively uniform channel density, the properties of the channels change with distance from the soma. Patches obtained at increasing distances from the soma exhibited a greater degree of prolonged inactivation, a feature of the  $\text{Na}^+$  channel responsible for the activity dependence of action potential back-propagation (Colbert et al., 1997; Mickus et al., 1999). The reasons for this nonuniformity in channel function are not known but might be mediated by a unique subunit composition ( $\alpha$ - and/or

$\beta$ -subunits), differential post-translational modification (e.g., phosphorylation), or protein-protein interactions (e.g., with the cytoskeleton). Little is known about the subcellular distribution of  $\text{Na}^+$  channel  $\alpha$ -subunits in the hippocampus, though the available data suggest that Nav1.2 is most abundant during the first few postnatal weeks, but that Nav1.6 is the dominant subunit in adults (Schaller and Caldwell, 2000).

Numerous  $\text{Ca}^{2+}$  imaging studies have demonstrated the presence of voltage-gated  $\text{Ca}^{2+}$  channels in CA1 dendrites. The presence of depolarization-induced  $\text{Ca}^{2+}$  transients in dendritic spines suggests that  $\text{Ca}^{2+}$  channels are also present in these postsynaptic specializations (Yuste and Denk, 1995; Sabatini et al., 2002). One imaging study used a pharmacological approach to determine that high-threshold  $\text{Ca}^{2+}$  channels are the major contributors to  $\text{Ca}^{2+}$  entry mediated by back-propagating action potentials in the soma and proximal dendrite, whereas low-threshold  $\text{Ca}^{2+}$  channels contribute more to the  $\text{Ca}^{2+}$  signal in the distal dendrites (Christie et al., 1995). The most direct information regarding  $\text{Ca}^{2+}$  channel distribution was provided by single-channel recordings along the length of the apical dendrite in CA1 neurons (Magee and Johnston, 1995a). This study revealed that the density of  $\text{Ca}^{2+}$  channels is approximately constant along the length of the apical dendrite, although there was a trend for more high-threshold channels to be encountered in the soma and proximal dendrites and more low-threshold channels to be encountered in more distal dendrites (Fig. 5–6B), which is consistent with the  $\text{Ca}^{2+}$  imaging results. Such a distribution is also consistent with an antibody-binding study for L-type (high-threshold)  $\text{Ca}^{2+}$  channels, which indicated the highest density of these channels is in the soma and proximal apical dendrites (Westenbroek et al., 1990). Unfortunately, more detailed information regarding the subcellular distribution of  $\text{Ca}^{2+}$  and  $\text{Na}^+$  channels in hippocampal neurons is not available. The availability of a number of high-quality  $\text{Ca}^{2+}$  and  $\text{Na}^+$  channel antibodies is required to provide this critical information in the future. Such studies will have to be performed using electron microscopy, as  $\text{Ca}^{2+}$  and  $\text{Na}^+$  channels are abundant in both axons and dendrites, making it difficult to determine the presynaptic versus postsynaptic localization of these channels using light microscopy. Although no data are available regarding the subtypes of  $\text{Ca}^{2+}$  channels in CA1 axons, pharmacological studies of synaptic transmission and presynaptic  $\text{Ca}^{2+}$  entry indicate that N-, P-, Q-, and R-type  $\text{Ca}^{2+}$  channels are most abundant in other axon terminals of the hippocampus (Wu and Saggau, 1994; Gasparini et al., 2001; Qian and Noebels, 2001).

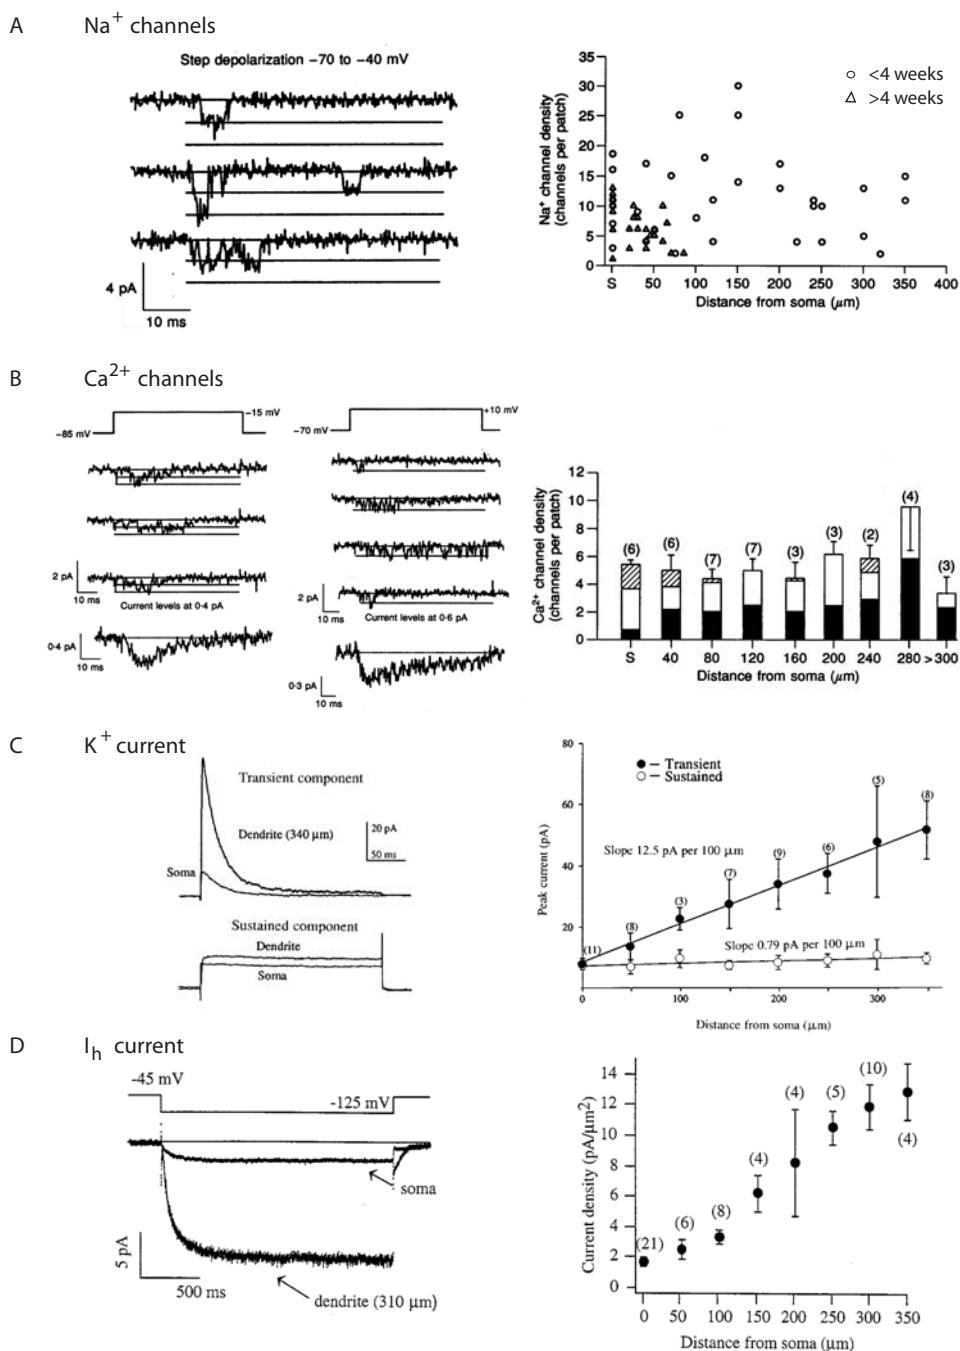

Information regarding  $\text{K}^+$  channel distribution has also been obtained using both indirect and direct approaches. Cell-attached patch-clamp recordings have provided the most direct information regarding  $\text{K}^+$  channel distribution in CA1 dendrites. Patches obtained at different distances from the soma revealed that the density of A-type  $\text{K}^+$  channels increases approximately linearly along the primary apical dendrite, whereas the density of noninactivating (or slowly inactivating)  $\text{K}^+$  channels is approximately constant (Hoffman et

al., 1997) (Fig. 5–6C). The farthest recordings, about 350  $\mu\text{m}$  from the soma, indicate that the density of the A-type  $\text{K}^+$  current is about five times its somatic level. This high density of dendritic A-type  $\text{K}^+$  current contributes to a dramatic decline in amplitude of back-propagating action potentials (Hoffman et al., 1997) (see Section 5.2.11).

$\text{Ca}^{2+}$  imaging experiments suggest that the density of A-type  $\text{K}^+$  channels may be especially high in oblique apical dendrites (Frick et al., 2003). Consistent with the high density of dendritic A-type  $\text{K}^+$  channels, application of 4-AP to the bath or selectively to the apical dendrite results in an increased amplitude of back-propagating action potentials (Hoffman et al., 1997; Magee and Carruth, 1999). 4-AP application also increases the occurrence of dendritic  $\text{Ca}^{2+}$  spikes, an effect that is likely attributable to block of both A-type and D-type  $\text{K}^+$  channels in the dendrites (Andreasen and Lambert, 1995a; Hoffman et al., 1997; Golding et al., 1999; Magee and Carruth, 1999; Cai et al., 2004). The most likely candidates for the  $\alpha$ -subunits of the A-type  $\text{K}^+$  channel in CA1 neurons are members of the Kv4 family (Sheng et al., 1992; Maletic-Savatic et al., 1995). Consistent with this, enhanced dendritic excitability has been observed in a mouse expressing a Kv4.2 dominant-negative construct (Cai et al., 2004). Pharmacological studies have also revealed that the AHP of back-propagating action potentials is much less sensitive to blockers of BK-type  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  channels than the AHP of somatic action potentials suggesting that there may be a higher density of these channels in the soma than in the apical dendrites (Andreasen and Lambert, 1995b; Poolos and Johnston, 1999). These channels are present in dendrites, however, and they have an important role in repolarizing dendritic  $\text{Ca}^{2+}$  spikes (Golding et al., 1999).

The hyperpolarization-activated, nonspecific cation current ( $I_h$ ) is also distributed nonuniformly along the length of the CA1 apical dendrite. Cell-attached patch recordings reveal a linear increase in density along the apical dendrite, with currents at 350  $\mu\text{m}$  approximately six times larger than in the soma (Magee, 1998) (Fig. 5–6D). In fact,  $I_h$  may reach an even higher density in more distal dendrites, as immunoreactivity for the channel is most intense in the distal dendrites (Santoro et al., 1997; Lorincz et al., 2002). This is also consistent with the dramatic increase in  $I_h$  observed in patch recordings from the distal dendrites of layer V pyramidal neurons (Williams and Stuart, 2000; Berger et al., 2001). In addition to the direct patch recordings, imaging studies reveal a large dendritic  $\text{Na}^+$  entry activated by hyperpolarization in hippocampal neurons (Tsubokawa et al., 1999). Modeling the effects of blocking  $I_h$  on voltage attenuation in CA1 dendrites is also consistent with a high density of  $I_h$  in CA1 apical dendrites (Golding et al., 2005). Of the four  $I_h$  genes cloned so far, HCN 1, 2, and 4 are the most abundant in CA1 neurons (Moosmang et al., 1999; Santoro et al., 2000; Bender et al., 2001). The presence of a high density of  $I_h$  channels in CA1 dendrites has some interesting functional consequences, which are discussed below.

These examples highlight the point that many channels (e.g., A-type  $\text{K}^+$  and  $I_h$  channels) are distributed nonuni-

**Figure 5–6.** CA1 dendritic voltage-gated channels. *A*. Single-channel recordings of voltage-gated  $\text{Na}^+$  channels in dendritic cell-attached patches (left) and a plot of  $\text{Na}^+$  channel density as a function of distance from the soma (right). Circles and triangles are from rats younger and older than 4 weeks, respectively. (Source: Adapted from Magee and Johnston, 1995.) *B*. Single-channel recordings of voltage-gated  $\text{Ca}^{2+}$  channels in dendritic cell-attached patches [low-voltage activated (left) and high-voltage activated (middle); ensemble averages are also shown for each set of traces] and a plot of  $\text{Ca}^{2+}$  channel density as a function of distance from the soma (right). Black portions of the bars correspond to low-voltage activated channels; open bars correspond to high-voltage

activated, medium conductance channels; hatched bars correspond to high-voltage activated large conductance channels. (Source: Adapted from Magee and Johnston, 1995a.) *C*. Voltage-gated  $\text{K}^+$  channels in cell-attached patches from dendrites and the soma, separated into sustained and transient components (left). The two components are plotted as a function of distance from the soma. The transient component is much larger in the dendrites. (Source: Adapted from Hofmann et al., 1997.) *D*. Hyperpolarization-activated current in cell-attached patches from dendrites and the soma (left).  $I_{\text{h}}$  current density is plotted as a function of distance from the soma (right).  $I_{\text{h}}$  is much larger in the dendrites. (Source: Adapted from Magee, 1998.)

formly along the somato-dendritic axis. Even when channel density is relatively uniform (e.g.,  $\text{Na}^+$  channels), the properties of the channels may differ between the soma and the dendrites. Although the mechanisms for establishing and maintaining these gradients are not known, more is known about the functional implications of ion channels and their nonuniform densities and properties in CA1 dendrites.

### **5.2.14 Functional Implications of Voltage-Gated Channels in CA1 Dendrites: Synaptic Integration and Plasticity**

Knowing that the dendrites of CA1 neurons contain many voltage-gated channels, it is logical to ask: What for? Clearly, dendrites are able to generate a variety of active responses, including back-propagating action potentials and dendritic  $\text{Na}^+$  and  $\text{Ca}^{2+}$  spikes. What is the purpose of these responses in excitable dendrites?

One obvious answer is that the occurrence of a dendritic spike generates output in the form of one or more axonal action potentials. This is correct for some dendritic spikes in CA1 neurons but not all. Large, broad  $\text{Ca}^{2+}$  spikes can trigger a burst of action potentials in the soma, indicating that these events produce a reliable axonal output (Golding et al., 1999), and under some conditions the forward propagation of dendritic spikes can be facilitated (Jarsky et al., 2005) (see Sections 5.2.10 and 5.2.11). Some dendritic  $\text{Na}^+$  and  $\text{Ca}^{2+}$  spikes, however, do not propagate well to the soma, so their influence there can be quite small (Golding and Spruston, 1998; Golding et al., 2002). This observation hints at the possibility of local functions for dendritic spikes.

A likely function for back-propagating action potentials is to inform the dendrites and the synapses on them about the level of output in the axon. The most compelling evidence supporting such a role for dendritic spikes comes from the demonstration of their importance in the induction of long-term potentiation (LTP). At Schaffer collateral synapses (from CA3 axons), pairing of small EPSPs with somatic action potentials induces a form of LTP that disappears when action potentials are prevented from actively invading the dendrites (Magee and Johnston, 1997). Thus, back-propagating action potentials seem to have an important role in providing the postsynaptic depolarization necessary for the induction of some forms of Hebbian LTP (see Chapter 10). At more distal synapses on CA1 neurons, in particular the perforant path input from entorhinal cortex, LTP does not depend on back-propagating action potentials (Golding et al., 2002). Rather, dendritically generated  $\text{Na}^+$  and  $\text{Ca}^{2+}$  spikes appear to provide an important component of the depolarization necessary to induce LTP at these synapses. A similar form of dendritic spike-induced LTP also occurs at the Schaffer collateral synapses if the stimulus intensity is increased to produce larger EPSPs during blockade of back-propagating action potentials (Golding et al., 2002). These findings indicate that both back-propagating action potentials and dendritically induced spikes can function to enhance the induction of LTP at synapses on the CA1 dendritic tree.

The function of dendritic  $\text{Na}^+$  and  $\text{Ca}^{2+}$  channels at membrane potentials below threshold for the induction of regenerative dendritic events is less clear. In principle, each of these channel types (especially the low-threshold, T-type  $\text{Ca}^{2+}$  channels) could be activated during nonregenerative depolarizations (e.g., moderate EPSPs) and generate additional depolarization and  $\text{Ca}^{2+}$  entry. In fact,  $\text{Na}^+$  channels have been shown to open during EPSPs, even when there are no obvious signs of regenerative activity (Magee and Johnston, 1995b). This finding is consistent with experiments showing that  $\text{Na}^+$  and  $\text{Ca}^{2+}$  channel blockers can reduce postsynaptic EPSPs without affecting the presynaptic input (Lipowsky et al., 1996; Gillessen and Alzheimer, 1997). The ability of  $\text{Na}^+$  and  $\text{Ca}^{2+}$  channels to amplify EPSPs effectively (without a dendritic spike), however, is compromised by coactivation of  $\text{K}^+$  channels, which can cancel the effect of  $\text{Na}^+$  and  $\text{Ca}^{2+}$  channel activation, resulting in linear summation of EPSPs (Cash and Yuste, 1998, 1999). It is likely, however, that neuromodulation, prior activity, and synaptic input pattern can alter the balance of  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{K}^+$  channel activation during synaptic integration, leading to nonlinearities in synaptic summation under some conditions.

The presence of a high density of hyperpolarization-activated, non-specific cation channels in CA1 dendrites has some interesting consequences for the temporal integration of EPSPs. Because some of  $I_h$  is active at the resting potential, it contributes a significant leak to the membrane. This has the effect of increasing attenuation of EPSPs as they propagate from the soma to the dendrite, as well as speeding the decay of EPSPs in the dendrite (Stuart and Spruston, 1998; Golding et al., 2005). This effect on the amplitude of EPSPs may be compensated in part by increased synaptic conductance at more distal synapses. Dendritic  $I_h$  has also been shown to normalize for the temporal filtering effects of dendrites (Magee, 1999). In passive dendrites, the filtering effects result in EPSPs generated at distal locations, producing slower EPSPs at the soma. As a result, distal dendritic EPSPs summate more at the soma than do size-matched EPSPs from more proximal locations. Dendritic  $I_h$  minimizes this spatial discrepancy of temporal summation by contributing a larger effective outward current (due to the turning off of inward  $I_h$ ) for distal synapses, thus compensating for the additional temporal summation that would otherwise occur at the soma (Magee, 1999).

### **5.2.15 General Lessons Regarding Pyramidal Neuron Function**

The CA1 pyramidal neuron is arguably the most extensively studied neuron with respect to resting membrane properties, dendritic function, and synaptic integration. These studies have produced a striking picture of the neuron in which the voltage attenuation in dendrites, is predicted to be enormous for the near-passive condition. CA1 dendrites impose powerful attenuation and filtering during both normal conditions and voltage clamp. The neuron appears to compensate for this by at least two key mechanisms: synapse conductance scaling and excitable dendrites containing myriad voltage-gated

channels. On the other hand, such specialized properties are unlikely to exist exclusively to overcome the filtering properties of dendrites. Rather, the structure and ion channel expression are likely central to the specialized function of CA1 pyramidal neurons. For instance, one emergent property of the complexity of the CA1 dendritic tree appears to be coincidence detection for perforant-path and Schaffer-collateral synaptic inputs (Remondes and Schuman, 2002; Jarsky et al., 2005).

As becomes evident in the sections that follow, it would be inappropriate to generalize specific conclusions drawn from studies of one cell type and assume that other cells behave the same way. It is possible, however, to emphasize some conclusions based on studies of CA1 pyramidal neurons that are likely to direct studies of other neuronal cell types.

1. Morphology is stereotypical but variable. Although all CA1 cells have basal dendrites and a main apical dendrite that gives rise to oblique and tuft branches, dendritic morphology varies considerably from one CA1 neuron to the next. It is not known, but reasonable to postulate, that such morphological variability may have functional consequences.
2. Physiological properties are also variable. As with morphological variability, differences in physiological properties may be functionally relevant. Distinguishing inconsequential variability about a mean from significant functional variability is challenging but important. Physiological variability could arise as a result of genetic determinism, history-dependent development and plasticity, or both.
3. Channel and receptor distributions are often nonuniform. In CA1 neurons, as in layer V neocortical pyramidal neurons, distal dendrites contain a higher density of hyperpolarization-activated cation channels (Magee, 1998; Williams and Stuart, 2000; Berger et al., 2001; Lorincz et al., 2002) than the soma and more proximal dendritic regions. These two cell types differ, however, in that the high density of A-type  $K^+$  channels in CA1 dendrites is not observed in layer V dendrites (Hoffman et al., 1997; Bekkers, 2000; Korngreen and Sakmann, 2000). Even though  $Na^+$  and  $Ca^{2+}$  channel densities are uniform (on average) in CA1 dendrites, the properties of these channels vary systematically along the main apical dendrite. AMPA receptors have a higher density in mushroom-shaped spines and perforated synapses, whereas dopamine receptors have the highest density in distal apical dendrites of CA1 neurons. Additional inhomogeneities of channel and receptor density and function are likely to be revealed by future studies.
4. Population studies inform only about average behavior but cannot reveal functional variability across cells. For example, if some cells have increasing  $Na^+$  channel density gradients from the soma into the dendrites, and others have decreasing gradients, they may have very different functional properties with respect to
- dendritic excitability. A population approach to determining  $Na^+$  channel distributions does not reveal such potentially important differences across cells.
5. Synaptic potentials attenuate dramatically between their site of origin in the dendrites and their final site of integration (with respect to action potential output) in the axon. Large synaptic depolarizations may serve local functions (e.g., release of retrograde messengers, initiation of dendritic spikes) independent of dendro-somatic attenuation. Because of the extensive filtering introduced by dendrites and the active responses that can be generated in dendrites, somatic voltage-clamp recordings must be interpreted with great caution.
6. Different excitatory and inhibitory inputs can target different subcellular domains. Excitatory inputs from different regions, such as the direct input from entorhinal cortex and the processed input from CA3 neurons in CA1, can contact distinct regions of the dendritic tree. Inhibitory interneurons, such as basket cells and oriens-alveus/lacunosum-moleculare (O-LM) neurons, can selectively innervate domains such as the soma or the distal apical dendrites. This differential targeting suggests important differences in postsynaptic actions, even among synapses using the same transmitter.
7. The threshold for action-potential initiation is lower in the axon than in the dendrites. This finding generalizes from CA1 neurons to many other neurons (Stuart et al., 1997). One possible exception has been noted: O-LM interneurons in the hippocampus have a low threshold for action potential initiation in the dendrites (Martina et al., 2000) (see section 5.9.7).
8. CA1 dendrites, like many other dendritic trees, contain voltage-gated channels that support action-potential back-propagation and dendritic spike initiation (Häusser et al., 2000). The presence of voltage-gated channels in dendrites is likely to have profound effects on synaptic integration.

These general conclusions share the common feature that they all imply a tremendous degree of complexity and specialization in neuronal function, even for a single cell type, such as the CA1 pyramidal neuron. As subsequent sections on the properties of other neurons in the hippocampus indicate, there are no shortcuts: The morphological and functional properties of each and every cell type must be explored in detail in the hippocampus as in the rest of the brain.

### 5.3 CA3 Pyramidal Neurons

Following the CA1 pyramidal layer back toward the dentate gyrus, one encounters the CA3 pyramidal layer. (Little is known about the physiology of neurons in the intervening CA2 region.) The CA3 pyramidal neurons have been studied

extensively, in large part because of the unique functional specializations formed by the mossy fiber inputs from the dentate gyrus and because of the extensive axon collaterals between CA3 neurons, which create a highly interconnected and excitable network.

### 5.3.1 Dendritic Morphology

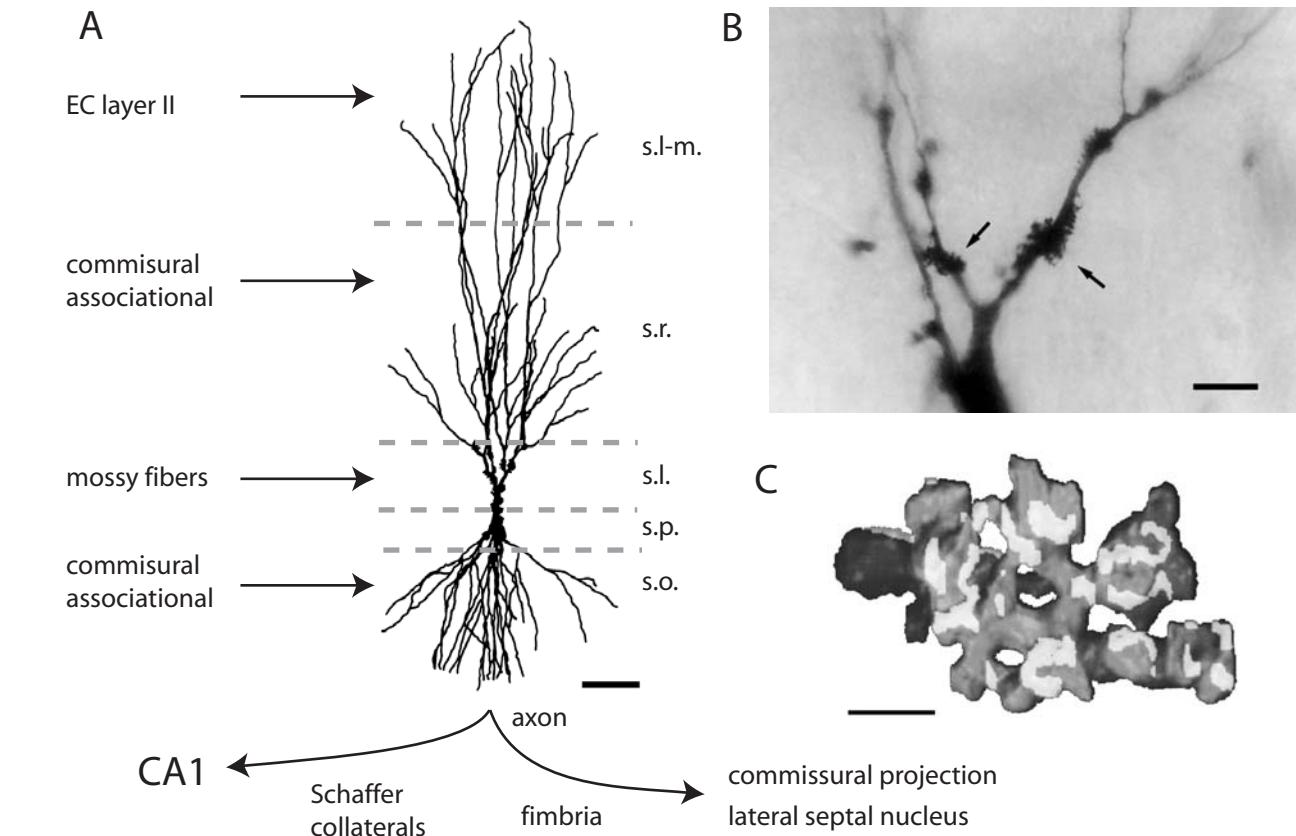

Pyramidal neurons in the CA3 region are structurally similar to CA1 neurons; they consist of pyramid-shaped somata that give rise to apical and basal dendritic trees (Fig. 5–7A). CA3 pyramidal neurons differ from their CA1 counterparts, however, in that the apical dendritic tree bifurcates closer to the soma. CA3 pyramidal neurons are typically somewhat larger than CA1 pyramidal cells, but their total dendritic length and organization is heterogeneous. The smallest CA3 pyramidal cells are located in the limbs of the dentate gyrus, and the largest cells are located in the distal portion of the CA3 subfield (Amaral et al., 1990).

Detailed morphometric analysis of dye-injected cells has allowed complete reconstruction of CA3 pyramidal neurons,

similar to that described above for CA1 pyramidal cells. CA3 pyramidal neurons, recovered from rat hippocampus *in vitro* slices from the mid-transverse hippocampal axis, possess extensive dendritic arborizations with four main features, (1) a basal arbor that extends throughout the stratum oriens, (2) a short apical trunk in the stratum lucidum that branches into two or more secondary trunks, (3) oblique apical dendrites in the stratum radiatum, and (4) an apical tuft that extends into the stratum lacunosum-moleculare. On average, the total dendritic length for the apical and basal dendritic arbors is similar to that of CA1, but with a larger range (9.3–15.8 mm) (Ishizuka et al., 1995; Henze et al., 1996). This variability of dendritic structure is attributable to systematic differences in the dendritic structure of pyramidal neurons in the various subregions of CA3 (Ishizuka et al., 1995) (see Section 5.3.3). Of particular interest, despite the greater total length and surface area of the apical arbor, the number of terminal branches and number of dendritic segments are similar for both the apical and basal arbors. This suggests that the distances between successive branch points are shorter for the basal dendrites (Henze et al., 1996). However, the basal dendrites

**Figure 5–7.** CA3 dendritic morphology, thorny excrescences, and synaptic inputs and outputs. A. Computer-generated plot showing dendritic morphology of a CA3 pyramidal neuron. Thorny excrescences are apparent on the proximal apical dendrites in the stratum pyramidale (s.p.) and stratum lucidum (s.l.). The major excitatory synaptic inputs to each layer are indicated, as are the major synaptic outputs. Bar = 50  $\mu$ m. (Source: Adapted from Gonzales et al.,

2001.) B. Photomicrograph of dendrites in a filled CA3 pyramidal neuron providing clear examples of thorny excrescences. Particularly large spine clusters are indicated with arrows. Bar = 25  $\mu$ m. (Source: Adapted from Gonzales et al., 2001.) C. Three-dimensional reconstruction of a large branched spine with 12 heads. The reconstructed thorn is light gray, and the PSDs are indicated in white. Bar = 1  $\mu$ m. (Source: Adapted from Chicurel and Harris, 1992.)

have approximately threefold fewer tips per primary dendrite (8.5 vs. 29.1). This, together with the lower maximum branch order for the basal dendrites (7.0 vs. 10.8), suggests that the individual basal dendritic trees are significantly less complex than the apical trees. Finally, in addition to being less complex, the mean distance to the basal dendritic tips is shorter than for the apical tree (212 vs. 425  $\mu\text{m}$ ) and suggests that synapses formed on the basal dendrites occupy a more restricted range of physical distances from the somata. The dendritic trees of CA3 pyramidal neurons also have a roughly symmetrical structure in their maximal transverse and septo-temporal extents (~ 300 and 270  $\mu\text{m}$ , respectively).

### 5.3.2 Dendritic Spines and Synapses

Like their CA1 counterparts, CA3 pyramidal neuron dendrites are studded with thousands of spines. Even greater diversity of spine morphology is apparent in CA3. In addition to the spine shapes observed in CA1, the CA3 neurons also have another major spine class, the “thorny excrescences” (Fig. 5–7B,C). There are about 40 of these specialized spine clusters on each CA3 neuron (Blackstad and Kjaerheim, 1961; Chicurel and Harris, 1992; Amaral and Witter, 1995; Gonzales et al., 2001). In the proximal regions of CA3 (closest to the dentate gyrus) the thorny excrescences are distributed on apical and basal dendrites relatively close to the soma. In more distal CA3 neurons (closer to CA1), the excrescences are found primarily on the apical dendrite prior to the first branch point located at distances of 10 to 120  $\mu\text{m}$  from the soma, where they form the postsynaptic targets of the mossy fiber synapses from granule cells of the dentate gyrus (Blackstad and Kjaerheim, 1961; Hamlyn, 1962; Chicurel and Harris, 1992; Gonzales et al., 2001). Three-dimensional reconstruction of thorny excrescences on CA3 pyramidal neurons have revealed many unusual features that are peculiar to the mossy fiber synapses and have not been described at other hippocampal synapses or indeed other brain areas. Typically, postsynaptic thorny excrescences at mossy fiber synapses comprise 1 to 16 branches that emerge from a single dendritic origin. These branched spines contain subcellular organelles typical of other spines (including ribosomes and multivesicular bodies), but they also contain organelles not found in other spines, such as mitochondria and microtubules. Multivesicular bodies occur most often in the spine heads, which also contain smooth endoplasmic reticulum; and ribosomes occur most often in spines that have spinules (nonsynaptic protruberances that emerge from the spine head). Branched spines are typically surrounded by a single mossy fiber bouton, which can establish synapses with multiple spine heads. The postsynaptic densities of these spines occupy ~ 10% to 15% of the spine head membrane. Individual mossy fiber boutons usually synapse with several branches belonging to more than one thorny spine excrescence but all originating from the same parent dendrite. Within a given branched spine, the dimension and volume of individual spine heads are comparable to those of the large mushroom spines found on CA1 pyramidal neurons, although the CA3 branches have more irregular

shapes (Blackstad and Kjaerheim, 1961; Chicurel and Harris, 1992).

The thorny excrescences (and hence the mossy fiber inputs) are concentrated in the first 100  $\mu\text{m}$  or so of the apical dendritic tree of CA3 pyramidal neurons (stratum lucidum). Across the remaining portions of both the apical and basal dendrites, the shape and distribution of spines are somewhat similar to CA1 pyramidal neurons, described above. Various calculations put the number of simple spines close to 30,000, which is similar to estimates of total spine number on CA1 pyramidal neurons (Jonas et al., 1993; Trommald et al., 1995).

### 5.3.3 Excitatory and Inhibitory Synaptic Inputs

The CA3 pyramidal neurons receive three prominent forms of excitatory synaptic input. The aforementioned mossy fiber input from the dentate granule cells is the most extensively studied of these inputs. CA3 neurons also receive direct input from layer II of the entorhinal cortex via the perforant path. As in the CA1 region, this direct cortical input is limited to the distal regions of the apical dendrites, in the stratum lacunosum-moleculare. The third prominent input to CA3 neurons comes from the axons of other CA3 neurons. These “commissural/associational” (C/A) inputs are numerous and originate from CA3 neurons on both sides of the brain. This extensive network of recurrent collaterals has led to the postulate that the CA3 region may function as an autoassociative network involved in memory storage and recall (Bennett et al., 1994; Rolls, 1996) (see Chapter 14). A side effect of this extensive interconnectivity, however, is that the CA3 network is highly excitable and prone to seizure activity when inhibition is suppressed (Jung and Kornmuller, 1938; Ben-Ari, 1985) (see Section 5.3.5). CA3 neurons also receive cholinergic input from the medial septal nucleus and the nucleus of the diagonal band of Broca, which terminate mostly in the stratum oriens (Amaral and Witter, 1995).

The organization of the dendritic tree and its synaptic inputs are highly variable and strongly depend on the location of the cell body within CA3. Cells located in the limbs of the dentate gyrus have dendrites with a limited elaboration and do not extend dendrites into the stratum lacunosum-moleculare (Amaral et al., 1990). In contrast, cells toward the more distal portion of the CA3 subfield project their dendrites throughout the stratum radiatum and stratum lacunosum-moleculare. Of particular importance regarding this heterogeneous anatomical organization, CA3 pyramidal cells at the most proximal and distal ends of the CA3 subfield are under differential control by the various afferent pathways projecting into the CA3 hippocampus. Most notably, CA3 pyramidal neurons closest to the dentate gyrus receive the proportionally largest input from the dentate granule cells; these CA3 neurons receive mossy fiber axonal inputs onto both the apical and basal dendritic trees, whereas those located more distally in CA3 have mossy fiber inputs primarily onto the proximal portion of their apical dendritic tree (Blackstad et al., 1970). This limited mossy fiber projection to the basal CA3 pyrami-

dal cell dendrites is referred to as the infrapyramidal projection and the granule cells in the infrapyramidal blade of the dentate gyrus are the primary source of this projection.

Although initial binding studies suggested that NMDA receptors were absent at mossy fiber synapses (Monaghan et al., 1983), subsequent physiological studies revealed that activation of NMDA receptors indeed occurs during activation of mossy fiber synapses (Jonas et al., 1993). Dendritic recordings from the apical dendrites of CA3 pyramidal cells in areas close to the mossy-fiber termination zone in stratum lucidum indicate that the properties of dendritic ionotropic glutamate receptors are remarkably similar to those expressed at the soma of CA3 pyramidal cells (Spruston et al., 1995). AMPA and NMDA-type glutamate receptors in CA3 neurons are also remarkably similar to these receptors in CA1 pyramidal neurons. One notable difference, however, is the deactivation kinetics of NMDA receptors, which were slower in CA1 than in CA3 pyramidal neurons. In addition, NMDA receptor-mediated  $\text{Ca}^{2+}$  entry is limited in CA3 spines (Reid et al., 2001; but see Pozzo-Miller et al., 1996). A comparison of the properties of mossy fiber synaptic transmission to AMPA receptor properties in CA3 dendrites suggests that a typical quantal event would consist of 35 AMPA receptors being activated by a single quantum of glutamate ( $\times 10 \text{ pS}$  single-channel conductance =  $350 \text{ pS}$  quantal conductance). About 70 receptors are estimated to be present at each release site, but only half of these receptors are open at the peak of the synaptic current (Jonas et al., 1993; Spruston et al., 1995). Immunocytochemical analysis suggests that about four times as many AMPA receptors are present at each mossy fiber synaptic specialization as at C/A synapses in CA3 or SC synapses in CA1 (Nusser et al., 1998). This high density of AMPA receptors and the large number of synaptic specializations on each thorny excrescence (Chicurel and Harris, 1992) accounts for the large size and variability of unitary mossy fiber synaptic currents, which have been estimated to comprise 2 to 16 quantal events (Jonas et al., 1993).

CA3 pyramidal neurons also receive substantial innervation from inhibitory interneurons. In addition to the somatic and axonal inhibition, which presumably limits action potential initiation, a number of interneurons target CA3 dendrites. This dendritic inhibition has been shown to limit the initiation and enhance termination of dendritic calcium spikes (Miles et al., 1996).

### 5.3.4 Axon Morphology and Synaptic Targets

Each CA3 pyramidal neuron gives rise to a single axon, which projects bilaterally to the CA3, CA2, and CA1 regions, as well as to the lateral septal nucleus (Ishizuka et al., 1990; Amaral and Witter, 1995). At the light microscopic level, individual axons are thin and myelinated with abundant en passant boutons or varicosities spaced, on average,  $4.7 \mu\text{m}$  apart (Ishizuka et al., 1990; Shepherd and Harris, 1998; Shepherd et al., 2002). CA3 axons project primarily to the CA1 region but also collateralize extensively within CA3. The total length of the CA3 collaterals in the ipsilateral hippocampus has been estimated

at 150 to 300 mm. These collaterals cover a large area in the longitudinal direction, extending more than one-third the length of the septo-temporal axis (Ishizuka et al., 1990; Sik et al., 1993; Li et al., 1994; Andersen et al., 2000). Pyramidal neurons in the CA3a subfield (closest to CA1) arborize primarily in the stratum oriens of CA1, whereas neurons in CA3c (closer to the hilus) collateralize more extensively in the stratum radiatum of CA1 (Ishizuka et al., 1990; Li et al., 1994). In one complete reconstruction, the highest density of boutons in CA1 clustered about  $600$  to  $800 \mu\text{m}$  from the CA3 neuron in both the septal and temporal directions (Sik et al., 1993). These axons contribute to the Schaffer collateral inputs to CA1 pyramidal neurons. Another group of axon collaterals is localized in the stratum oriens and stratum radiatum of CA3, comprising the extensive associational connection common between CA3 pyramidal neurons. Boutons are located approximately every  $4 \mu\text{m}$  along the CA3 axon, but boutons are distributed unevenly, with somewhat variable spacing (Shepherd et al., 2002). Estimates of the total number of synapses formed by a single axon in the ipsilateral hippocampus range from 15,000 to 60,000 (Sik et al., 1993; Li et al., 1994). A subset of the CA3 axon boutons contacts interneurons. Each axon contacts each interneuron at a single location, forming one synaptic release site. As in CA1, pyramidal cell-to-interneuron synapses are powerful enough that a single axon is capable of producing an action potential in postsynaptic interneurons (Miles, 1990; Gulyás et al., 1993a; Sik et al., 1993).

Three-dimensional reconstruction of CA3 pyramidal neuron axons in the CA1 region revealed that most of the varicosities or presynaptic boutons contained synaptic vesicles and were opposed to a postsynaptic specialization that comprised a single postsynaptic density (PSD). Approximately 20% of presynaptic varicosities were apposed to postsynaptic specializations comprising multiple PSDs (Shepherd and Harris, 1998). CA3 pyramidal neuron axonal varicosities are typically oblong in shape and demonstrate considerable variation in their length ( $\sim 1 \mu\text{m}$ ) and volume ( $\sim 0.13 \mu\text{m}^3$ ). The intervaricosity axonal shaft is narrow, tubular, and remarkably consistent in its diameter ( $\sim 0.17 \mu\text{m}$ ). The narrow axonal shafts resemble dendritic spine necks, an arrangement that raises the possibility of functional compartmentalization along individual axons. Importantly, serial electron microscopy has revealed that a small number of CA3 axons ( $\sim 20\%$ ) may make multiple synapses on a single CA1 cell (Sorra and Harris, 1993).

### 5.3.5 Resting Potential and Action Potential Firing Properties

Like CA1 pyramidal cells, CA3 pyramidal cells possess a repertoire of conductances that allow them to respond to suprathreshold stimuli with either single action potentials or bursts. Although bursting also occurs in CA1 pyramidal neurons (see Section 5.2.5), bursting is more prominent in CA3, both *in vivo* and in the *in vitro* slice preparation (Kandel and Spencer, 1961; Spencer and Kandel, 1961; Wong and Prince, 1978) and is therefore considered a hallmark feature of CA3

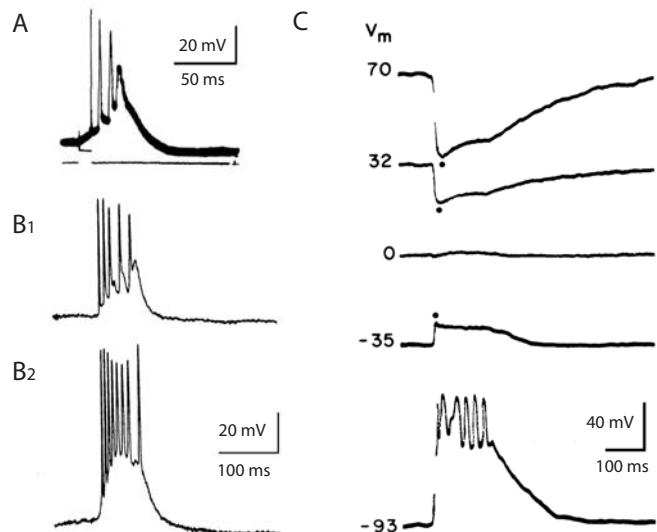

pyramidal neurons. Bursts in CA3 neurons typically comprise several action potentials riding atop a depolarizing waveform, often accompanied by smaller calcium-dependent spikes late in the waveform. Each burst is an “all or nothing” event lasting approximately 30 to 50 ms, with the frequency of action potentials in the range of 100 to 300 Hz (Wong et al., 1979; Wong and Prince, 1981; Traub and Miles, 1991).

Bursts can be triggered in several ways in CA3 neurons, and the mechanism underlying bursting depends in large part on the way the burst is evoked. One mechanism for burst generation is entirely intrinsic to the neuron and does not require synaptic connectivity. A brief current injection via a somatic recording electrode can produce an all-or-none burst of action potentials in some CA3 neurons (Wong and Prince, 1981) (Fig. 5–8A), and in some cases these bursts occur spontaneously (Cohen and Miles, 2000). The burst is caused by an ADP that follows a single action potential, which is likely to be mediated by calcium current, as pharmacological blockade of calcium current converts burst firing to single spiking (Wong and Prince, 1981).

The CA3 neurons can also generate intrinsic bursts in response to brief synaptic activation or dendritic current injection (Wong et al., 1979; Masukawa et al., 1982; Masukawa and Prince, 1984). Under these conditions the ADP may contribute to the bursting, but dendritically generated calcium spikes are likely to be a more important mechanism driving the burst (Wong and Prince, 1978; Wong et al., 1979). Continuous current injection into the apical dendrites of CA3 pyramidal neurons evokes rhythmic bursts at frequencies of at least 8 Hz (Traub and Miles, 1991). The burst pattern in the dendrite differs markedly from that observed in the soma, with dendritic fast spikes (presumed  $\text{Na}^+$ ) usually having a lower amplitude than slower spikes (presumed  $\text{Ca}^{2+}$ ); this probably reflects a greater distance of the dendrite from the axon initial segment, a low density of  $\text{Na}^+$  channels in the dendrite, or both (Traub et al., 1999).

The most robust bursts are generated in CA3 neurons when the entire network becomes synchronously active, usually in response to suppression of synaptic inhibition or reduction of  $\text{K}^+$  currents (Prince and Connors, 1986). Under these conditions, the network produces a paroxysmal depolarization shift (PDS), which is a hallmark of seizure activity in cortical networks. The PDS is a synchronous network depolarization driven primarily by giant synaptic potentials (Johnston and Brown, 1981, 1984, 1986; Lebeda et al., 1982). Thus, intrinsic conductances can generate bursts that are likely to serve as important signals in a normally functional network, whereas massive, synchronous glutamate release contributes to synchronous bursting during hippocampal seizures (Fig. 5–8B,C). Because CA3 pyramidal neurons generate seizures, they have been extensively studied as the possible pacemakers of interictal epileptiform activity in a variety of animal models of electrographic seizures (see Schwartzkroin, 1993 for a number of relevant reviews).

Just as the mechanisms for generating normal and pathological bursts are different, the mechanisms for terminating them are different as well. During normal intrinsic burst-

**Figure 5–8.** CA3 pyramidal neuron bursting and epilepsy. *A*, Intrinsic burst firing in response to a short current injection in a CA3 pyramidal neuron. (*Source:* Adapted from Wong and Prince, 1981.) *B*, Similar appearance of intrinsic and network-driven bursts in CA3 pyramidal neurons. *B*<sub>1</sub> shows an endogenous burst in a recording with the slice bathed in normal solution. *B*<sub>2</sub> shows a network-driven burst during a paroxysmal depolarization shift (PDS), a network discharge induced by bathing the slice in a solution containing penicillin. Recordings are from two different cells. (*Source:* Adapted from Johnston and Brown, 1984.) *C*, The synaptic nature of the PDS is shown by its reversal in polarity at a holding potential of around 0 mV. The PDS was induced by bathing the slice in a solution containing d-tubocurarine. (*Source:* Adapted from Lebeda et al., 1982.)

ing, each burst is terminated by a slow AHP (~1 second) mediated by a variety of voltage- and  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  conductances (Alger and Nicoll, 1980; Hotson and Prince, 1980; Schwartzkroin and Stafstrom, 1980; Lancaster and Adams, 1986; Lancaster and Nicoll, 1987; Storm, 1989). In contrast, there is good evidence that network bursts are terminated by depletion of glutamate-containing synaptic vesicles during the giant EPSPs that drive the PDS. Replenishment of these vesicle pools is an important factor determining the rate at which the PDS can recur during seizure activity (Staley et al., 1998).

Interestingly, not all CA3 pyramidal neurons respond to suprathreshold stimuli with intrinsic bursts. Intrinsic bursting is most typical of cells located at the distal portion of CA3, closest to CA2. In guinea pig slices, cells located closer to the dentate gyrus typically respond with only a series of single action potentials (Masukawa et al., 1982). Furthermore, CA3 pyramidal neurons with somata located close to the stratum pyramidale/oriens border are more predisposed to burst generation than those located closer to the stratum radiatum (Bilkey and Schwartzkroin, 1990). One notable morphological distinction between these two cell groups is the length of the initial portion of their apical dendrite; cells with somata closer to the stratum pyramidale/oriens border have a significantly longer initial apical dendrite. Consistent with the correlation

between anatomy and burst behaviors, L-type voltage-gated  $\text{Ca}^{2+}$  channels are clustered with high density on the base of major dendrites of CA3 pyramidal neurons (Westenbroek et al., 1990). Such an arrangement would permit large  $\text{Ca}^{2+}$  fluxes in response to summed excitatory inputs and perhaps may account for the predisposition of certain “deep” CA3 pyramidal neurons to bursting activity.

### 5.3.6 Resting Membrane Properties

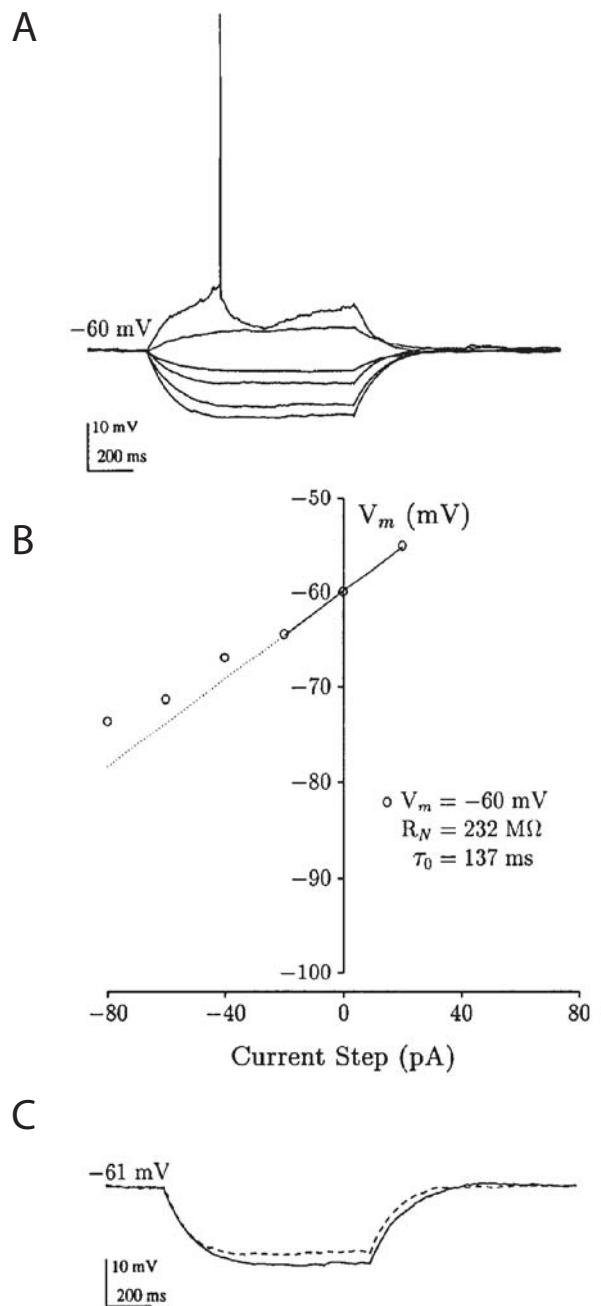

As discussed above for CA1 pyramidal neurons, accurate estimation of the resting membrane properties of central neurons has been problematic, so the conditions of any particular measurement must be carefully considered. At resting membrane potentials ( $-60$  to  $-70$  mV) and with  $I_h$  blocked, the input resistance of CA3 neurons is slightly higher than in CA1 neurons, at about  $160\text{ M}\Omega$  (Spruston and Johnston, 1992) (Fig. 5–9). Estimates of the membrane time constant of CA3 neurons in slices from adult guinea pig yield a mean value of 90 ms, which is considerably slower than for CA1 neurons under the same conditions (Spruston and Johnston, 1992). Similar estimates in slices from young rats at room temperature resulted in even slower membrane time constants (112 ms), also without block of  $I_h$  (Jonas et al., 1993). Assuming a  $C_m$  of  $1\text{ }\mu\text{F/cm}^2$  implies a membrane resistivity of 60,000 to 120,000  $\Omega\text{cm}^2$  of CA3 neurons, which is more than twice as high as  $R_m$  in CA1 neurons. It is not known whether  $R_m$  is lower in dendrites of CA3 neurons than in the soma, as it is in CA1 neurons (Spruston and Johnston, 1992; Stuart and Spruston, 1998).

As with CA1 pyramidal neurons, estimates of  $\tau_m$  and  $R_N$  are larger at more depolarized potentials, consistent with the notion that voltage-dependent conductances, active near the resting membrane potential, contribute to the resting membrane properties of CA3 neurons (Spruston and Johnston, 1992). Pharmacological elimination of  $I_h$  increases the magnitude of  $R_N$  and  $\tau_m$  but did not alter their voltage dependence. This is in contrast to CA1 pyramidal cells, where blocking  $I_h$  reverses the voltage dependence of  $R_N$  and  $\tau_m$ .

The high value of  $R_m$  for CA3 neurons implies that their dendrites may be electrically compact for the steady-state condition. As is the case for CA1 neurons, however, neuronal models indicate that attenuation of transient changes in membrane potential is substantial, and voltage control of synaptic and voltage-gated currents using a somatic electrode would be nearly impossible for conductances located in CA3 dendrites, even at rather modest distances from the soma (Spruston et al., 1993; Major et al., 1994).

### 5.3.7 Active Properties of CA3 Dendrites

Passive models of CA3 pyramidal neurons predict large attenuation of EPSPs between the dendrites and the soma (Carnevale et al., 1997; Jaffe and Carnevale, 1999). Although it is not known whether the conductance of distal synapses are larger to compensate for this attenuation (as shown in CA1) (Magee and Cook, 2000), dendritic attenuation is likely to be

**Figure 5-9.** CA3 passive properties and sag. *A*. Voltage responses to step current injections from  $-80$  to  $+40\text{ pA}$  in  $20\text{-pA}$  increments ( $+20\text{ pA}$  not shown). *B*. (Source: A–C: Adapted from Spruston and Johnston, 1992.)

overcome, at least in part, by the presence of voltage-gated conductances in the dendrites. Although CA3 pyramidal neurons possess most if not all of the same intrinsic conductances described for the CA1 pyramidal cell, and in general these currents share many of the same properties and identities, the density of channels and/or the subcellular location often differ. For example,  $I_h$  is found in both CA1 and CA3 pyramidal

neurons. However, the channels underlying the generation of this current in the two cell types appear to be different. Within the hippocampus two  $I_h$  subunit mRNA transcripts have been detected: HCN1 and HCN2. Labeling for HCN1 is heavy in the CA1 pyramidal cells, whereas only moderate expression is observed in the CA3 pyramidal cell layer. The opposite distribution pattern is true for HCN2. Functionally, despite the differing expression patterns of HCN1 and HCN2, there appears to be little overall difference between the biophysical properties of  $I_h$  in either cell type (Santoro et al., 2000; Fisahn et al., 2002).  $I_h$  measured at the CA3 pyramidal neuron soma is considerably smaller than those observed in CA1 pyramidal neurons (Santoro et al., 2000), however, suggesting a different  $I_h$  channel density in the two cell types. It is not known whether  $I_h$  is distributed at higher density in CA3 dendrites, as it is in CA1.

Because CA3 pyramidal cells lack a large primary apical dendrite such as that found in CA1, studies of dendritic excitability and ion channels in CA3 dendrites have lagged behind those in CA1. Consequently, little is known about the identities and properties of specific ion conductances in the dendrites of CA3 pyramidal neurons. A few studies have used sharp microelectrodes to record spikes from the dendrites of CA3 pyramidal neurons (Wong et al., 1979; Miles et al., 1996). Calcium imaging experiments also indicate that voltage-gated conductances are located in CA3 dendrites and spines (Pozzo-Miller et al., 1993; Jaffe and Brown, 1997). Although much of what we know about dendritic excitability in CA3 has been inferred from a relatively small number of dendritic recordings and calcium imaging, some interesting computer models have been developed for CA3 neurons. Roger Traub and colleagues used such computer models to demonstrate the importance of dendritic  $\text{Ca}^{2+}$  conductances in generating action potential bursts, as well as the importance of these bursts in the synaptic propagation of seizure activity through a model of the CA3 network (Traub and Miles, 1991; Traub et al., 1999). Another model of a CA3 pyramidal neuron demonstrated that bursting behavior does not require any special distribution of  $\text{Ca}^{2+}$ -dependent channels or mechanisms. Furthermore, a simple increase in the  $\text{Ca}^{2+}$ -independent  $\text{K}^+$  conductances was sufficient to convert the firing mode of modeled CA3 pyramidal neurons from bursting to nonbursting (Migliore et al., 1995). Hopefully, these models will stimulate additional experimental studies of the excitable properties of CA3 dendrites.

## 5.4 Subiculum Pyramidal Neurons

The subiculum lies on the opposite side of the CA1 region than CA3, directly adjacent to the distal extent of area CA1. It begins where the Schaffer collaterals end, a point distinguishable by the transition from the tightly packed CA1 pyramidal layer to the more diffuse pyramidal layer of subiculum. The subiculum plays an important role in the hippocampal formation, as it receives convergent input from numerous

sources and constitutes the major output of the hippocampus (Naber et al., 2000) (see Chapter 3). Although neurons in this region have been studied much less than their neighbors in CA1 and CA3, the pronounced tendency of neurons in this region to fire bursts of action potentials has led to considerable interest in understanding the cell physiology of these neurons.

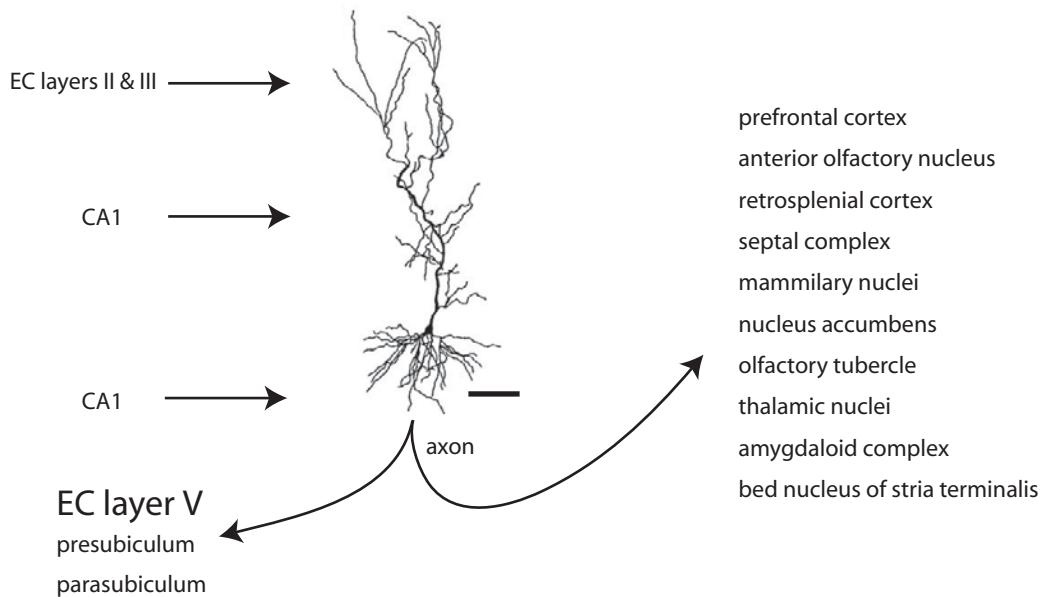

### 5.4.1 Dendritic Morphology

Almost all principal neurons in the subiculum have a typical pyramidal morphology, with apical dendrites extending into the molecular layer and in many cases reaching the hippocampal fissure (Harris et al., 2001) (Fig. 5–10). A quantitative comparison of dendritic branching in the subiculum and CA1 revealed that subiculum pyramidal neurons have slightly fewer branches in both the basal and apical dendritic trees, with the largest difference in the proximal apical dendrites (Staff et al., 2000). No differences have been observed between the dendritic morphology of regular-spiking and bursting neurons in the subiculum (Mason, 1993; Taube, 1993; Greene and Totterdell, 1997; Staff et al., 2000; Harris et al., 2001).

### 5.4.2 Dendritic Spines and Synaptic Inputs

As in CA1, the dendrites of subiculum pyramidal neurons are studded with spines. Virtually no quantitative data are available regarding spine density, however, and little is known about the distribution of the numerous cortical and subcortical inputs to the dendritic trees of subiculum pyramidal neurons. Two of the most prominent inputs to subiculum include topographical projections from CA1 and the entorhinal cortex (see section 5.4.3 and Chapter 3 for details). The projection from the entorhinal cortex originates in both layer II (which also projects to the dentate gyrus and CA3) and layer III (which also projects to CA1) and forms synapses restricted to the distal portions of the apical dendrites (Witter and Amaral, 1991; Lingenhöhl and Finch, 1991; Tamamaki and Nojyo 1993; Amaral and Witter, 1995). These EC projections form functional excitatory synapses on subiculum pyramidal neurons (van Groen and Lopes da Silva, 1986; Behr et al., 1998; Gigg et al., 2000). Axons from CA1 pyramidal neurons also form excitatory synapses on the dendrites of subiculum pyramidal neurons (Finch and Babb, 1980, 1981; Tamamaki and Nojyo 1990; Amaral et al., 1991; Taube, 1993; Gigg et al., 2000).

Among the subcortical structures projecting to the subiculum are the thalamic nucleus reuniens and weak cholinergic projections from the septal nucleus and the nucleus of the diagonal band. Modulatory inputs from the brain stem also innervate the subiculum, including the locus coeruleus (noradrenergic), ventral tegmental area (dopaminergic), and raphe nuclei (serotonergic). In addition to a direct input from the entorhinal cortex, the subiculum receives inputs from many of the same cortical areas that project to the entorhinal cortex. Almost nothing is known about the inhibitory interneurons and their targeting of pyramidal neurons in the subiculum.

**Figure 5–10.** Subiculum dendritic morphology, spines, and synaptic inputs and outputs. Camera lucida drawing shows the dendritic morphology of a subiculum pyramidal neuron, with its major inputs and outputs indicated. Bar = 100  $\mu\text{m}$ . (Source: Adapted from Staff et al., 2000.)

Synaptic stimulation in the CA1 region or entorhinal cortex results in apparently monosynaptic EPSPs that are blocked by AMPA-type glutamate receptor antagonists and are only modestly affected by NMDA receptor blockers (Stewart and Wong, 1993; Stewart, 1997; Stanford et al., 1998; Staff et al., 2000). When inhibition is not blocked, synaptic stimulation in CA1 also produces a strong inhibitory postsynaptic potential (IPSP), presumably mediated in part by feedforward inhibition resulting from activation of interneurons in the subiculum (Menendez de la Prida, 2003).

#### 5.4.3 Axon Morphology and Synaptic Targets

The axons of subiculum pyramidal neurons collateralize extensively in the subiculum as well as projecting out of the subiculum (Harris et al., 2001). The local collaterals are believed to form glutamatergic synapses contacts (Harris and Stewart, 2001). Pyramidal neurons with deeper cell bodies tend to form vertically oriented columns of local collaterals, whereas superficial pyramidal neurons exhibit a greater horizontal spread (toward CA1 and EC) in their local axon collaterals (Harris et al., 2001).

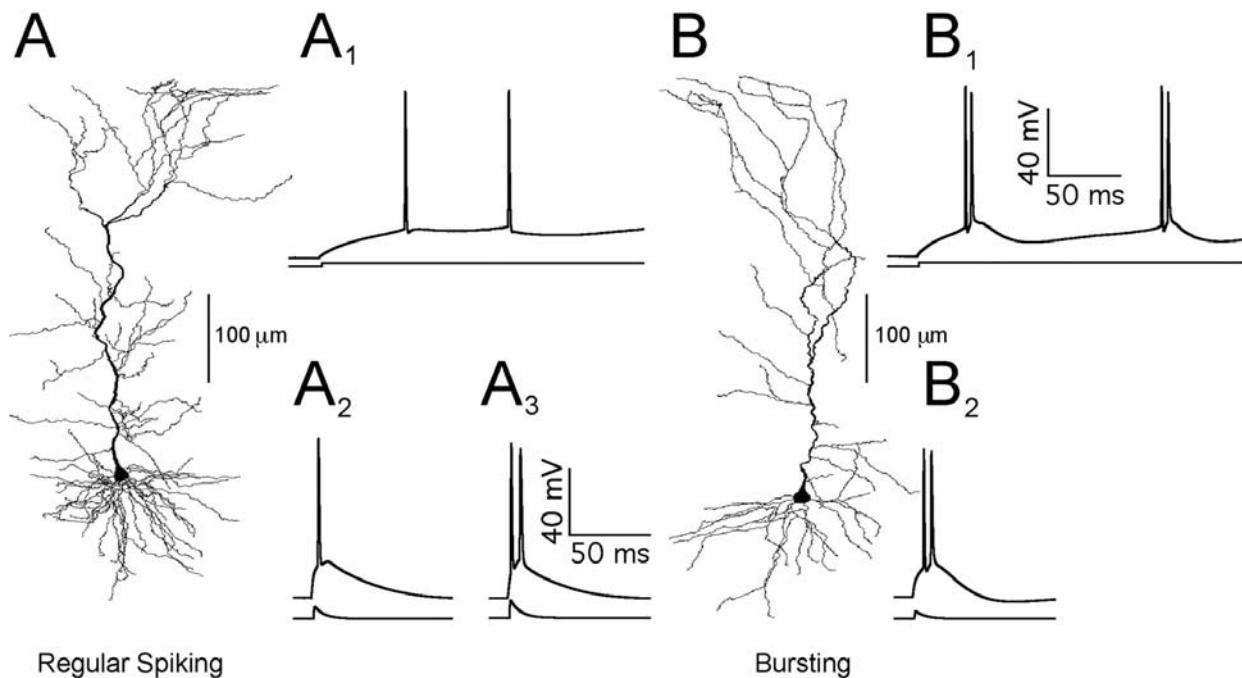

Projecting axon collaterals target a number of cortical and subcortical structures (Fig. 5–10). They do not project back to CA1 but do project to the entorhinal cortex and the pre- and parasubiculum (Amaral and Witter, 1995). The projection to the entorhinal cortex terminates primarily in layer V. These connections are organized such that subiculum projects back to the same regions of the entorhinal cortex from which it receives input. This reciprocal projection is organized in an arrangement similar to the CA1-subiculum projection, in that

the proximal subiculum (closest to CA1) projects to the most distal regions of the entorhinal cortex (the lateral entorhinal area), and the distal subiculum projects to the proximal entorhinal cortex (the medial entorhinal area).

Among the other numerous targets of the subiculum are the medial prefrontal cortex, anterior olfactory nucleus, retrosplenial cortex, septal complex, mammillary nuclei, nucleus accumbens, olfactory tubercle, several thalamic nuclei (including reunions), amygdaloid complex, and the bed nucleus of the stria terminalis (Amaral and Witter, 1995) (see Chapter 3 for more details). An interesting organizational feature of the axonal projections from the subiculum is that they are organized along the septo-temporal (dorsal-ventral) axis of the hippocampus as well as along the proximo-distal (CA1 to presubiculum) axis. Neurons from four regions defined by these axes (septal-proximal, septal-distal, ventral-proximal, ventral-distal) project to different targets, and most subiculum neurons project to only a single cortical or subcortical target (Naber and Witter, 1998).

#### 5.4.4 Resting and Active Properties

In awake, freely moving rats, subiculum cells exhibit firing in “place fields,” which are larger and noisier than those seen in CA1 (Sharp and Green, 1994; O’Mara et al., 2001) (see Chapter 11). A prominent feature of the firing patterns observed *in vivo* is action potential bursting. Indeed, bursting is much more prominent in the subiculum than in CA1. In both *in vitro* and *in vivo* studies, pyramidal cells in the subiculum have been shown to fall into two broad physiological categories: bursting cells and regular-spiking cells (Mason, 1993;

**Figure 5–11.** Subiculum action potential bursting. *A*, Subicular pyramidal neuron classified as “regular spiking” because of its response to a threshold-level step current injection ( $A_1$ ). A single spike occurs in response to a threshold-level current injection in the shape of an EPSC ( $A_2$ ), but larger EPSC-like current injections produce bursting ( $A_3$ ). *B*, Subicular pyramidal neuron classified as

“bursting” because of its response to a threshold-level step current injection ( $B_1$ ). A single two-spike burst occurs in response to a threshold-level current injection in the shape of an EPSC ( $B_2$ ). (Source: *A, B*: Adapted from Cooper et al., 2003.)

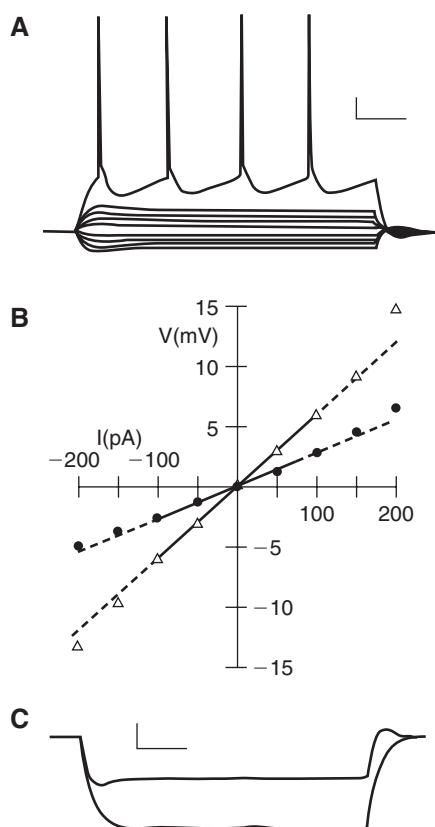

Mattia et al., 1993; Stewart and Wong, 1993; Taube, 1993; Staff et al., 2000; Menendez de la Prida et al., 2003) (Fig. 5–11).

Given the large number of brain areas innervated by subicular neurons, it is tempting to speculate that strong bursting cells target different areas than weaker bursting or regular spiking cells. Some evidence supports this hypothesis, as it has been shown that bursting cells project preferentially to the presubiculum and parasubiculum, whereas regular-spiking cells project preferentially to the entorhinal cortex (Stewart, 1997; Funahashi et al., 1999). There is also some evidence for preferential localization of bursting and regular-spiking neurons in the subiculum, but the spatial gradients are weak. Two studies showed that regular spiking cells are more prevalent in superficial layers (Greene and Totterdell, 1997; Harris et al., 2001). Evidence for a proximo-distal gradient is less consistent. A microelectrode study in slices showed a preference for regular-spiking cells near the middle of the proximo-distal axis of the subiculum (Greene and Totterdell, 1997), whereas a patch-clamp study showed a slightly higher proportion of bursting cells in the distal subiculum (Staff et al., 2000). A variety of technical differences could account for these different conclusions, but the message emerging from these studies, taken together, is that proximo-distal gradients of bursting are weak, if they exist at all.

The resting and active properties of subicular pyramidal neurons have been examined in several studies. The measurements of resting potentials are remarkably consistent, ranging

from  $-69$  to  $-64$  mV in microelectrode and patch-clamp recordings (Mason, 1993; Mattia et al., 1993, 1997a; Stewart and Wong, 1993; Greene and Totterdell, 1997; Staff et al., 2000).  $R_N$  ranged from 24 to  $42\text{ M}\Omega$  and  $\tau_m$  from 7 to 20 ms. Most studies have revealed that these values are not significantly different between bursting and regular-spiking neurons in the subiculum (Taube, 1993; Staff et al., 2000). Compared to CA1 pyramidal neurons, however, a recent patch-clamp study showed that subicular neurons have significantly lower  $R_N$  and faster  $\tau_m$  (Staff et al., 2000; but see Mason, 1993 and Taube, 1993). Like CA1 neurons, pyramidal neurons in the subiculum contain a substantial  $I_h$  current, which produces the characteristic sag toward the resting potential during hyperpolarizing or depolarizing current pulses (Stewart and Wong, 1993; Staff et al., 2000; Menendez de la Prida et al., 2003) (Fig. 5–12).

Action potentials were also found to be the same in bursting and regular spiking pyramidal neurons in the subiculum but were somewhat different from CA1 pyramidal neurons. Comparing single CA1 action potentials with subiculum action potentials (either the first in a burst or single action potentials in regular-spiking cells), the subicular action potentials were found to have slightly slower rise times and smaller amplitudes but shorter half widths (Staff et al., 2000). The dendritic morphology was also similar across all subicular neurons but distinct from that of CA1 cells (Staff et al., 2000). Taken together, these findings suggest that the dichotomy

**Figure 5-12.** Subiculum passive properties and sag. *A*, Voltage responses to step current injections from  $-200$  to  $+300$  pA in 50-pA increments ( $+250$  pA response not shown). Bar = 10 mV, 100 ms. *B*, Voltage–current plot of the steady-state responses shown in *A*. Solid lines are the points used for linear fits to the data. Dashed lines are extrapolations of the fits. *C*, Effect of 5 mM CsCl on the hyperpolarizing voltage response to a current step of  $-150$  pA. Note the block of sag in the voltage response. Bar = 3 mV, 100 ms. (Source: Adapted from Staff et al., 2000.)

between bursting and regular-spiking neurons in the subiculum may be somewhat artificial. Another possibility is that subicular pyramidal neurons all have similar basic properties (yet distinct from those of CA1 cells), but that they vary along a continuum with respect to the strength of the burst-generating mechanism (Staff et al., 2000; Jung et al., 2001).

#### 5.4.5 Mechanisms of Bursting

The mechanism responsible for bursting in the subiculum has been a matter of some controversy. Two early studies identified a calcium-dependent spike that could contribute to bursting, possibly as a result of dendritic spike initiation (Stewart and Wong, 1993; Taube, 1993). Another study, published about the same time, reported that bursting persisted in the presence of  $\text{Ca}^{2+}$  channel block but not  $\text{Na}^+$  channel block and concluded that bursting is driven by  $\text{Na}^+$  currents (Mattia et al., 1993; see also Mattia et al., 1997a). These seemingly contradictory findings were reconciled, to some extent, by a study showing that  $\text{Ca}^{2+}$  currents drive bursting, but they are acti-

vated by  $\text{Na}^+$ -dependent action potentials (Jung et al., 2001).  $\text{Ca}^{2+}$  channels are activated by each action potential, and current flows through these channels during spike repolarization as a result of an increased driving force and slow channel deactivation. The resulting  $\text{Ca}^{2+}$  tail current produces a spike afterdepolarization (ADP), which triggers additional spikes comprising the burst (Jung et al., 2001). This study also showed that block of  $\text{Ca}^{2+}$  channels can lead to an abnormal form of bursting in part due to indirect block of  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  channels. This finding reproduces and explains earlier demonstrations of the lack of effectiveness of some  $\text{Ca}^{2+}$  channel blockers to block bursting despite the fact that  $\text{Ca}^{2+}$  channels do play a pivotal role in producing the bursts under normal conditions. The results also explain the effectiveness of TTX as a blocker of bursting. Even at concentrations too low to eliminate the first spike, the threshold for the second spike was raised to a point that the ADP no longer triggers additional spikes (Jung et al., 2001).

#### 5.4.6 Membrane Potential Oscillations

Another important feature of pyramidal neurons in the subiculum is their ability to generate subthreshold membrane potential oscillations in the theta frequency range of 4 to 9 Hz (Mattia et al., 1997b). These oscillations increase in amplitude as the membrane potential is depolarized above rest, reaching a peak amplitude of about 3 mV just below the action potential threshold. If the membrane is depolarized further, clusters of action potentials fire at a rate of about 1 to 2 Hz. Subthreshold theta oscillations in subicular pyramidal cells are abolished by the  $\text{Na}^+$ -channel blocker TTX but not by blockers of glutamate or GABA receptors or by  $\text{Ca}^{2+}$  channels, suggesting that oscillations are an intrinsic property that depends critically on voltage-gated  $\text{Na}^+$  channels (Mattia et al., 1997b). Similar oscillations have also been observed in CA1 pyramidal neurons, where they have been shown to arise from interactions between voltage-gated  $\text{Na}^+$  current,  $\text{K}^+$  current ( $I_M$ ), and  $I_h$  (Leung and Yu, 1998; Hu et al., 2002). Subicular pyramidal cells also participate in synaptically mediated oscillations in the gamma frequency range of 20 to 50 Hz. Bursting neurons in subiculum fire doublets of action potentials during these oscillations, which likely promote the spread of network activity in the gamma range (Stanford et al., 1998).

#### 5.5 Dentate Granule Neurons

The main cell type of the dentate gyrus is the granule cell. These neurons have been studied extensively, in part because they were the first to be shown to exhibit LTP and in part because they receive spatially segregated synaptic inputs on different regions of their dendrites. Granule cells were also the first cell type in which it was shown that mRNA could be translated into proteins in dendrites, which has significant

implications for plasticity and learning (Jiang and Schuman, 2002; Steward and Worley 2002).

### 5.5.1 Dendritic Morphology and Spines

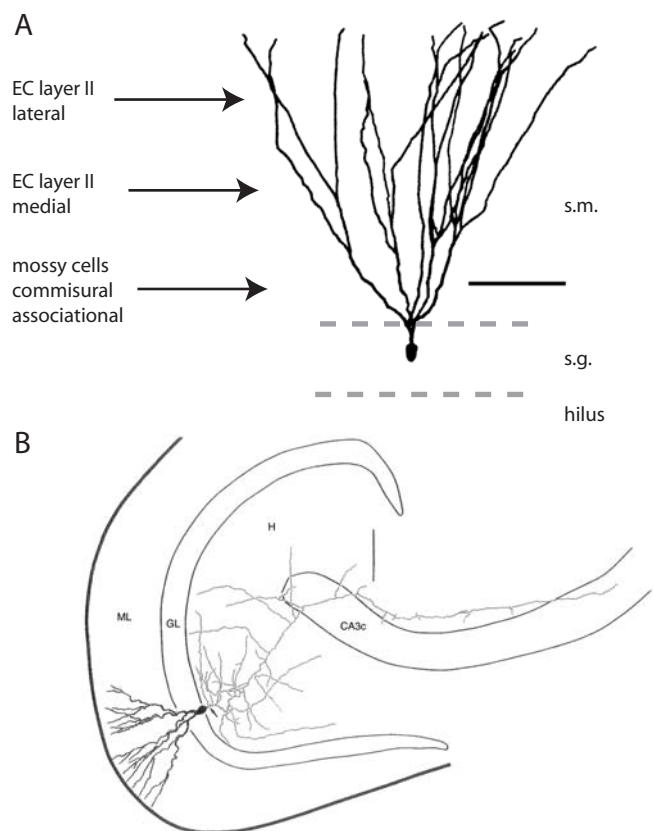

The principal neurons of the dentate gyrus are distinctly different from all of the neurons discussed so far because they are not pyramidal in morphology. Rather, they comprise a small, ovoid cell body with a single, approximately conical (but somewhat elliptical) dendritic tree (Fig. 5–13). The granule cells lie in densely packed columnar stacks underneath the relatively cell-free molecular layer and the cell-rich polymorphic layer (also known as the hilus). Typically, granule cell somata are about 10 µm in diameter and about 18 µm in length, with their long axis oriented perpendicular to the granule cell layer. Interestingly, the packing density of dentate granule cells and CA3 pyramidal cells vary along the septo-temporal axis of the hippocampus but in opposite directions. Thus, the ratio of granule cells to CA3 cells ranges from about 12:1 at the septal pole to 2:3 at the temporal pole, implying substantial differences in connectivity along this axis (Amaral and Witter, 1995).

Granule cell dendrites all extend into the molecular layer and terminate near the hippocampal fissure. The number of dendritic branches is highly variable, with the calculated sum of the dendritic lengths ranging from 2.3 to 4.6 mm. These dendritic lengths are significantly shorter than those of the CA1 pyramidal neurons. Dendritic morphology also varies depending on the position in the dentate gyrus. Neurons located in the suprapyramidal blade (closest to CA1) are generally larger (greater total dendritic length, more dendritic segments, and a greater transverse spread) than those in the infrapyramidal blade (Desmond and Levy 1982, 1985; Claiborne et al., 1990).

Like pyramidal neurons, the dendrites of granule cells are heavily studded with spines. Estimates of spine density indicate that there are two to four spines per linear micrometer of dendrite. The number of spines increases (within this range) in progressively more distal dendrites, and there are slightly more spines in the suprapyramidal blade than in the infrapyramidal blade (Desmond and Levy 1982; Hama et al., 1989). The available data suggest that a granule cell located in the suprapyramidal layer would have close to 5600 spines, whereas a cell located in the infrapyramidal cell layer would have significantly fewer spines, at about 3600. These values are considerably lower than the spine densities and total spine numbers calculated for both CA1 and CA3 pyramidal neurons.

### 5.5.2 Excitatory and Inhibitory Synaptic Inputs

Dentate granule cells receive synaptic input from several sources. Granule cell dendrites are generally divided into thirds according to the differential inputs they receive. The proximal third (closest to the cell body) receives input from the commissural/associational fibers, which consist primarily of axons from the mossy cells (see Section 5.6). The middle

**Figure 5-13.** Dentate granule cell dendritic morphology, spines, and synaptic inputs and outputs. *A*. Computer-generated plot of a reconstructed granule cell from the suprapyramidal blade of the dentate gyrus showing the cell body in the stratum granulosum (s.g.) and the dendrites in the stratum moleculare (s.m.), with the major inputs indicated. (*Source:* Adapted from Claiborne et al. 1990, with permission.) *B*. Camera lucida drawing of the dendritic morphology and axonal arborization of a granule cell in the infrapyramidal blade of the dentate gyrus. The axons are in the molecular layer (ML, same as s.m.). The major targets of the mossy fiber axon (thin structure extending right of the granule layer, GL) are the mossy cells and CA3 pyramidal neurons, as well as interneurons in the hilus (H) and CA3 regions. (*Source:* Adapted from Lübke et al., 1998, with permission. A color version of this figure with the axon in red is available online.)

third receives input from relatively medial regions of the entorhinal cortex, and the distal third receives input from the lateral entorhinal cortex (Blackstad 1958; Amaral and Witter, 1995). Inputs to the dentate gyrus from layer II of the entorhinal cortex arrive via the perforant path. The spatial separation of lateral and medial perforant path inputs was elegantly exploited in early studies that described the cooperative and associative properties of LTP (McNaughton et al., 1978; Levy and Steward 1979) (see Chapter 10). Both inputs are primarily glutamatergic, although the medial perforant path inputs also contain cholecystokinin, and the lateral perforant path contains enkephalin (Amaral and Witter, 1995). Several differences between synaptic transmission at the medial and lateral perforant path have been reported, including differences in NMDA receptor activation as well as modulation by choliner-

gic, adrenergic, and metabotropic glutamate receptor activation (Abraham and McNaughton, 1984; Kahle and Cotman, 1989; Dahl et al., 1990; Pelletier et al., 1994; Macek et al., 1996).

The dentate gyrus receives several neuromodulatory inputs, including diffuse projections from the septal nuclei (acetylcholine), locus coeruleus (norepinephrine), and ventral tegmental area (dopamine). The supramammillary region of the hypothalamus (possibly containing substance P) projects to the proximal third of the molecular layer, and the raphe nuclei (serotonin) project primarily to the hilus (Amaral and Witter, 1995).

Granule cells also receive inputs from a variety of interneurons, mostly lying in the hilus. Basket cells and chandelier cells target primarily somata, whereas various interneurons target the dendrites. In addition, both the commissural/associational and perforant path inputs contain minor GABAergic components (Amaral and Witter, 1995). Of particular interest, almost all of the serotonergic input to the hilus terminates on GABAergic interneurons that project to the distal dendrites of granule cells (Halasy et al., 1992).

### 5.5.3 Axon Morphology and Synaptic Targets

The somata of granule cells taper at their base, where a single unmyelinated axon emerges and is directed toward the hilus. Ramon y Cajal termed the axons of granule cells “mossy fibers” for their anatomical similarity to the fibers in the cerebellum. The large varicosities and filopodial extensions are reminiscent of moss, thus providing the name for these pathways. Anatomically, as far as it is known these axons are unique among hippocampal and cortical neurons (and indeed throughout the mammalian CNS) in that they form anatomically specialized synapses depending on the nature of their postsynaptic targets.

Each granule cell gives rise to a single unmyelinated axonal fiber about 0.2  $\mu\text{m}$  in diameter, with a total length (including collaterals) of more than 3 mm (Claiborne et al., 1986; Frotscher et al., 1991; Acsády et al., 1998). The axons form numerous collaterals throughout the hilus that innervate the numerous cell types present in the hilar subfield before projecting to the apical dendrites and in some cases basal dendrites of CA3 pyramidal neurons (Claiborne et al., 1986). The mossy-fiber projection to CA3 forms a tight bundle running parallel to the CA3 pyramidal cell body layer in a suprapyramidal region termed the stratum lucidum because of its appearance at the light microscopic level. This region corresponds to approximately the first 100  $\mu\text{m}$  of the CA3 pyramidal neuron apical dendrite. After leaving the hilar region, the mossy fiber axon contains no further branch points.

Three basic types of mossy fiber terminal exist along the entire length of the main axon: large mossy terminals (4–10  $\mu\text{m}$ ), filopodial extensions that project from the large mossy boutons (0.5–2.0  $\mu\text{m}$ ), and small en passant varicosities (0.5–2.0  $\mu\text{m}$ ) (Amaral, 1979; Claiborne et al., 1986; Frotscher et al., 1991; Acsády et al., 1998). The latter two small terminals are somewhat larger than varicosities in axons of CA3 pyramidal neurons (Acsády et al., 1998). The total number of large

mossy terminals along a single axon is about 10 in the hilar region and about 12 (range 10–18) in the CA3 region, with the terminals being distributed more or less evenly along the mossy fiber axon. Mossy cells constitute the principal target of the large mossy terminals in the hilus (see Section 5.6), and the small filopodial and en passant terminals selectively innervate only inhibitory interneuron targets (Acsády et al., 1998). These terminals form only single, often perforated, asymmetrical synapses on the cell bodies, dendrites, and spines of GABAergic inhibitory interneurons. This anatomical arrangement stands in marked contrast to the large mossy fiber terminals, which contain numerous release sites housing thousands of both small, clear vesicles and large, dense-core vesicles. The mossy fibers are glutamatergic but also contain GABA (Sandler and Smith, 1991; Sloviter et al., 1996; Walker et al., 2001, 2002a) and the opiate peptide dynorphin (McGinty et al., 1983). Each mossy fiber bouton contains smooth endoplasmic reticulum and a large number of mitochondria (Chicurel and Harris, 1992). The main body of the large mossy bouton envelops the thorny excrescences of the CA3 pyramidal neuron, as described above.

Of particular interest, the filopodial extensions and small, en passant synapses outnumber the large mossy fiber terminals by about 10-fold, raising the intriguing idea that the primary targets of dentate gyrus granule cells are inhibitory interneurons (Acsády et al., 1998). This anatomical segregation of terminal types is unprecedented throughout the mammalian CNS and suggests that it may provide functional specialization of synaptic output.

Electrophysiological experiments have largely confirmed the hypothesis that the large and small synaptic specializations of the mossy fibers are functionally distinct. Individual mossy fiber release sites onto principal cells have a low initial release probability, which allows a high degree of short-term and frequency-dependent facilitation (Jonas et al., 1993; Salin et al., 1996; Toth et al., 2000; Lawrence et al., 2004). In contrast, mossy fiber synapses onto interneurons in the stratum lucidum demonstrate either mild facilitation or depression in response to brief stimulus trains (Toth et al., 2000). In addition, a form of NMDA receptor-independent LTP observed at mossy fiber synapses onto principal cells (which is thought to be expressed entirely in the presynaptic terminal) is absent at mossy fiber to interneuron synapses (Maccaferri et al., 1998) (see Chapter 10). Instead, paradigms that induce LTP at principal cell synapses induce two forms of long-term depression at interneuron synapses (Lei and McBain, 2002, 2004).

### 5.5.4 Resting Potential and Action Potential Firing Properties

The resting membrane potential of granule cells is typically more hyperpolarized than that of either CA1 or CA3 pyramidal neurons, being close to  $-84\text{ mV}$ , based on recordings made *in vivo* (Penttonen et al., 1997) and *in vitro* brain slices (Spruston and Johnston, 1992; Staley et al., 1992). Measurements of the action potential threshold have provided numbers similar to those observed for both CA1 and CA3

pyramidal cells:  $-45$  mV. Given the relatively negative resting membrane potential of granule cells, larger depolarizations are required to bring single granule cells to threshold for action potential generation. These properties likely underlie the low spontaneous firing frequencies associated with granule cells *in vivo* (Penttonen et al., 1997). Surprisingly, little accurate information exists regarding granule cell firing patterns *in vivo*. This is due in part to the difficulty associated with unambiguously identifying granule cell activity during extracellular recordings. During behavioral tasks, granule cell firing frequencies are very low, except when the animal is in a place field (Jung and McNaughton, 1993; Skaggs et al., 1996) and during odor-guided tasks (Wiebe and Staubli, 1999) (see Chapter 11).

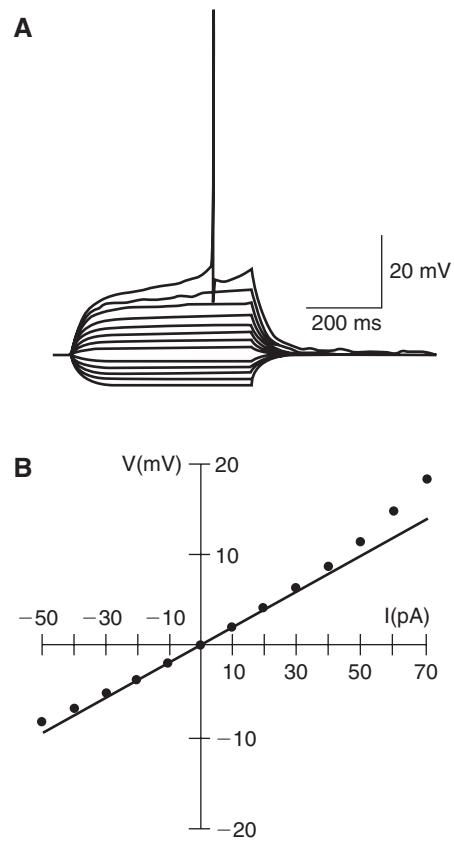

Upon reaching threshold for action potential initiation, in response to long depolarizing pulses granule cells typically fire trains of action potentials that demonstrate marked accommodation (Staley et al., 1992; Penttonen et al., 1997). As with pyramidal cells, spike accommodation is largely due to the activation of  $\text{Ca}^{2+}$ -dependent, voltage-gated  $\text{K}^+$  conductances; addition of  $\text{Ca}^{2+}$  buffers to intracellular recording electrodes removes such accommodation (Staley et al., 1992).

### 5.5.5 Resting Membrane Properties

At the resting membrane potential granule cells have input resistances considerably higher than those of both CA1 and CA3 pyramidal cells, with estimates ranging from 230 to 450  $\text{M}\Omega$  (Spruston and Johnston, 1992; Staley et al., 1992) (Fig. 5–14) and a  $\tau_m$  between 30 and 50 ms. These parameters are also developmentally regulated, a factor that is especially pertinent because granule cells continue to be born and develop in adults (Spigelman et al., 1992; Gould and Cameron, 1996; Liu et al., 1996). Lower values are obtained with sharp micro-electrode recordings, but these values are likely to be affected by the microelectrode-induced leak (Spruston and Johnston, 1992; Staley et al., 1992). Leak-induced effects are likely to be larger in granule cells than in pyramidal cells because the smaller cell body and thinner dendrites mean that a leak constitutes a larger fraction of the total conductance.

As in pyramidal neurons, estimates of passive membrane properties are highly nonlinear across small deviations from the resting membrane potential (Spruston and Johnston, 1992), indicating that voltage-dependent conductances close to the resting membrane potential contribute to their passive membrane properties. Blockers of  $I_h$  have little effect on the passive membrane properties of granule cells (Spruston et al., 1992), thus implicating other conductances as influencing the resting membrane properties.

Granule cells have a relatively simple dendritic branching pattern. Their dendrites branch rather symmetrically, with each of the daughter branches being smaller in diameter than the parent dendrite. In fact, the branch points in granule cell dendrites come close to obeying the assumptions necessary to collapse the dendritic tree to an equivalent cylinder. In addition, each dendritic branch has similar geometry and terminates at approximately the same distance (the hippocampal

**Figure 5-14.** Dentate granule cell passive and active properties. *A*, Voltage responses to current injections of  $-50$  to  $+80$  pA in 10-pA increments. *B*, Voltage-current plot of the data in *A*. The line represents an extrapolated linear fit to the steady-state voltage responses to  $-20$  to  $+20$  pA current injections. (Source: Adapted from Lübke et al., 1998, with permission.)

fissure) as others in the same cell. Because of this dendritic geometry, it is reasonable to consider an equivalent cylinder model of granule cell dendrites (Durand et al., 1983; Turner and Schwartzkroin, 1983; Desmond and Levy, 1984; Turner, 1984). Unfortunately, the methods for determining electrotonic length ( $L$ ) from the time course of somatic voltage transients (applied to granule cells and others by several investigators during the 1980s) are limited by the existence of a soma and further complicated by the presence of a micro-electrode leak (Rall, 1969). Furthermore, anatomical data alone cannot be used to determine  $L$  because an important parameter, the intracellular resistivity ( $R_i$ ) is not known for granule cells. The effects of a microelectrode leak on  $R_N$  and the apparent  $\tau_m$  in granule cells, however, are strongly dependent on  $L$ . Using this approach, the electrotonic length of granule cells in the suprapyramidal blade of adult guinea pig slices has been estimated at 0.74 (Spruston and Johnston, 1992). In an equivalent cylinder of this length, a voltage imposed at the soma would be expected to attenuate only 22% by the end of the dendritic tree (Rall, 1959). Similar attenuation estimates were obtained independently using computer models (Carnevale et al., 1997).

Based on these analyses, one might be tempted to conclude that dentate granule cells are “electrotonically compact.” However, steady-state voltage attenuation is much less than the attenuation of transient potentials, such as EPSPs. Furthermore, in the voltage-clamp condition, space-clamp errors are compounded because they are bidirectional (synapse to soma and back) and because escape of the dendritic potential from the command value introduces additional errors (Spruston et al., 1993). For these reasons, it may be argued that the descriptor “electrotonically compact” is at best misleading and at worst false for most neurons and experimental conditions. The term is best used as a comparator; indeed, computer models predict that granule cells are more electrotonically compact than most pyramidal neurons (Carnevale et al., 1997).

Despite the severity of EPSP attenuation, distal dendritic synapses on granule cells are likely to be more effective than synapses at similar distances on pyramidal cells. The reason is the absence of a large, main apical dendrite and the smaller soma in granule cells. A fixed current entering a synapse on a granule cell dendrite is not subject to as much attenuation as in pyramidal cell dendrites and can therefore generate a significant somatic EPSP even after its attenuation in the dendritic tree (Jaffe and Carnevale, 1999). In fact, because the diameter of granule-cell dendrites decreases with distance from the soma, the local depolarization from a fixed somatic current increases with distance from the soma in a way that largely cancels the effect of the increased voltage attenuation. Thus, synapses are at least partially normalized for their position on the dendritic tree. This effect has been called “passive normalization of synaptic integration” because the mechanism depends entirely on dendritic geometry and does not require any scaling of synaptic conductances with distance or interaction with voltage-gated conductances in the dendritic tree (Jaffe and Carnevale, 1999). Passive normalization has been shown to be plausible in other cell types that lack a large primary apical dendrite, including CA3 pyramidal neurons and interneurons. In CA1 neurons, passive normalization does not occur in the apical dendritic tree because of the long primary dendrite, but it could occur (at least partially) in the basal dendritic tree, which lacks a primary dendrite (Jaffe and Carnevale, 1999). These differences highlight the importance of dendritic architecture in synaptic integration and the functional relevance of variability of dendritic structure across the various regions of the hippocampus.

### 5.5.6 Active Properties of Granule Cells

Similar to pyramidal neurons, granule cells have a wide repertoire of voltage-gated currents. Granule cells express two forms of the voltage-gated, transient K<sup>+</sup> current (Riazanski et al., 2001). One of these currents is indistinguishable from the transient currents expressed in most neurons, which have a low threshold for inactivation and block by 4-AP. The second current, however, activates at more depolarized potentials and is sensitive to low micromolar concentrations of TEA and the

anemone toxin BDS-I, properties consistent with it being carried by channels containing the Kv3.4 subunit. In granule cells this current has its highest density in nucleated patches excised from the basal end of the granule cell body, consistent with its immunohistochemical detection in the axons of granule cells.

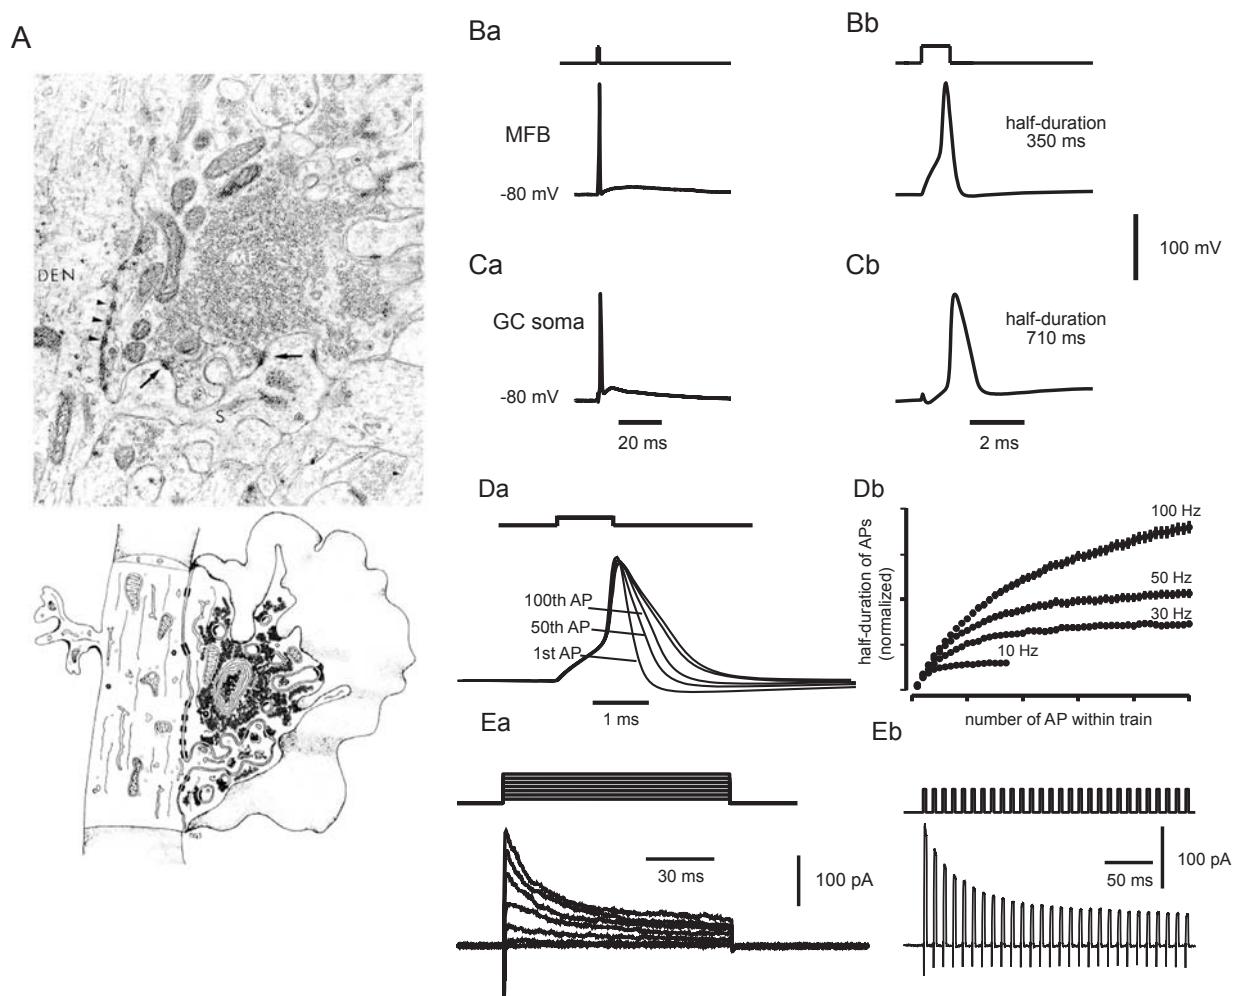

In a technically superb series of experiments, Geiger and Jonas (2000) provided direct evidence for voltage-gated ion channels in the presynaptic mossy fiber terminals of granule cells (Fig. 5–15). In whole-cell recordings made directly from visually identified large mossy fiber boutons, action potential waveforms were observed to be remarkably brief (half duration 380 μs) compared to action potentials measured at the soma (half duration about 600 μs). Action potentials measured at the soma were typically followed by a prominent after-depolarization, whereas those at the mossy fiber terminal had a brief after-hyperpolarization followed by an after-depolarization. Action potentials at mossy fiber terminals were dynamically modulated during brief periods of high-frequency activity, with appreciable spike broadening occurring as a result of a decrease in the rate of repolarization. In contrast, only modest spike broadening was observed in similar experiments recorded at the granule cell soma, indicating differential expression of voltage-gated currents in the soma and the axon. Consistent with this hypothesis, voltage-gated K<sup>+</sup> currents in axon terminals inactivated rapidly but recovered from inactivation very slowly, suggesting that cumulative channel inactivation mediated the activity-dependent spike broadening. Prolongation of the presynaptic spike waveform directly increased the amount of calcium that entered the presynaptic terminal during action potential activity, resulting in a significant increase in evoked synaptic currents. Pharmacological identification of the responsible conductance implicated channels formed by Kv1.1/Kv1.4 or Kv1.1/β-subunit combinations (Geiger and Jonas, 2000).

Propagation of action potentials into the granule cell dendritic structure has been much less studied than in pyramidal neurons. This is primarily due to the small diameter of granule-cell dendrites, which has made dendritic recording extremely difficult. Dendritic field potential recordings and current-source density analysis, however, have indicated that action potentials spread actively from an initiation zone near the soma into the dendrites (Jeffreys, 1979).

### 5.6 Mossy Cells in the Hilus

Numerous cell types are present in the polymorphic layer (hilus) between the dentate granule cells and the CA3 pyramidal neurons (Amaral, 1978). The most prominent and well studied principal neurons in this region are the mossy cells. These cells have been studied quite extensively because of the observation that they are among the first neurons to degenerate during epilepsy and ischemia (Sloviter, 1987, 1991; Hsu and Buzsáki, 1993; but see Ratzliff et al., 2002).

**Figure 5–15.** Dentate granule cell mossy fiber terminals. *A*. Ultrastructure of the mossy fiber synaptic complex. Upper panel: Electron micrograph through a mossy fiber synaptic complex. The postsynaptic CA3 pyramidal cell dendrite is indicated (DEN) to the left of the presynaptic mossy fiber terminal. The presynaptic terminal contains numerous small vesicles and mitochondria. The postsynaptic thorny excrescence is indicated (S) where it penetrates the terminal. Several symmetrical junctions between the dendritic shaft and the terminal are observed (arrowheads) and are representative of puncta adherentia. Note that these symmetrical junctions do not have any vesicles nearby. In contrast, asymmetrical junctions (arrows) onto the thorn show a significant clustering of vesicles. Lower panel: Representation of a mossy fiber synaptic complex depicting the various features observed at the electron microscopic level. (*Source:* Adapted from Amaral and Dent, 1981; from Henze et al., 2000.) *B, C*. Action potentials recorded from a presynaptic mossy fiber bouton (MFB, panel *B*) and in a granule cell soma (GC, panel *C*) evoked by a 1 ms current pulse and shown at different time bases. The properties of action potentials in the presynaptic mossy fiber bouton differ markedly from those in the granule cell

somata, which had a significantly longer half duration and were followed by a more pronounced afterdepolarization. *D*. Action potentials in presynaptic mossy fiber boutons show marked activity-dependent broadening. Trains of action potentials were evoked at 50 Hz. *Da*. Every 50th action potential is shown superimposed with the first action potential in the train. *Db*. Plot of the action potential duration at half-maximal amplitude in whole cell recorded mossy fiber boutons against the number of action potentials in the train for the frequencies indicated. *E*. Frequency-dependent spike broadening is explained in part by the biophysical properties of voltage-gated outward potassium currents present in the presynaptic mossy fiber bouton. *Ea*. K<sup>+</sup> currents activated in a mossy fiber bouton outside-out patch by test pulses between -70 and +20 mV. *Eb*. Cumulative inactivation of K<sup>+</sup> channels induced by repetitive activation. Traces are K<sup>+</sup> currents activated by a series of test pulses to +20 mV (3 ms duration, 7 ms interpulse interval). Such cumulative inactivation plays a significant role in shaping the action potential trajectory in response to high frequency stimulation. (*Source:* *B–E:* Geiger and Jonas, 2000.)

### 5.6.1 Dendritic Morphology and Spines

Mossy cells are located primarily in a C-shaped region of the hilus directly below the granule cell layer (zone 4 of Amaral, 1978). They consist of ovoid cell bodies that give rise to several primary dendrites (Fig. 5–16A,B). Each of these dendrites branches three or four times while remaining roughly parallel to the granule cell layer and with almost all branches remaining within the hilus (Amaral, 1978; Ribak et al., 1985; Buckmaster et al., 1992; but see Frotscher et al., 1991 and Scharfman, 1991).

The mossy cells are named for the mossy appearance created by the numerous thorny excrescences covering their proximal dendrites within 40 to 80  $\mu\text{m}$  from the soma (Amaral, 1978; Ribak et al., 1985; Frotscher et al., 1991; Lübke et al., 1998) (Fig. 5–16B). These excrescences are similar, though not identical, to the thorny excrescences on CA3 pyramidal neurons. The major difference is a paucity of necks on the spines, with each excrescence formed by a cluster of spine heads (Amaral, 1978). The remaining portions of mossy cell dendrites are covered in more conventional spines.

### 5.6.2 Excitatory and Inhibitory Synaptic Inputs

Mossy cells receive direct excitatory input from the granule cell mossy fibers, which contact the thorny excrescences and at least some of the conventional spines on more distal dendrites (Frotscher et al., 1991; Buckmaster et al., 1992; Scharfman, 1994). An additional excitatory input arises from a subset of CA3 pyramidal neurons that send axon collaterals back into the hilus (Ishizuka et al., 1990; Scharfman, 1994). Intracellular recordings have revealed that mossy cells receive frequent, often large, spontaneous EPSPs (Scharfman and Schwartzkroin, 1988). Consistent with the large size of these spontaneous EPSPs, kinetic analysis has revealed that spontaneous EPSCs in mossy cells are slower than in aspiny hilar interneurons, a difference attributed to different glutamate receptor subtypes on these two classes of neurons (Livsey and Vicini, 1992; Livsey et al., 1993).

In addition to these powerful excitatory synaptic inputs, mossy cells receive substantial inhibitory inputs. After blocking glutamate receptors, a high frequency of spontaneous IPSCs are observed in all hilar neurons, including mossy cells (Scharfman, 1992; Soltesz and Mody, 1994; Acsady et al., 2000). It is likely that inhibitory synaptic input arrives from a variety of sources, including dentate basket cells, aspiny hilar interneurons (ipsilaterally and contralaterally), and GABAergic input from the medial septum.

### 5.6.3 Axon Morphology and Synaptic Targets

The mossy cell axon specifically targets the inner third of the molecular layer of the dentate gyrus (Ribak et al., 1985; Buckmaster et al., 1992). More than two-thirds of mossy cell axon collaterals ramify in this region, and the remainder

form synapses in the hilus and the granule cell layer (Buckmaster et al., 1996). The axon terminals in the inner molecular layer form asymmetrical synaptic contacts, primarily with granule cell dendrites. In the hilus, mossy cells form asymmetrical synapses on GABA-positive dendritic shafts and GABA-negative dendritic spines (Wenzel et al., 1997). Mossy cells stain positive for glutamate and negative for GABA, suggesting an excitatory function (Soriano and Frotscher, 1994; Wenzel et al., 1997), but may also contain peptide neurotransmitters (Fredens et al., 1987; Freund et al., 1997).

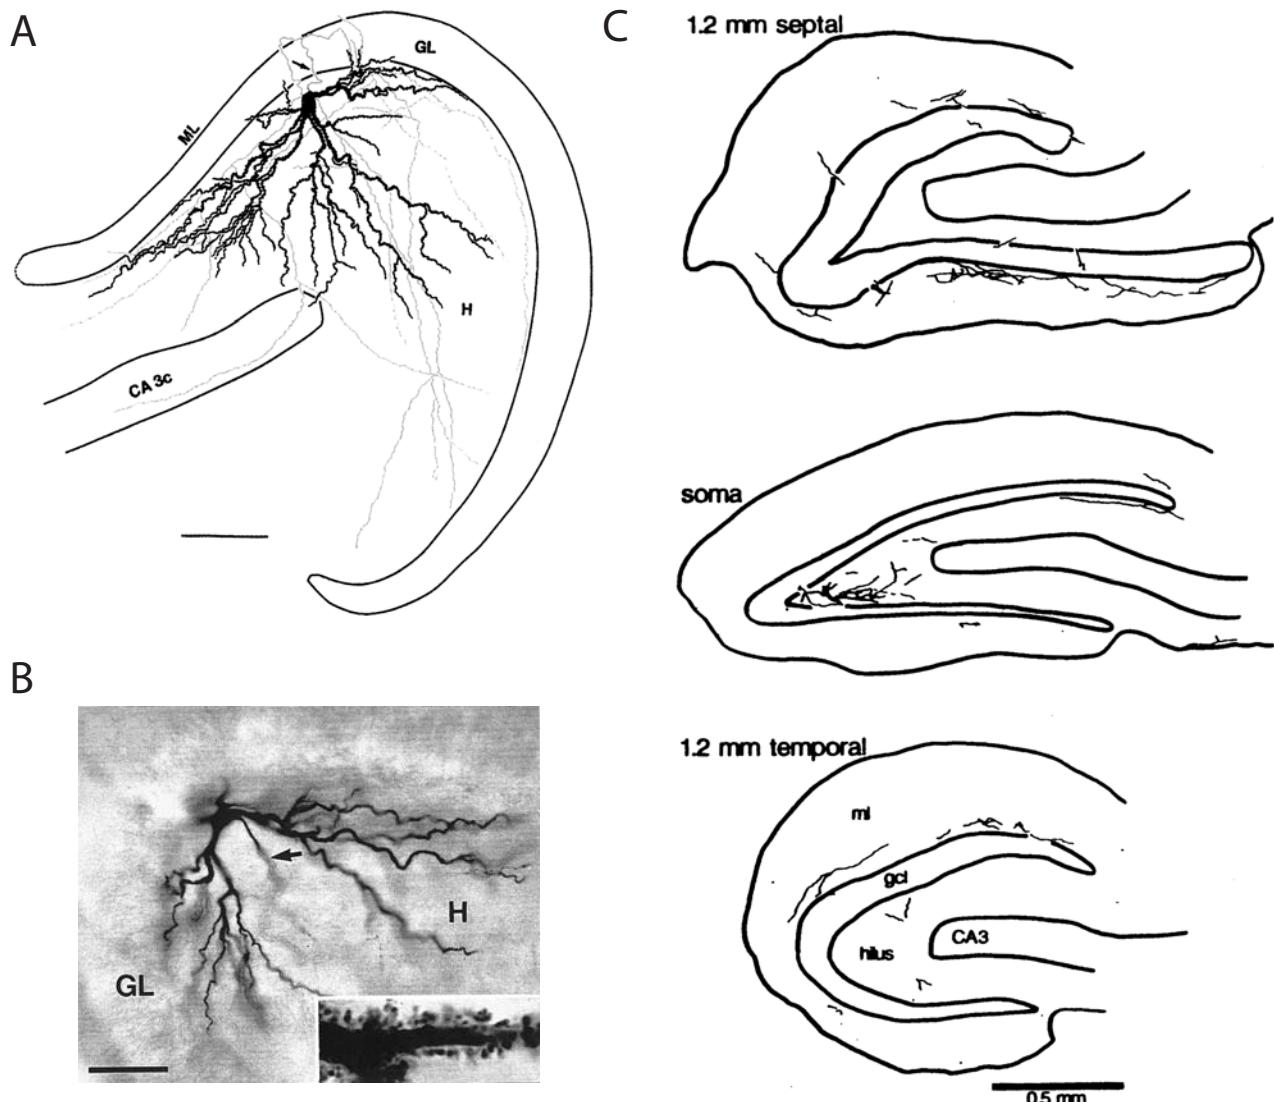

Two particularly important features of the mossy cell axon projection are that it is bilateral and it has an unusually extensive longitudinal component (Soltesz et al., 1993; Buckmaster et al., 1996) (Fig. 5–16C). In fact, each mossy cell forms synaptic contacts spanning more than half the length of the hippocampus, with most of the synaptic contacts formed by distal segments of the axon. These features imply that mossy cells allow granule cell activity to spread longitudinally and bilaterally in the dentate gyrus. Like the recurrent collaterals of the CA3 network, the positive feedback network formed by mossy cells has been suggested to contribute to the ability of the hippocampus to encode memories via an autoassociative network (Buckmaster and Schwartzkroin, 1994).

### 5.6.4 Resting and Active Properties

Mossy cells in vitro have resting potentials of  $-61$  to  $-65$  mV,  $R_N$  of 67 to 200  $\text{M}\Omega$ , and  $\tau_m$  of 16 to 41 ms (Fig. 5–17). These ranges represent the mean values taken from sharp-microelectrode recordings and patch-clamp recordings, respectively (Scharfman and Schwartzkroin, 1988; Buckmaster et al., 1993; Lübke et al., 1998). Mossy cells can fire up to about 50 spikes during a 1-second current injection. Maximum spike rates can be higher, however, as mossy cells can exhibit both bursting and spike-frequency accommodation. These physiological features readily distinguish mossy cells from granule cells or basket cells of the dentate gyrus, but they are not easily distinguished from other neurons in the hilus (Scharfman, 1992; Lübke et al., 1998). Functionally, the most relevant functional features of mossy cells are likely to be their frequent and large EPSPs, which can trigger bursts of action potentials (Scharfman and Schwartzkroin, 1988). This unusual excitability of mossy cells has been proposed to be relevant during normal function and pathology (Sloviter, 1991; Buckmaster and Schwartzkroin, 1994; Ratzliff et al., 2002).

### 5.6.5 Other Spiny Neurons in the Hilus

A population of spiny neurons in the hilus that differs from mossy cells has also been identified. These neurons, fewer in number than mossy cells, are distinguishable by a lack of thorny excrescences and the presence of axon collaterals that extend to the outer molecular layer of the dentate gyrus

**Figure 5-16.** Mossy cell dendritic morphology, spines, and synaptic inputs and outputs. *A*, Camera lucida drawing of a mossy cell with the cell body in the hilus near the granule layer (GL) and dendrites extending farther into the hilus. (A color version of this figure with the axon in red is available online.) Note that axon collaterals are restricted to the hilus and inner molecular layer (ml, near the granule cell layer, gcl). (Source: Adapted from Buckmaster et al., 1996, with permission.)

(Lübke et al., 1998). Although these neurons are spiny, it is not clear if they form excitatory or inhibitory synapses on their targets in the molecular layer. They have higher  $R_N$  than mossy cells (despite similar  $\tau_m$ ), presumably owing to more limited dendritic arborization. They can also fire at higher rates, on average, although the overlap in ranges of these values makes it difficult to distinguish them conclusively from mossy cells or aspiny hilar interneurons on the basis of physiological properties alone (Lübke et al., 1998).

## 5.7 Pyramidal and Nonpyramidal Neurons of Entorhinal Cortex

The entorhinal cortex is the major gateway between the hippocampal formation and the rest of the brain. It receives both intrinsic inputs from the hippocampus (primarily subiculum) and pre/parasubiculum as well as extrinsic inputs from numerous cortical areas. Various neurons in the entorhinal

**Figure 5-17.** Mossy cell passive and active properties. *A*, Voltage responses of a mossy cell (same as Figure 5-16) to step current injections of  $-150$  to  $+150$  pA in 50-pA increments and  $-40$  to  $+40$  pA in 10-pA increments. Input resistance is  $181\text{ M}\Omega$ , and resting potential is  $-64\text{ mV}$ . *B*, Voltage-current relation of the steady-state (●) and peak (+) voltage responses shown in *A*. The line represents an extrapolated linear fit of the points between  $-50$  and  $+50$  pA. (Source: *A, B*: Adapted from Lübke et al., 1998, with permission.)

cortex provide the major input to the dentate gyrus and the hippocampus; they receive input back from the hippocampus and in turn project to other cortical areas, often the same areas that provide input to the entorhinal cortex.

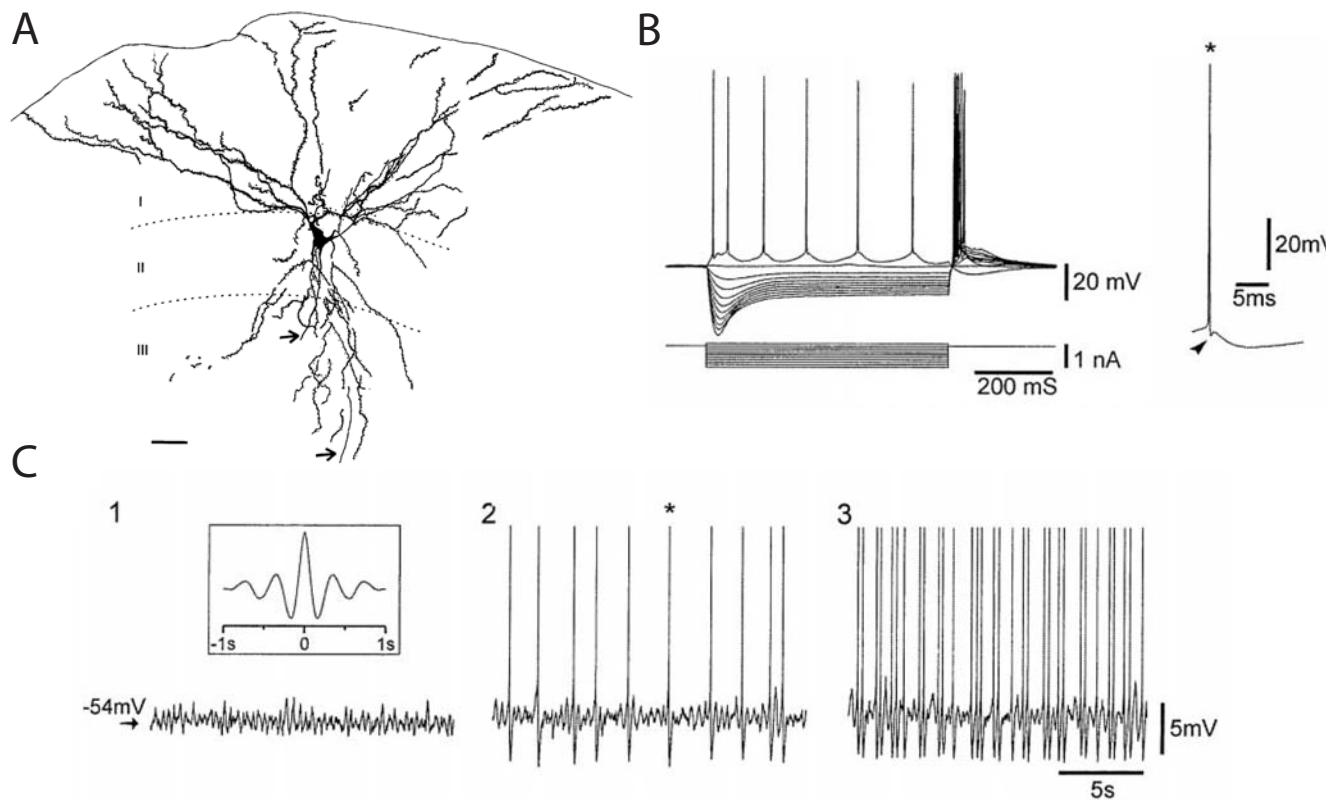

The entorhinal cortex is a conventional six-layered structure comprising several excitatory cell types (Ramon y Cajal, 1904; Schwartz and Coleman, 1981; Carboni et al., 1990; Germroth et al., 1991; Belichenko, 1993; Mikkonen et al., 2000). Neurons in the superficial layers (II/III) receive most of their input from other cortical areas (largely olfactory in the rodent) as well as from presubiculum and parasubiculum. These layer II/III neurons then constitute the principal inputs to the dentate gyrus and hippocampus, and they provide feedback to other cortical areas. Neurons in the deep

layers (IV-VI) receive extensive input from the hippocampus (subiculum) and presubiculum. In addition to projections back to other cortical areas, a projection from the deep layers back to the superficial layers of entorhinal cortex completes the closed-loop structure of the hippocampal formation (Chrobak and Buzsáki, 1994; Chrobak et al., 2000) (see Chapter 3 for more details). Here we consider three cell classes about which detailed physiological and morphological information is available: stellate cells in layer II, pyramidal cells in layers II/III, and pyramidal neurons in layers V/VI.

### 5.7.1 Stellate Cells of Layer II

Stellate cells are the most abundant cell type in layer II and are especially numerous in the medial entorhinal cortex. They derive their name from their star-like appearance, with numerous dendrites radiating out from the soma (Fig. 5-18A). In a typical stellate cell of rat medial entorhinal cortex, about five thick ( $5$ – $6\text{ }\mu\text{m}$  diameter) primary dendrites emerge from the cell body (Klink and Alonso, 1997a). In most cases, one or two of the primary dendrites extend upward toward layer I, and a few primary dendrites extend downward toward layer III. Each of these two groups of dendrites branches extensively, giving rise to bitriangular dendritic arborization. On average, each primary dendrite gives rise to 15 terminal dendrites (Lingenhöhl and Finch, 1991). The upper dendritic tree (layer I) has a mediolateral expanse (up to  $700\text{ }\mu\text{m}$  in the rat) that is greater than that of the lower dendritic tree (layer III) and exceeds that of most pyramidal neurons with apical dendrites in layer I (Klink and Alonso, 1997a). The dendrites of stellate cells are uniformly studded with spines, usually having a long, thin neck and a larger spine head. Dendritic branches often terminate in bouquets of about six dendritic spines (Klink and Alonso, 1997a). The dendritic spines presumably form the sites of contact for the synaptic inputs reaching layers I to III from other cortical areas as well as from the pre/presubiculum.

The stellate cell axon usually emerges from a primary dendrite, close to the soma. The axon descends to the angular bundle, which eventually forms the perforant path. As described in Chapter 3, axons from stellate cells in the lateral entorhinal cortex terminate on the distal third of granule cell dendrites, whereas those from the medial entorhinal cortex terminate on the middle third of granule cell dendrites. Detailed reconstructions have revealed that the axonal arborization from a single layer II stellate cell is extensive, encompassing both the suprapyramidal and infrapyramidal blades of the dentate gyrus and encompassing more than two-thirds of the septo-temporal extent of the dentate gyrus (Tamamaki and Nojyo, 1993; Tamamaki, 1997; see also Paré and Llinás, 1994). The axons of layer II stellate cells also form synapses on CA3 pyramidal neurons. Importantly, many stellate cell axons do not cross the hippocampal fissure; rather, they project along one side of the fissure to CA3 and bend around the fissure toward the dentate gyrus. The presence of varicosities on axons in both CA3 and the dentate gyrus sug-

**Figure 5-18.** Stellate cells of layer II. *A*, Camera lucida drawing of a spiny stellate cell in layer II of entorhinal cortex showing its dendritic tree, which extends into layers I and III, and the axon emerging from the base of the soma (arrows). Bar = 40  $\mu$ m. (*Source:* Adapted from Klink and Alonso, 1997a, with permission.) *B*, Voltage responses to step current injections as shown. Note the prominent sag in hyperpolarizing voltage responses and rebound firing at the offset of the current injection. The single action potential shown on an expanded time scale at the right (from C<sub>2</sub>) shows a

gests that axons from individual stellate cells can project to both areas (Witter, 1989). Axon collaterals also branch and form synaptic connections within the entorhinal cortex (superficial and deep layers) and subiculum (Germroth et al., 1991; Lingenhöhl and Finch, 1991; Tamamaki and Nojyo, 1993; Klink and Alonso, 1997a).

In microelectrode recordings from layer II of rat medial entorhinal cortex, stellate cells have resting potentials of about  $-62$  mV,  $R_N$  of about  $36$  MΩ, and  $\tau_m$  of about  $9$  ms (Klink and Alonso, 1993; see also Jones, 1994). However, stellate cells also exhibit active nonlinearities near the resting potential, including TTX-sensitive amplification of subthreshold depolarizations and ZD-72688-sensitive sag of small hyperpolarizing and depolarizing responses (Fig. 5-18B). These two properties, mediated by voltage-gated  $\text{Na}^+$  channels and  $I_h$  channels, respectively, contribute to pronounced inward rectification (the voltage response to current injection is larger for depolarization than for hyperpolarization) in stellate cells (Klink and Alonso, 1993).

The action potential threshold is about  $-52$  mV and the action potential duration about  $1.2$  ms in stellate cells. The

fast AHP, an ADP, and a medium AHP. (*Source:* Adapted from Dickson et al., 2000a, with permission.) *C*, Membrane potential oscillations (1 and 2) and spike clustering (3) in a layer II stellate cell held at membrane potentials positive to  $-55$  mV. Oscillations in 1–3 are at increasingly depolarized membrane potentials. The autocorrelation (inset in 1) demonstrates the rhythmicity of the subthreshold membrane potential oscillations. (*Source:* Adapted from Dickson et al., 2000a, with permission.)

inward rectification properties of stellate cells contribute to a hump at the onset of depolarizing current pulses. Hence, action potential firing occurs near the beginning of long current injections above threshold.  $I_h$  and  $\text{Na}^+$  current also contribute to a depolarizing hump at the offset of hyperpolarizing current injections, which in some cases produce rebound spike firing (Fig. 5-18B). Action potentials in stellate cells are followed first by a fast AHP of about  $10$  mV, then a depolarizing after-potential of about  $1$  mV, and finally a medium AHP of about  $11$  mV. In response to long current injections stellate cells exhibit strong spike frequency accommodation; and a large, slow AHP occurs following the offset of the current injection (Klink and Alonso, 1993).

One of the most striking physiological features of layer II stellate cells in entorhinal cortex is the theta frequency oscillation that occurs during subthreshold depolarizations (Alonso and Llinás, 1989). These 5- to 15-Hz oscillations begin upon depolarization from rest and reach an amplitude of about  $3$  mV when  $V_m$  is around  $-55$  mV (Fig. 5-18C). Further depolarization results in spike firing in a characteristic cluster pattern, with an interspike frequency of about  $20$  Hz and an

intercluster frequency of 1 to 3 Hz (Alonso and Klink, 1993). Subthreshold theta oscillations in stellate cells are blocked by either TTX or ZD-72688, indicating that they result from interplay between voltage-gated  $\text{Na}^+$  current and  $I_h$  (Klink and Alonso, 1993; Dickson et al., 2000a,b). The  $\text{Na}^+$  dependence of the subthreshold oscillations in layer II stellate cells has prompted careful analysis of the voltage-gated  $\text{Na}^+$  channels in these neurons.  $\text{Na}^+$  currents in neurons dissociated from layer II have almost 10-fold larger  $\text{Na}^+$  conductance than is seen in cells dissociated from layer III (Fan et al., 1994). Furthermore, compared to layer III neurons,  $\text{Na}^+$  currents in layer II activate at lower voltages and inactivate at higher voltages, resulting in a substantial window current, a steady-state current in the voltage range where activation is significant but inactivation is incomplete (Fan et al., 1994). Biophysical analysis has revealed that a high-conductance, persistent  $\text{Na}^+$  current is responsible for most of the window current, which is likely to produce subthreshold oscillations in layer II stellate cells (Magistretti et al., 1999a; Magistretti and Alonso, 1999). These currents are present in the dendrites as well as the soma of layer II neurons (Magistretti et al., 1999b). Although the subthreshold oscillations are blocked by high concentrations of TTX (Klink and Alonso, 1993), the  $\text{Na}^+$  channels thought to mediate the oscillations have been termed “TTX resistant” because of the relatively high concentration of TTX required to block  $\text{Na}^+$  currents in layer II neurons (White et al., 1993).

The membrane properties of layer II stellate cells are also subject to modulation by muscarinic receptor activation (Klink and Alonso, 1997b). Carbachol causes an increase in input resistance and membrane depolarization, which produces subthreshold voltage oscillations at a lower frequency (about 6 Hz) than the depolarization-induced theta oscillations that occur in the absence of the agonist. Because the effects of carbachol are potentiated by  $\text{Ca}^{2+}$  influx, it has been suggested that  $\text{Ca}^{2+}$ -activated, nonspecific-cation conductance may be activated by muscarinic receptor activation (Klink and Alonso, 1997c; Gloveli et al., 1999; Shalinsky et al., 2002).

### 5.7.2 Pyramidal Cells of Layer II

Most of the pyramidal neurons in layer II have their cell bodies in the deepest third of the layer. Their morphology is typical of pyramidal neurons, with a somewhat triangular soma, a thick apical dendrite extending into layer I, and thinner basal dendrites extending into layer III (Fig. 5–19A). Both apical and basal dendrites branch extensively and are studded with spines at even higher density than in layer II stellate cells (Klink and Alonso, 1997a).

The axon of layer II pyramidal neurons emerges from the base of the soma and extends through layers II and III toward the angular bundle. Extensive axon collaterals are also located within entorhinal cortex (Klink and Alonso, 1997a). The axons of layer II pyramidal cells, like those of the stellate cells in the same layer, form the perforant path, which projects to the dentate gyrus and CA3 (Schwartz and Coleman, 1981).

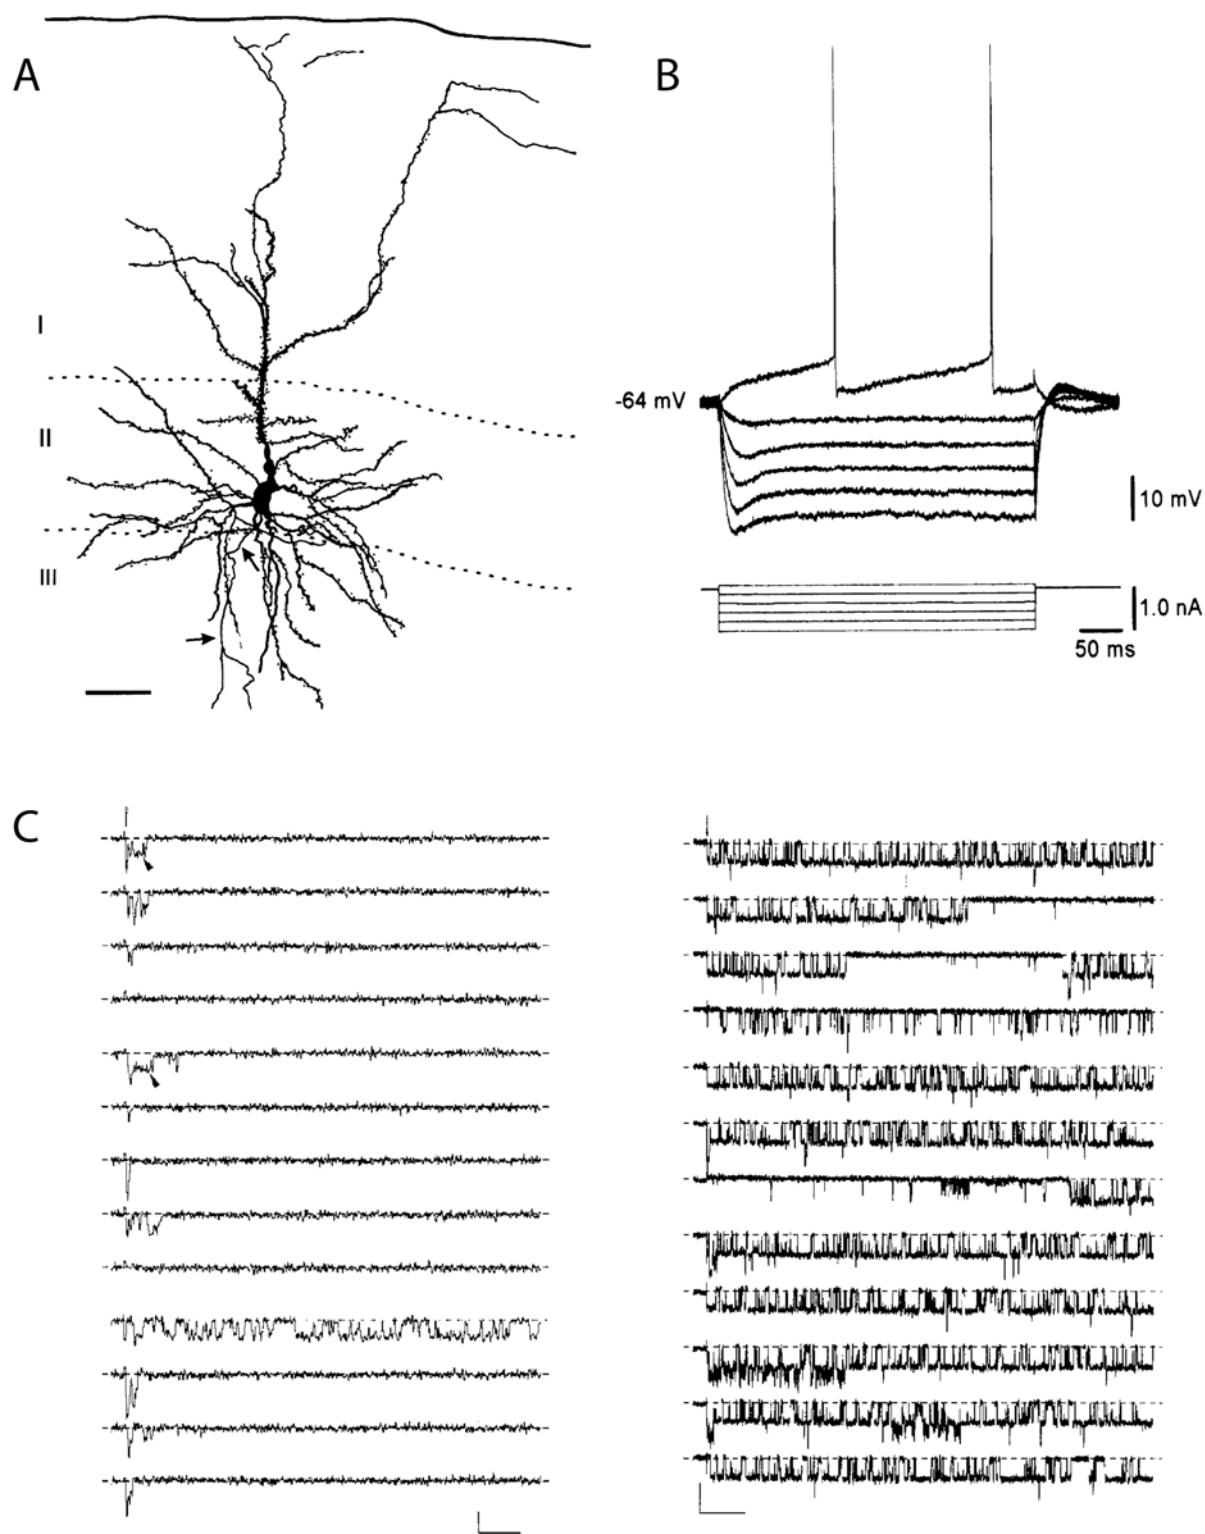

Many of the basic properties of layer II pyramidal neurons are similar to those of their stellate counterparts ( $V_{rest} -64$  mV,  $R_N$  40 M $\Omega$ ,  $\tau_m$  12 ms, threshold -49 mV); both exhibit spike-frequency accommodation and a prominent TTX-resistant, persistent  $\text{Na}^+$  current, which is also present in the dendrites (White et al., 1993; Magistretti et al., 1999) (Fig. 5–19C). However, several physiological properties clearly distinguish pyramidal cells from stellate cells in layer II (Alonso and Klink, 1993). First, the action potential duration is significantly longer in pyramidal cells than in stellate cells (1.8 vs. 1.2 ms at threshold). Second, pyramidal cells exhibit less sag than stellate cells, especially in the depolarizing direction. As a result, layer II pyramidal neurons do not exhibit rebound spike firing, even following large hyperpolarizations; and they exhibit longer latencies to spiking than do stellate cells (Fig. 5–19B). Third, pyramidal cells lack the outward rectification that is prominent in stellate cells in the presence of TTX. Fourth, spike repolarization in pyramidal cells is severely impaired in the absence of  $\text{Ca}^{2+}$  compared to the modest increase in spike duration observed under the same conditions in stellate cells (Alonso and Klink, 1993; Klink and Alonso, 1993). Finally, the membrane potential oscillations generated below threshold and the spike clusters occurring above threshold in stellate cells are absent in layer II pyramidal neurons (Alonso and Klink, 1993). Activation of muscarinic receptors, however, produces depolarization and low-frequency (0.2–0.5 Hz) oscillations of action potential bursting in layer II pyramidal neurons (Klink and Alonso, 1997b).

### 5.7.3 Pyramidal Cells of Layer III

Intracellular recordings followed by biocytin labeling have revealed two types of pyramidal neurons in layer III, each with distinct morphological and physiological properties (Gloveli et al., 1997a; but see Dickson et al., 1997). These two types of pyramidal neuron were distinguished primarily on the basis of dendritic spines, which are present on the dendrites of type 1 but not type 2 layer III pyramidal neurons (Gloveli et al., 1997a). Both types have pyramidal morphology (Fig. 5–20A), but the type 1 (spiny) cells cover broader expanses in both the apical and basal dendritic trees. The apical dendrites of both cell types extend toward the cortical surface, whereas basal dendrites remain largely restricted to layer III (Gloveli et al., 1997a; but see Dickson et al., 1997).

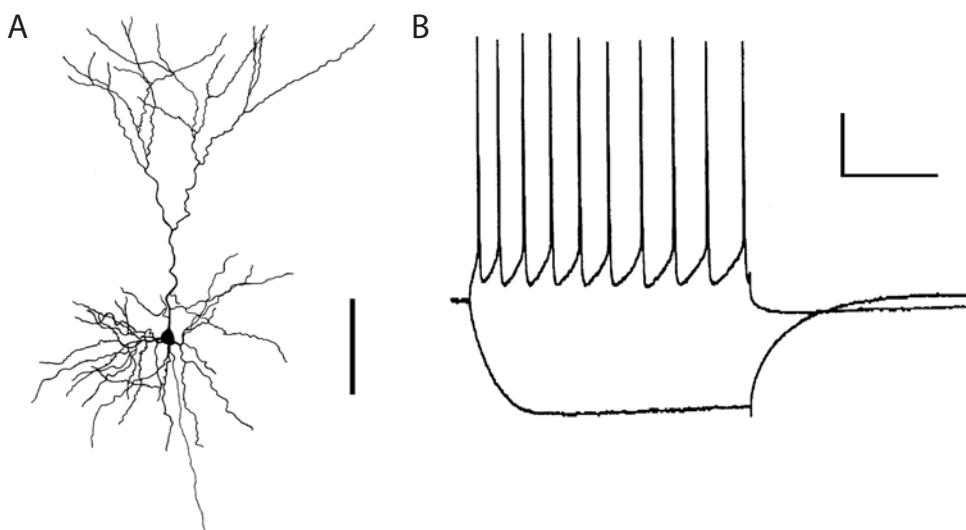

The axons of both types of layer III pyramidal neurons could be traced to the angular bundle, but only the axons of the type 1 (spiny) neurons could be followed to CA1 and the subiculum (Gloveli et al., 1997a). Thus, spiny pyramidal neurons give rise to the perforant-path projection to CA1 (or temporo-ammonic path), but the targets of type 2 (aspiny) neurons are less clear.

Layer III pyramidal neurons are easily distinguished from their layer II counterparts by the absence of sag (Dickson et al., 1997; Gloveli et al., 1997a; van der Linden and Lopes da Silva, 1998) (Fig. 5–20B). Type 1 (spiny) pyramidal neurons of layer III have relatively high  $R_N$  (70 M $\Omega$ ) and long  $\tau_m$  (20 ms),

**Figure 5-19.** Pyramidal cells of layer II. *A*, Camera lucida drawing of a spiny pyramidal neuron in layer II of entorhinal cortex showing its dendritic morphology, which consists of an apical tree extending to the limit of layer I and a basal tree in layers II and III. with permission.) *C*, Voltage-gated  $\text{Na}^+$  channels in the dendrites of layer II stellate cells showing transient (left) and persistent (right) gating. Channel activity was elicited by consecutive depolarizing voltage steps to -30 mV (beginning at arrow) in two cell-attached patches from the dendrites of isolated layer II pyramidal cells. Bars = 2 pA, 5 ms (left); 2 pA, 50 ms (right). (*Source*: Adapted from Magistretti et al. 1999b, with permission.)

**Figure 5-20.** Pyramidal cells of layer III. A. Camera lucida drawing of a pyramidal neuron in layer III of medial entorhinal. Bar = 200  $\mu\text{m}$ . B. Hyperpolarizing and depolarizing voltage responses to current injections of  $-300$  and  $+300$  pA. Bars = 20 mV, 100 ms. (Source: A, B. Adapted from van der Linden and Lopes da Silva, 1998, with permission.)

whereas type 2 (aspiny) pyramidal neurons have lower  $R_N$  ( $30 \text{ M}\Omega$ ) and shorter  $\tau_m$  (8 ms) (Gloveli et al., 1997a; see also Dickson et al., 1997). The resting potentials (about  $-70$  mV) and action potential thresholds (about  $-55$  mV) are similar in the two cell types, but type 2 (aspiny) pyramidal cells showed more spike-frequency accommodation than type 1 (spiny) cells (Gloveli et al., 1997a). An interesting difference between the pyramidal cells of layers II and III is that layer II neurons tend to be activated by synaptic activation at frequencies above 5 Hz, whereas layer III neurons respond best to frequencies below 10 Hz (Gloveli et al., 1997b).

#### 5.7.4 Pyramidal Cells of Deep Layers

Layer III of the entorhinal cortex is separated from the next layer of cells by a cell-free zone called lamina dissecans. In Cajal's nomenclature, this acellular layer is synonymous with layer IV, in which case there are neurons in layers V and VI. In some other studies, however, the acellular layer is considered separately and the cellular layers are divided into layers IV to VI (see Chapter 3). At least two-thirds of the projecting neurons in the deep layers of entorhinal cortex are pyramidal neurons, and the rest are polymorphic or multipolar neurons (Lorente de Nò, 1933; Lingenhöhl and Finch, 1991; Hamam et al., 2000, 2002; Egorov et al., 2002a).

Although the pyramidal neurons and polymorphic neurons comprise heterogeneous groups of neurons, these groups are clearly distinguished by their dendritic architecture. Pyramidal neurons consist of a large apical dendrite extending to layer I or II and multiple basal dendrites with variable distributions, whereas polymorphic neurons consist of numerous dendrites radiating in all directions from the cell body. Pyramidal cells have been further subdivided into small and

large pyramidal neurons. Small pyramidal cells have basal dendrites in layers V and VI, whereas large pyramidal cells have dendrites that extend horizontally within layer V and have therefore been alternately described as horizontal cells (Hamam et al., 2002) (Fig. 5-21A).

In layer V of the lateral entorhinal cortex, both small and large pyramidal neurons have an average of six to seven primary dendrites: one apical dendrite (average diameter 4.2  $\mu\text{m}$  in small and 5.2  $\mu\text{m}$  in large pyramidal cells) and three to eight primary basal dendrites (average diameter 1.7  $\mu\text{m}$  in small and 3.3  $\mu\text{m}$  in large pyramidal cells) for a total dendritic length of about 8 mm. Polymorphic cells also have an average of six to seven primary dendrites with an average diameter of 3.4  $\mu\text{m}$  and a total dendritic length of about 10 mm (Hamam et al., 2002; see also Lingenhöhl and Finch, 1991; Hamam et al., 2000).

Spines are present on the dendrites of all deep-layer pyramidal neurons and polymorphic cells (Lingenhöhl and Finch, 1991; Hamam et al., 2000, 2002). The synaptic inputs to these principal neurons presumably originate from multiple sources, including other cortical areas, presubiculum, parasubiculum, and subiculum (Amaral and Witter, 1989; Lopes da Silva et al., 1990) (see Chapter 3).

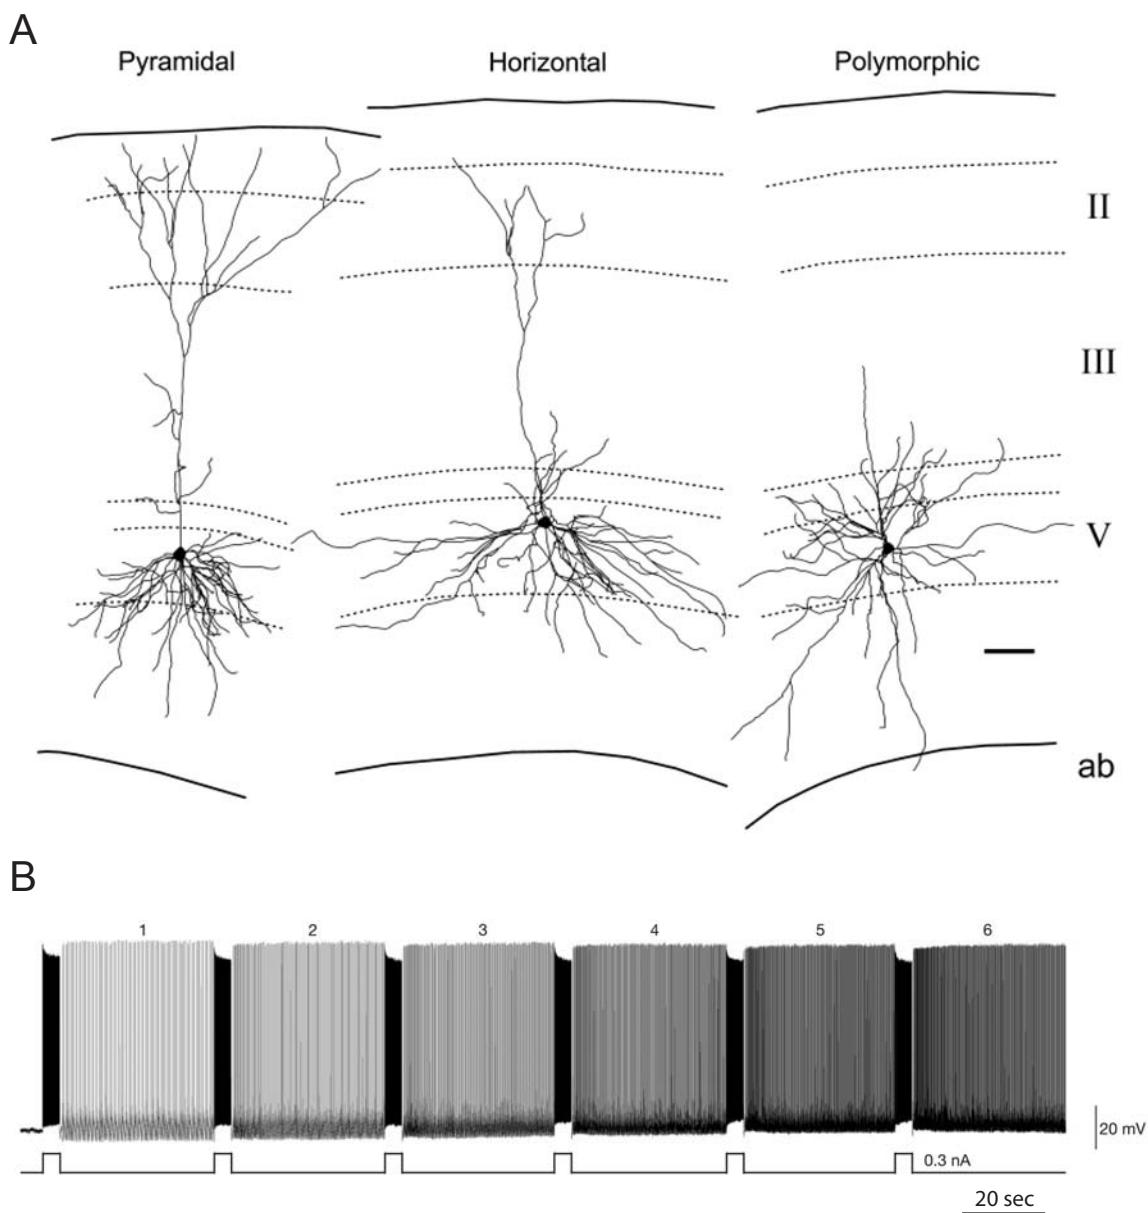

The axons of deep-layer pyramidal and nonpyramidal projecting neurons of entorhinal cortex extend into the angular bundle, from which they project to other cortical areas, including many of the same regions that provide input to the superficial layers of entorhinal cortex (see Chapter 3). There is also considerable evidence, however, that deep-layer neurons project back to the dentate gyrus and hippocampus as part of the perforant path (Swanson and Cowan, 1977; Köhler, 1985; Deller et al., 1996b; Gloveli et al., 2001). In addition to entering the angular bundle, axons of both pyramidal

and nonpyramidal neurons in the deep layers of the entorhinal cortex give off numerous branches, which are abundant in layers V and VI but in some cases also extend into the superficial layers (Gloveli et al. 2001; Hamam et al., 2000, 2002). Collaterals in layers V and VI form part of an associational system, which may contribute to the susceptibility of the entorhinal cortex to epileptic activity (Jones and Heinemann, 1988). Collaterals to the superficial layers complete a closed loop from layers II and III to the hippocampus, to layers V and VI, and back to layers II and III (Chrobak and Buzsáki, 1994; Chrobak et al., 2000).

**Figure 5-21.** Pyramidal cells of layer V–VI. A. Reconstructions of three subtypes of neuron in layer V of lateral entorhinal cortex. Bar = 100  $\mu$ m. (Source: Adapted from Hamam et al., 2002, with permission.) B. Responses of a layer V pyramidal neuron to successive current injections (300 pA, 4 seconds each) in the presence of the

Intracellular microelectrode recordings from deep-layer neurons in entorhinal cortex slices indicate that the basic electrophysiological properties of small pyramidal cells, large pyramidal cells (horizontal cells), and polymorphic cells are heterogeneous but not statistically different among the morphological groups (Hamam et al., 2000, 2002). Average resting potentials were  $-62$  to  $-65$  mV,  $R_N$  values were 50 to 80 M $\Omega$ , and  $\tau_m$  values were 11 to 15 ms. Similar values have been reported in other studies (Jones and Heinemann, 1988; Egorov et al., 2002a). Voltage-current plots revealed inward rectification, in most cases consistent with a time-dependent

muscarinic AChR agonist carbachol (10  $\mu$ M). Note the progressive increase in persistent action potential firing that continues after each current injection is terminated. Each depolarizing current step is 4 seconds in duration. (Source: Adapted from Egorov et al., 2002b, with permission.)

voltage sag, presumably due to activation of  $I_h$  (Hamam et al., 2000, 2002). In pyramidal neurons, sag was much smaller than reported for layer II stellate cells (Klink and Alonso, 1993), and one study reports that sag is absent from nonpyramidal neurons in the deep layers of the entorhinal cortex (Egorov et al., 2002a). Action potentials were about 65 mV in amplitude (threshold to peak) followed by an AHP of about 17 mV. Polymorphic neurons exhibit a voltage-dependent delay to spike firing, which is mediated by a D-type  $K^+$  current (Egorov et al., 2002a). Repetitive firing was largely regular spiking with some spike-frequency accommodation, but burst firing was not observed (Hamam et al., 2000, 2002; Egorov et al., 2002a; but see Jones and Heinemann, 1988).

Another important characteristic of pyramidal neurons in the deep layers of the entorhinal cortex is that most exhibit membrane-potential oscillations in the theta range when held just below threshold for action potential firing (Dickson et al., 2000b). These oscillations have amplitudes of 2 to 7 mV and frequencies of 5 to 15 Hz (Dickson et al., 2000b; Hamam et al., 2000, 2002). Like the prominent oscillations in stellate cells of layer II, the oscillations in layer V neurons are TTX-sensitive and therefore require voltage-gated  $Na^+$  current. An important difference, however, is that the oscillations in layer V do not seem to require  $I_h$ , as pyramidal cells lacking voltage sag still exhibit prominent theta oscillations (Dickson et al., 2000b). The relation between intracellular theta oscillations and the network theta, gamma, and ripple (sharp-wave) oscillations observed in the entorhinal cortex during various behavioral states remains unclear (Chrobak and Buzsáki, 1994, 1996; Buzsáki, 1996).

Perhaps the most intriguing property of layer V pyramidal cells in the entorhinal cortex is their ability to integrate neural activity over long periods of time. During activation of muscarinic acetylcholine receptors, stimuli lasting a few seconds can lead to sustained action potential firing for several minutes (Egorov et al., 2002b). Furthermore, repeated stimulation during cholinergic activation leads to sustained firing at higher frequencies (Fig. 5–21B). This unique form of neural integration, which is mediated by a calcium-activated, non-specific cation current, has been proposed to contribute to the function of the entorhinal cortex in working and long-term memory (Egorov et al., 2002b).

## 5.8 Pyramidal and Nonpyramidal Neurons of Presubiculum and Parasubiculum

The presubiculum and parasubiculum are considered separately from the subiculum for two important reasons. First, these regions are distinct from the subiculum in that they are multilaminar (Fig. 5–22A). The parasubiculum has a conventional six-layered cortical structure. Presubiculum has also been described as a six-layered cortex, but the layers are not as well defined, so it may be more appropriately considered an

anatomical transition zone between the three-layered hippocampus and the six-layered parasubiculum. The second reason for considering the pre- and parasubiculum separately from the subiculum is that these regions have distinctly different physiological properties (see below).

The major projection from the presubiculum is to layer III of the medial entorhinal cortex, whereas the major projection from the parasubiculum is to layer II of the medial and lateral entorhinal cortex. Both pre- and parasubiculum also project weakly back to the stratum lacunosum-moleculare of the hippocampus and to the superficial molecular layer of the dentate gyrus. Both regions also have numerous other cortical and subcortical inputs and outputs (see Chapter 3).

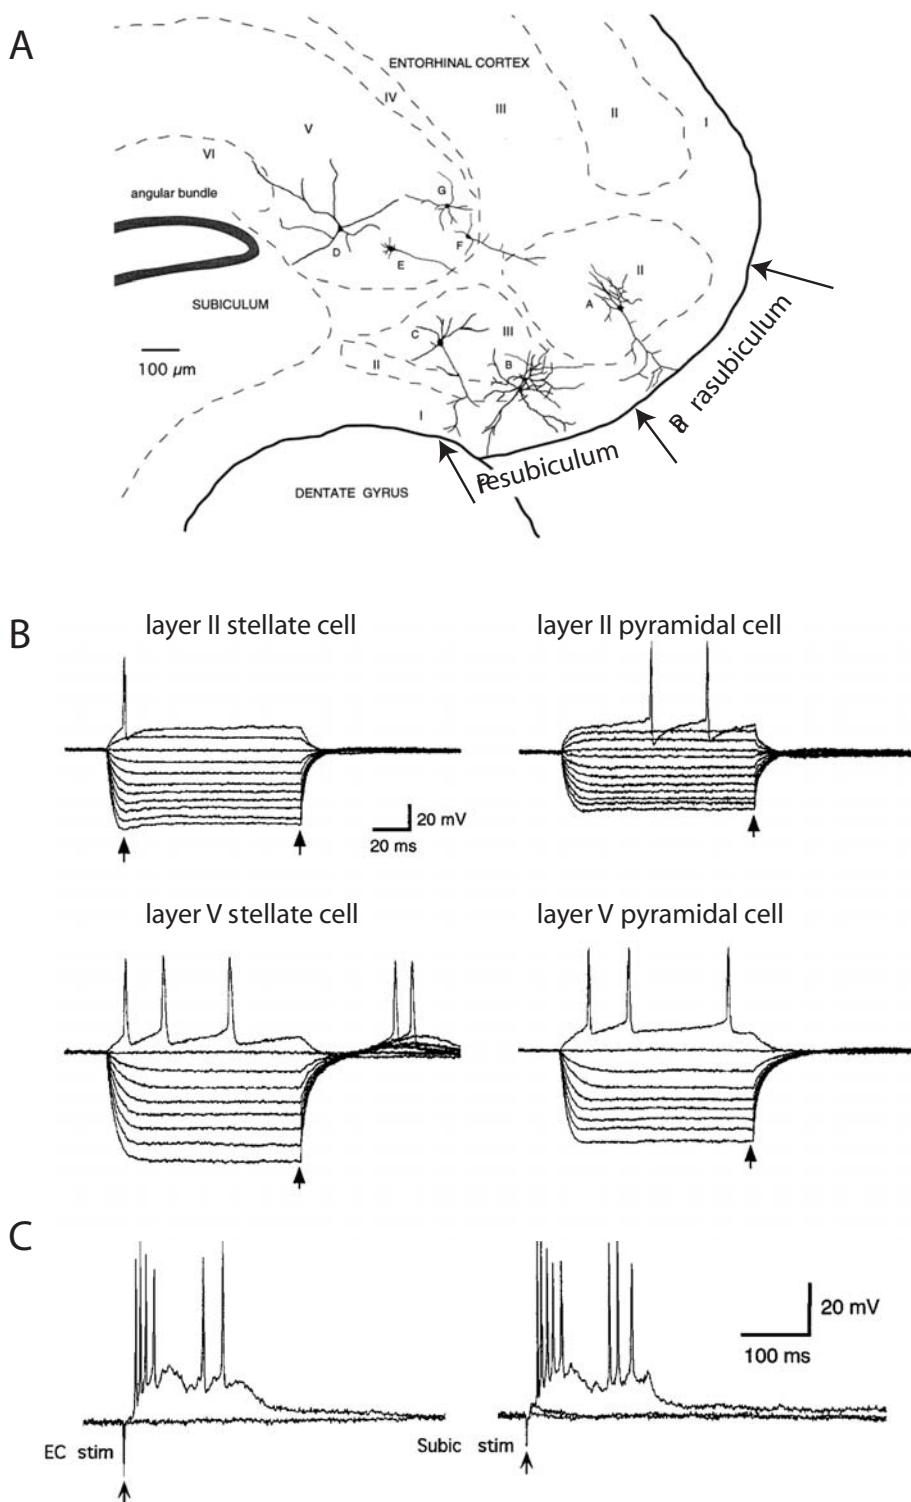

Microelectrode recordings have been used to study the electrophysiological properties of neurons in the pre- and parasubiculum (Funahashi and Stewart, 1997a). Despite the fact that pyramidal and nonpyramidal (stellate) neurons are present in all layers of the cortex, the basic resting and active properties of neurons in the pre- and parasubiculum are remarkably homogeneous, with resting potentials in the range of  $-60$  to  $-68$  mV,  $R_N$  of 42 to 84 M $\Omega$ , and  $\tau_m$  of 8 to 12 ms. A modest degree of membrane sag was observed in superficial neurons, while sag was absent in deep-layer pyramidal and stellate neurons (Fig. 5–22B). In this respect, the properties of these neurons are functionally quite distinct from their neighbors in the subiculum and entorhinal cortex.

Another major difference between neurons in the pre- and parasubiculum and the subiculum is the absence of intrinsic burst firing. In response to depolarizing current injection, neurons in these regions were found to fire only regular trains of action potentials (Funahashi and Stewart, 1997a). Despite the absence of intrinsic burst firing, neurons in the deep layers of the pre- and parasubiculum exhibit synaptically driven burst discharges (Fig. 5–22C). In response to brief stimulation of either the subiculum or the deep medial entorhinal cortex, deep-layer neurons in the pre- and parasubiculum depolarize and fire for hundreds of milliseconds (Funahashi and Stewart, 1997b). These bursts are driven by giant, glutamatergic EPSPs and may be sustained by reciprocal connections with intrinsically bursting neurons in the subiculum (Funahashi et al., 1999). Neurons in the superficial layers of the pre- and parasubiculum respond to synaptic stimulation of the subiculum or entorhinal cortex with EPSPs and can produce synaptically driven bursts. The superficial neurons send axon collaterals to the deep layers of the pre- and parasubiculum, but reciprocal connections are absent (Funahashi and Stewart, 1997b).

## 5.9 Local Circuit Inhibitory Interneurons

Whereas most principal (i.e., glutamatergic) cell types of the hippocampus have their cell bodies organized into highly structured lamina (e.g., CA3/CA1 stratum pyramidale), the somata of local circuit GABAergic inhibitory interneurons

show no such apparent organization. In fact, the somata of this highly diverse population of neurons are scattered throughout almost all subfields and strata of the hippocampus (Fig. 5–23). Moreover, despite representing only ~10% of the total hippocampal neuronal population, inhibitory interneurons represent perhaps one of the most diverse cell populations, a claim based not only on their highly divergent anatomical properties but also on their functional properties.

The axons of this diverse cell population make mainly short-range projections and release the inhibitory neurotransmitter GABA onto their targets. Consequently, hippocampal

inhibitory interneurons have traditionally been considered as little more than the regulators of principal neuron activity—the yin to the excitatory yang. Evidence suggests, however, that in addition to that role their network connectivity and properties of intrinsic voltage-gated currents are finely tuned to permit inhibitory interneurons to generate and control the rhythmic output of large populations of principal cells and other populations of inhibitory interneurons. The axons of these cells are often targeted to specific dendritic domains of pyramidal neurons as well as to other inhibitory interneuron types; this has led to the suggestion that specific interneuron

**Figure 5–23.** Inhibitory interneuron diversity. A. Composite drawing of characteristic hippocampal and dentate gyrus inhibitory interneuron types assembled from reconstructions of *in vivo* (5, 10–13) or *in vitro* (1–3, 6–9) intracellularly labeled or immunostained (4, 14, 15) neurons in the rat (1–5, 10–15) and guinea pig (6–9). Thick lines represent the dendritic trees; thin lines are the axons. B. Summary diagram shows the laminar distribution of dendritic and axonal arborizations of various types of calcium-binding protein- and neuropeptide-containing interneurons in the hip-

pocampus. Filled circles mark the general cell body location of each interneuron type that gives rise to thick horizontal and/or vertical lines, indicating the predominant orientation and laminar distribution of the dendritic tree. Boxes represent the laminae, where the axon of each interneuron type typically arborizes. Shaded boxes indicate that other interneurons, rather than principal cells, are the primary targets. The transverse extent of the dendrites or axon is not indicated. (Source: Modified from Freund and Buzsáki, 1996; from McBain and Fisahn, 2001.)

types are “tailor-made” to play fundamental roles in controlling the generation of  $\text{Na}^+$ - and  $\text{Ca}^+$ -mediated action potentials, the regulation of synaptic transmission and plasticity, and the generation and pacing of large-scale synchronous oscillatory activity.

### 5.9.1 Understanding Interneuron Diversity

By definition, all local circuit inhibitory interneurons synthesize and release GABA as their primary neurotransmitter. Anatomically, however, interneurons represent one of the most diverse populations in the mammalian CNS. To understand anything of inhibitory interneuron function one must first consider the diversity of the population and the efforts made by numerous anatomical and physiological investigators alike to break this population down into subpopulations based on anatomical, neurochemical, or functional properties. A major problem that has invariably plagued any study of interneuron function, however, has been the inability to classify interneurons neatly into functional or anatomical subpopulations. Even within a single region of the hippocampus, classifying interneurons is difficult and leads to different numbers of types depending on the classification scheme chosen. Because of this problem, we have chosen not to organize the discussion of hippocampal interneurons around an arbitrary classification scheme. Rather, this section is organized around a variety of commonly accepted features observed in interneurons. Such features can include anatomical, neurochemical, or functional commonalities that at the most elementary level allow identification of themes across neurons in different regions of the hippocampal formation. Ultimately, however, when such features are cross-referenced, such rigid classification schemes tend to break down and can often prove unhelpful, as is discussed below. Although we have chosen this approach, a detailed understanding of hippocampal function eventually requires that models be developed for several classes of interneurons, and different models may require different classification schemes. Thus, some discussion of the numerous attempts to classify these neurons into distinct subpopulations is warranted.

Historically, initial attempts to classify interneurons primarily used two approaches: classification based on anatomy or based on neurochemical markers (for review see Freund and Buzsáki, 1996). Classifications based solely on anatomy (Table 5–1) tell us little about interneuron function, but the recent mapping of axonal arbors to specific domains across the dendritic trees of their targets and the position of dendrites in specific hippocampal subfields have provided important clues to specific functional roles played by various interneuron subtypes (Fig. 5–23). For example, interneurons with axons that innervate either pyramidal cell somata or axon initial segments (basket cells, chandelier cells, axo-axonic cells) almost certainly regulate the local generation of  $\text{Na}^+$ -dependent action potentials. In contrast, inhibition arriving at dendritic locations likely has little direct influence over somatic action potential generation but may strongly influence local dendritic integra-

tion, shunt excitatory inputs on their way to the soma, or regulate dendritic spike initiation and/or propagation. Each of these interneuron types exhibits both differences and similarities in their physiological properties. Even within a single layer of the hippocampus, interneurons with unique axon targeting and physiological properties can be identified (Fig. 5–24).

Perhaps one of the most useful characterizations of interneuron subtypes has been based on neurochemical content (Table 5–2). Although the precise physiological roles played by this wide repertoire of peptide transmitters and  $\text{Ca}^{2+}$ -binding proteins contained in specific inhibitory interneuron subpopulations is largely unclear, their role in aiding anatomical and functional characterization of interneurons cannot be overemphasized. Much of our current understanding of interneuron anatomy has its origins in studies utilizing antibodies raised against these markers. Neurochemically identical cells can, however, have surprisingly different functional properties, somewhat undermining this attempt to provide convenient interneuron subdivisions. For example, “fast-spiking” parvalbumin (PV)-containing interneurons were once considered to comprise only basket and axo-axonic cells types, but this interneuron class has

**Figure 5-24.** Differential axon targeting of various inhibitory interneurons. Three types of interneuron are shown, each with a cell body and dendrites in the stratum oriens of CA1 but having distinct axonal projection patterns and physiological properties. *A*, An O-LM cell targets the distal dendrites of CA1 pyramidal cells (*A*<sub>1</sub>). Upon injection of a depolarizing current pulse, O-LM interneurons exhibit an accommodating train of action potentials followed by a slow AHP. A prominent sag indicative of  $I_h$  is present upon hyperpolarization (*A*<sub>2</sub>). *B*, Interneuron type exhibiting a diffuse axonal arborization pattern suggestive of a septally projecting interneuron. These interneurons are typically somatostatin

immunoreactive and target other interneurons (*B*<sub>1</sub>) (Gulyás et al., 2003). In contrast to O-LM cells, this cell rapidly accommodated upon depolarization, firing only a single spike (*B*<sub>2</sub>). Furthermore, upon repolarization, the cell fired a spike with a slow component suggestive of a T-type  $\text{Ca}^{2+}$  current. *C*, Stratum oriens interneuron type targeting the proximal dendritic trees of CA1 pyramidal cells (*C*<sub>1</sub>). Also in contrast to O-LM interneurons, this cell exhibited a reduced fast AHP following each spike and a spike with a pronounced  $\text{Ca}^{2+}$  component upon repolarization (*C*<sub>2</sub>). (Source: Lawrence and McBain, unpublished.)

recently seen new additions (Maccaferri et al., 2000). Interneurons with cell bodies in the stratum oriens and axons in the stratum lacunosum-moleculare (O-LM cells) or in both stratum radiatum and stratum oriens (bistratified cells) also contain PV. Given the dendritic location of their axonal targeting, it is highly unlikely that the latter cell types perform roles similar to those of the basket or axoaxonic cells. Similar additions to the somatostatin- and cholecystokinin (CCK)-containing families have also been described, further complicating classification systems based solely on neurochemical content (Oliva et al., 2000; Cope et al., 2002). Although these two methods of classification (morphology and neurochemistry) may be considered separately, substantial effort has been made to relate the two criteria. For example, neurons express-

ing distinct neurochemical markers have been found to also have different dendritic morphology (Gulyás et al., 1999) (Fig. 5-25).

Characterization based on function has proven even more problematic. The classic subdivisions were originally based solely on action potential firing patterns (e.g., fast-spiking versus regular spiking). However, action potential generation results from the combined activity of numerous voltage-gated channels, with each channel type potentially having a unique expression pattern throughout the interneuron subpopulations that imparts subtle characteristics to action potential firing. Therefore, although this classification has been historically useful, it has only limited value given the ever-expanding repertoire of voltage-gated channels being identi-

fied on inhibitory neurons. Subdivisions of interneurons based on responses to neuromodulators, properties of intrinsic currents and conductances, or expression of ligand-gated channels have all had limited success. Comparisons across these groups, however, have underscored problems with such classification systems and have threatened the very notion of homogeneous interneuron subpopulations. In fact, interneurons are excited or inhibited by a bewildering number of combinations of modulators; and when these properties are mapped onto their respective anatomical properties, a staggering number of subpopulations may exist (Parra et al., 1998).

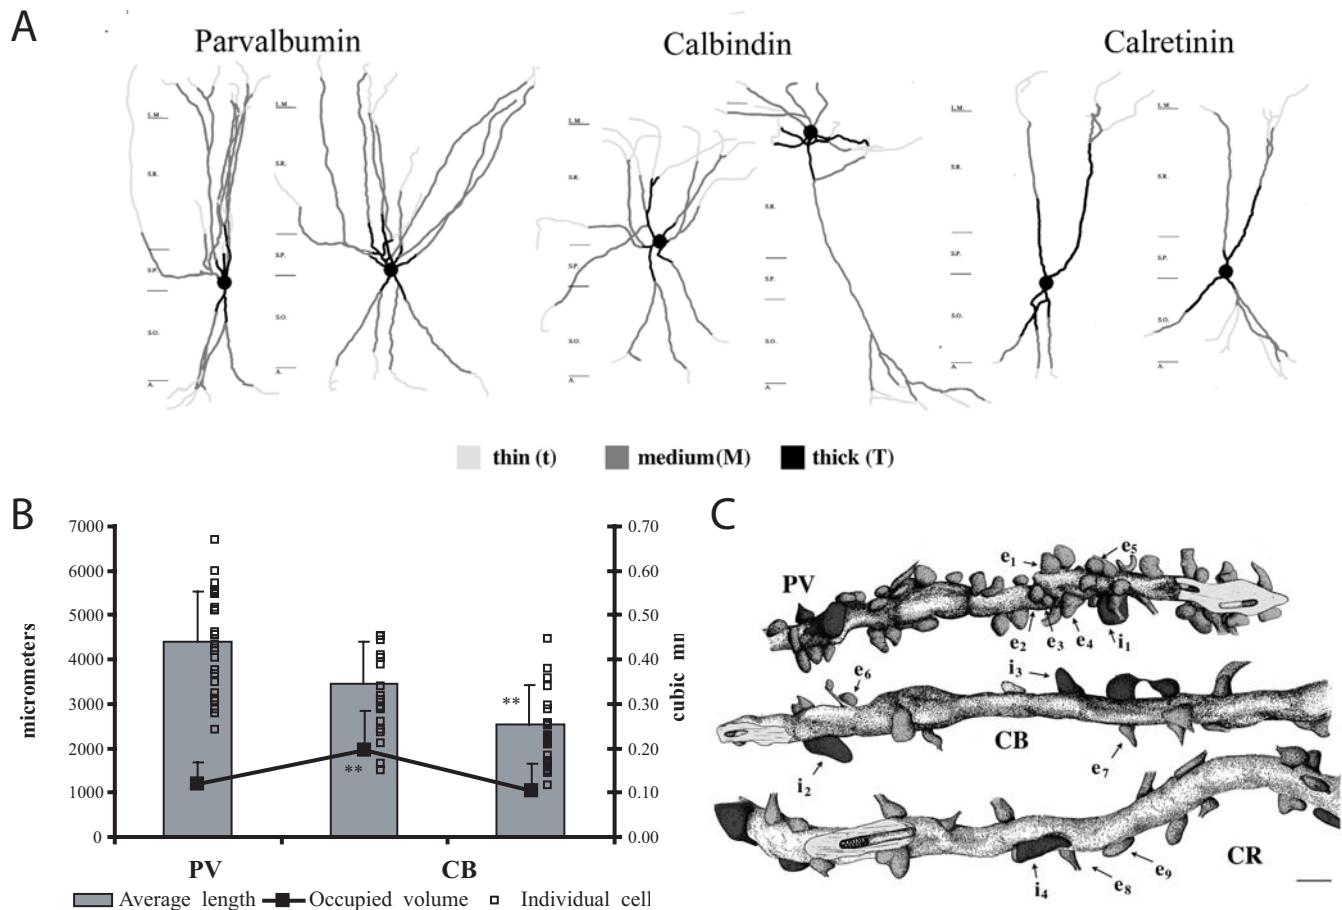

Classifications based on the nature of excitatory synaptic transmission have become increasingly common. In hippocampal circuits, repetitive activation of glutamatergic afferents progressively increases (augmentation/facilitation) or decreases (depression) the amplitudes of excitatory synaptic events. The list of synapses that demonstrate facilitation or depression has become increasingly lengthy over the last few years primarily from studies involving connected pairs of neurons. One of the best examples of this characterization comes from studying CA1 pyramidal cell-mediated feedback excitation of interneurons in the stratum oriens (Pouille and

Scanziani, 2004). In this study, two groups of interneurons were identified: one whose probability of firing was highest at the onset of a series of presynaptic stimuli and then fell rapidly with subsequent stimuli (“onset transient interneurons”) and a second where the probability of spike generation was lowest after the first stimuli but increased to a plateau in response to later events in the stimulus train (“late-persistent interneurons”). Of particular interest, the axons of onset transient interneurons were largely distributed around the somata of pyramidal cells (suggestive of basket, axo-axonic, or bistratified cells), whereas the axons of “late-persistent interneurons” largely innervated the stratum radiatum-lacunosum moleculare (indicative of dendrite-targeting O-LM interneurons). This anatomical and functional characterization suggests that two distinct inhibitory interneuron subclasses can be sequentially recruited to produce inhibition that first targets the soma of pyramidal cells followed by inhibition targeted to pyramidal cell dendrites.

This study, together with numerous others (Maccaferri et al., 1998; Markram et al., 1998; Scanziani et al., 1998), highlights an important feature of this type of classification scheme—that single axons may transmit information in a target-specific manner. This target specificity of transmission can be governed by both the transmitter release mechanisms of individual presynaptic boutons and the type of ionotropic or metabotropic receptors present at the postsynaptic face. In addition, this can be further complicated by the observation that whether a particular synapse demonstrates short-term depression or facilitation may be developmentally regulated (for further discussion see McBain and Fisahn, 2001; Maccaferri and Lacaille, 2003).

### 5.9.2 Dendritic Morphology

Despite representing only ~10% of the total hippocampal neuron population, inhibitory interneurons have highly variable morphologies even within distinct subpopulations (Figs. 5–23 to 5–25). For example, cells of a given neurochemical subclass can have dendrites that are organized in a widely heterogeneous orientation. Despite this marked heterogeneity, however, a few cell types are highly recognizable based on their cell morphology. A good example of this is the O-LM cell, which typically has its soma and dendrites oriented parallel to the pyramidal cell layer in the stratum oriens-alveus. The O-LM cell typically projects its main axon across the stratum pyramidale to ramify predominantly in the stratum lacunosum-moleculare, with few collaterals projecting back to the stratum oriens-alveus. This cell belongs to the subpopulation of somatostatin-containing interneurons; but other than this neurochemical feature, it has little in common with other somatostatin-containing interneurons. As discussed above, this presents a problem when attempting to define the basic anatomical features of inhibitory interneurons. Consequently, we describe in detail only those interneuron subpopulations whose anatomical features have been subject to rigorous morphometric analysis.

**Figure 5-25.** Inhibitory interneuron neurochemistry and dendritic morphology. *A*. Reconstructed dendritic trees of parvalbumin (PV)-, calbindin (CB)-, and calretinin (CR)-containing interneurons from the CA1 region of the rat hippocampus. Two examples of each cell type are shown, illustrating the characteristics of the branching patterns. The different types of dendritic segments separated on the basis of their diameter are indicated with different levels of gray. Note the variance in the total length of the dendrites of individual cells within a given group and the differential distribution of dendrites in distinct layers for the three cell populations. *B*. Parvalbumin cells have the largest dendritic tree and calretinin the smallest. The horizontal extent of the dendritic tree was widest for calbindin cells and is reflected in the largest occupied volume obtained for this class of cells. *C*. Distribution of excitatory and

inhibitory inputs on medium-diameter dendrites of PV-, CB-, and CR-containing interneurons in CA1 stratum radiatum. The dendrites and synapses were reconstructed from serial ultrathin sections immunostained for GABA. A large difference can be seen in the absolute and relative numbers of excitatory and inhibitory synapses terminating on the three types of dendrite. The surface of the PV-positive dendrite is densely covered by synapses, in contrast to the sparse innervation of CB- and CR-positive dendrites. On the other hand, the proportion of inhibitory terminals compared to all synaptic inputs is lowest on the PV and highest on the CB dendrites. Excitatory terminals are colored light gray (e.g., e<sub>1</sub>-e<sub>9</sub>), GABAergic boutons are dark (e.g., i<sub>1</sub>-i<sub>4</sub>). Note the large variance in the size of the axon terminals. (Source: Data are from Gulyás et al., 1999.)

Arguably the largest of all the inhibitory interneuron subpopulations, the PV-containing, fast-spiking basket cells are found throughout the hippocampal formation (Fig. 5-25). Their cell bodies in general are restricted to the stratum pyramidale, and its border with both the stratum oriens and stratum radiatum. Occasionally, however, PV-containing interneuron cell bodies are found in the stratum radiatum. Among interneurons, PV-containing cells have the most elaborate dendrites, which on average measure > 4 mm in their full extent (Gulyás et al., 1999). The surface area of PV-containing interneuron somata has been estimated at ~1000  $\mu\text{m}^2$ . PV-containing interneurons have two to six (mean 5.5) pri-

mary dendrites that arise from the somata and run radially into the stratum oriens or through the stratum radiatum into the stratum lacunosum-moleculare making infrequent branches. Although PV-containing interneurons have the largest dendritic tree of all interneuron types, these cells demonstrate large variation in individual cell size, with a more than twofold variation in the range of dendritic length being reported (Gulyás et al., 1999). The distribution of dendrites among layers suggests that these cells are likely to collect most of their inputs in the strata radiatum and oriens and only a smaller portion in the strata lacunosum-moleculare and pyramidale (Gulyás et al., 1999).

The cross-sectional diameters of PV-containing interneuron dendrites are highly variable (0.3–2.7  $\mu\text{m}$ ) but are, in general, among the thickest of all interneuron classes studied to date. The thickest dendrites typically arise from the somata and then taper rapidly after the first branch point. Apical dendrites have about eight branch points, whereas basilar dendrites have about five. The number of terminal branches is also highly variable but is, on average, ten and seven for apical and basilar dendrites, respectively. Although PV-containing interneurons can be subclassified into several functionally distinct subgroups (i.e., basket and axo-axonic cells), there appears to be little anatomical difference between the measured somata and dendrites of these two subclasses.

Similar morphological estimates have been derived from physiologically characterized fast-spiking basket cells of the CA1 stratum pyramidale, which presumably represent either PV- or CCK-containing interneurons, although their neurochemical content was not determined (Thurbon et al., 1994). The mean total dendritic surface area of fast-spiking interneurons was estimated at  $\sim 5000 \mu\text{m}^2$  and  $\sim 2000 \mu\text{m}^2$  for apical and basilar dendrites, respectively. Thus, the total surface area of a CA1 fast-spiking basket cell is close to 7000 to 10,000  $\mu\text{m}^2$ . By comparison the total surface area of CA1 pyramidal neurons has been estimated at around 24,400  $\mu\text{m}^2$  (Turner, 1984).

Calbindin (CB)-containing nonpyramidal neurons (some CA1 pyramidal neurons have high CB content) have the highest density within the stratum radiatum, with the greatest numbers of cells located at the border with the stratum lacunosum-moleculare. Smaller numbers of CB-containing interneurons are found in the strata oriens and pyramidale, with few cell bodies located in the stratum lacunosum-moleculare (Freund and Buzsáki, 1996). Two types of CB-containing interneuron can be distinguished based on morphology (Gulyás et al., 1999) (Fig. 5–25). The so-called type I cells are most numerous in the stratum radiatum, with lower numbers in the strata pyramidale and oriens. These cells have highly variable morphologies and are typically multipolar or bitufted with three to six primary dendrites (mean of four) running in all directions, often descending to the stratum oriens but only rarely entering the stratum lacunosum-moleculare. Their calculated somatic surface area is  $\sim 800 \mu\text{m}^2$ . The primary dendrites arising from the soma are thick and branch within 50 to 100  $\mu\text{m}$  of the soma. The lengths of the dendrites of these cells are highly variable but, on average, they are in excess of 3000  $\mu\text{m}$  (mean 3441  $\mu\text{m}$ ), with  $\sim 75\%$  of the entire dendritic tree located in the stratum radiatum. Generally the dendritic diameter of CB-containing interneurons is small, ranging from 0.2 to 1.8  $\mu\text{m}$ .

Type II CB-containing interneurons represent a special class of inhibitory interneurons; they are atypical because they project out of the hippocampus to the medial septum (i.e., axons are long-ranging and not “local circuit”) (see Chapter 3). These cells, typically found in the stratum oriens, have large, fusiform cell bodies and several long horizontally oriented dendrites. Accurate morphometric analysis of this cell type has not been reported (Gulyás et al., 2003).

Similar to CB-containing interneurons, calretinin (CR)-containing interneurons can be subdivided into at least two classes based on morphology: a spiny type and a spine-free type (Fig. 5–25). In the CA1 subfield only spine-free CR-containing interneurons are found, whereas both classes are found in CA3, with spiny CR-containing interneurons being highly enriched in the stratum lucidum, suggesting they receive innervation primarily from mossy fiber axons of dentate gyrus granule cells (Gulyás et al., 1992). In the CA1 subfield, spine-free CR-containing interneurons are found throughout all layers, from the alveus to the hippocampal fissure. The cell bodies of this class of interneurons have surface areas about one-half that of PV-containing interneurons, with a mean surface area calculated at  $\sim 500 \mu\text{m}^2$ . The dendrites of CR-containing interneurons arise from highly diverse multipolar, bipolar, or fusiform cell bodies and primarily run radially, traversing several layers. Of particular interest, dendrites of CR-containing cells often form extensive dendrodendritic contacts with neighboring cells (Gulyás et al., 1999).

CR-containing interneurons have a comparatively small total dendritic length (mean  $\sim 2500 \mu\text{m}$ ) and so are significantly smaller than both PV- and CB-containing interneurons. Unlike PV- and CB-containing interneurons, CR-containing interneurons have rather homogeneous features, with few primary dendrites (mean of three) that ascend or descend radially to invade all layers of the CA1 subfield. The diameters of CR-containing interneurons are approximately the same as those of CB-containing interneurons, with the surface of the thickest dendritic branches often being beaded.

Spiny CR-containing interneurons are present largely in the hilus of the dentate gyrus and the CA3 stratum lucidum (i.e., areas where mossy fiber axons of dentate gyrus granule cells are at their highest density). The dendrites of this cell class often bear numerous long protrusions that penetrate bundles of mossy fibers (Freund and Buzsáki, 1996). In the dentate gyrus, their dendrites are restricted to the hilus, never entering the granule cell layer. In CA3 stratum lucidum the dendrites run parallel with the pyramidal cell layer and typically do not penetrate the stratum pyramidale or stratum radiatum. Detailed morphometric analysis of this cell type has not been performed.

### 5.9.3 Dendritic Spines

The conspicuous absence of dendritic spines on most interneuron types undoubtedly has a major impact on their computational properties, in particular synapse specificity and intracellular calcium handling. Some well characterized interneurons are, however, covered densely by dendritic spines. These are the hippocampal O-LM and the dentate gyrus hilar perforant path-associated (HIPP) cells. Both cell types contain the neuropeptide somatostatin; and their dendrites, with prominent spines, can be visualized by immunostaining against mGlur1, substance P receptors, or in some cases calretinin (Freund and Buzsáki, 1996).

When present, spines on interneurons show profound differences from their counterparts on pyramidal neurons. For example, pyramidal cell spines have a spine apparatus, an organelle not detected in the spines of interneurons, despite examining many immunocytochemically visualized spines in serial sections (Gulyás et al., 1992; Acsady et al., 1998). Another important difference between interneuron and pyramidal cell spines is the number of synaptic boutons. The spines of interneurons are covered by numerous excitatory synaptic boutons (four to eight synapses per spine). By contrast, most pyramidal cell spines have only one bouton, occasionally two; typically, when a second synaptic bouton is encountered on a pyramidal cell spine, it forms a symmetrical, presumably GABAergic synapse (Gulyás et al., 1992; Acsady et al., 1998). The large number of excitatory synapses on interneuron spines raises the possibility that spines of interneurons serve to increase the synaptic surface area and do not function as a compartmentalization device as in pyramidal cells (McBain et al., 1999). Spines on pyramidal cells have traditionally been considered to be structures that provide functional microdomains or compartments essential for input-specific synaptic plasticity. Yuste and colleagues (Goldberg et al., 2003a) provided the first direct observation that functional microdomains restricted to less than 1  $\mu\text{m}$  of dendritic space can exist on interneurons in the absence of spines. This compartmentalization was determined by the combination of rapid-kinetic,  $\text{Ca}^{2+}$ -permeable AMPA receptor-containing synapses located close to a fast extrusion mechanism governed by the  $\text{Na}^+/\text{Ca}^{2+}$  exchanger.

#### 5.9.4 Excitatory and Inhibitory Synapses

Within the hippocampal circuit, interneurons receive afferent excitatory input from a number of intrinsic and extrinsic sources. The nature of the afferents innervating specific populations of interneurons depends of course on the location of their soma and the extent of their dendritic tree. For example, interneurons with somata and dendrites located in the CA1 stratum radiatum primarily receive excitatory input from the CA3 Schaffer collateral projections (i.e., are activated in a feedforward manner) (Gulyás et al., 1999; Pouille and Scanziani, 2001). In contrast, interneurons located in the stratum oriens/alveus receive little or no innervation from the Schaffer collateral input and are primarily excited by the axons of CA1 pyramidal neurons to provide feedback (recurrent) inhibition to CA1 pyramidal neurons (Blasco-Ibanez and Freund, 1995; Maccaferri and McBain, 1996). The myriad roles that interneurons play in neuronal networks are often crucially dependent on the rapid, temporally precise conversion of an excitatory synaptic input to an inhibitory synaptic output (Jonas et al., 2004). Consequently, glutamatergic inputs to interneurons are often very powerful; combined with the typically more depolarized resting membrane potentials and higher input resistances, these synapses tend to discharge the postsynaptic cell reliably and rapidly (within 1–2 ms) (Lawrence and McBain, 2003; Jonas et al., 2004).

In addition to their inhibitory inputs onto principal cells, interneurons provide inhibitory input to other interneurons. In contrast to our appreciation of inhibitory transmission onto principal cells, much less is known regarding the nature of inhibition between interneuron subpopulations. Although poorly appreciated, specificity appears to exist between the targets of identified populations of inhibitory interneurons. Both CCK- and PV-containing interneurons innervate the soma and proximal dendrites of other CCK- and PV-containing cells (as well as contacting other interneuron populations), respectively. Of particular interest, some subpopulations of interneurons [e.g., vasoactive inhibitory peptide (VIP)-containing, calretinin-containing] have axons that exclusively innervate only other interneurons. Moreover, the targets of these subpopulations of interneuron-selective interneurons are extremely specific; for example, the interneuron selective CR-positive cells innervate the CCK-containing cells but not the PV-containing cells (Gulyás et al., 1996). Like excitatory synaptic transmission onto interneurons, the time course of the GABA-mediated inhibitory postsynaptic currents (IPSCs) in cortical interneurons is markedly faster than the kinetics of IPSCs in principal neurons of the same circuit (Bartos et al., 2001; Jonas et al., 2004). Another distinction between inhibition on principal cells and inhibitory interneurons is that the inhibitory synaptic reversal potential in interneurons is often more depolarized and close to the resting membrane potential (Banke and McBain, 2005; Vida et al., 2006), such that inhibition in these cells is primarily shunting. In identified fast-spiking basket cells, this shunting inhibition improves the robustness of gamma oscillatory activity (Vida et al., 2006). In interneurons of the stratum lucidum, placing the inhibitory synaptic reversal potential close to the resting membrane potential allows rapid reversal of the polarity of synaptic inhibition during high-frequency transmission, such that  $\text{GABA}_A$  receptor-mediated events depolarize other interneurons and recruit coordinated inhibitory input onto principal cell targets (Banke and McBain, 2005).

Precise estimates of synapse numbers and ratios of excitatory to inhibitory synapses have been performed for only a handful of interneuron subtypes, primarily the neurochemically defined PV-, CCK-, CB-, and CR-containing interneuron subtypes (Gulyás et al., 1999, Mátyás et al., 2004). Although the total number of synapses (excitatory plus inhibitory) is several-fold higher on PV-containing cells (~16,000) than on CCK- (~8200), CB- (~4000), or CR-containing (~2200) interneurons, the percentage of GABAergic inputs is higher in CB- (~30%), CCK- (~35%), and CR-containing interneurons (~20%) than in PV-containing interneurons (~6%). The pattern of excitatory innervation also varies among the three cell types. Whereas the dendritic and synaptic arrangements suggest that both PV- and CR-containing interneurons receive afferent input in all layers of the hippocampus, CB-containing cells receive input largely from Schaffer collateral afferents in the stratum radiatum (Gulyás et al., 1999). This high input specificity of CB-containing cells suggests that they are activated primarily in a feedforward

manner, whereas PV- and CR-containing interneurons are activated in both a feedforward manner by CA3 (Schaffer collaterals), entorhinal cortex (perforant path), and thalamic (nucleus reuniens) afferents and a feedback manner by local CA1 recurrent collaterals.

Activation of inhibitory interneurons by feedforward or feedback afferent projections often permits individual interneurons to perform a dual role in the hippocampal circuit (Lei and McBain, 2002; Walker et al., 2002b). Indeed, glutamate receptors expressed at synapses formed between various afferent projections onto single interneurons are often comprised of AMPA and NMDA receptors of distinct molecular composition (Toth and McBain, 1998; Lei and McBain, 2002). AMPA receptors at synapses formed between the recurrent collaterals of CA3 pyramidal cells and interneurons of the stratum lucidum have a highly edited GluR2 content, making them essentially impermeable to calcium ions. In contrast, AMPA receptors at the synapses made by mossy fibers and the same interneuron lack, or have a low, GluR2 content, rendering these receptors highly permeable to calcium (Toth and McBain, 1998). It is particularly interesting that the time course of synaptic conductances associated with these two afferent projections are also markedly different despite the synapses having overlapping electrotonic locations (Walker et al., 2002b). Such an arrangement of synaptic receptors allows the output of the single interneurons to respond differentially to different afferent inputs, thus increasing the computational repertoire of the interneuron.

In addition to excitatory glutamatergic innervation, many interneurons also express muscarinic and nicotinic receptors and receive cholinergic input from the medial septum. There is also evidence for noradrenergic input from the locus coeruleus, serotonergic input from the raphe nucleus, and histaminergic input from the supramammillary nucleus, to name a few. Although the roles of many of these neuromodulatory systems are poorly understood, several studies have elucidated the roles of a few of these modulators in influencing interneuron activity. For example, histamine excitation of somato-statin- and PV-containing interneurons via H<sub>2</sub> receptors modulates the activity of voltage-gated potassium channels formed by Kv3.2 subunits (Atzori et al., 2000). Following H<sub>2</sub> receptor activation, PKA phosphorylates channels containing Kv3.2 to decrease their outward current, consequently reducing the upper firing frequency of these fast-spiking interneurons. This reduction in interneuron firing frequency has a major influence on high-frequency oscillatory activity in the CA3 hippocampus. Similarly, muscarinic receptor activation has a differential effect on interneuron function that depends on the subclass of interneuron being activated and suggests differential expression of muscarinic receptors (Hajos et al., 1998; McQuiston and Madison, 1999a,b). Activation of M1 and M3 muscarinic acetylcholine receptors on stratum oriens-lacunosum moleculare (O-LM) interneurons enhances their firing frequency and produces large, sustained after-depolarizations (Lawrence et al., 2006). The generation of after-depolarization results from the coordinated inhibition

of both an M current and a slow calcium-activated potassium current and activation of a calcium-dependent nonselective cationic current ( $I_{CAT}$ ). In contrast, stratum oriens cell types with axon arborization patterns different from O-LM cells lacked this large muscarinic after-depolarization, suggesting that cholinergic specializations may be present in anatomically distinct subpopulations of hippocampal interneurons.

### 5.9.5 Axon Morphology and Synaptic Targets

The axonal arborization of local-circuit inhibitory interneurons constitutes another diverse feature of their anatomy. Each cell type or subclass of inhibitory neuron innervates distinct subcellular compartments of each of their targets. As described above, such an arrangement of axonal distribution predicts what role each interneuron plays in influencing activity of the postsynaptic cell. A detailed discussion of the axonal arborization of each type of interneuron is provided elsewhere (see Freund and Buzsáki, 1996). However, it is worthwhile discussing the axons of some of the most studied classes of inhibitory interneuron for comparison with the axons of CA1 and CA3 pyramidal neurons described earlier in the chapter.

Fast-spiking basket cells (presumably PV-containing) of the CA1 hippocampus (Halasy et al., 1996) typically have axons that emerge from either the soma or a proximal dendrite. The axon makes collaterals that extend into the stratum radiatum but primarily arborize throughout the pyramidal cell layer (Halasy et al., 1996). Basket cell axons have a mediolateral extent of > 700  $\mu\text{m}$ . The initial part of the primary axon and secondary branches are typically myelinated, and axonal branches wrap around the somata and proximal dendrites of pyramidal cells establishing numerous synaptic contacts. In contrast, the axon initial segments and spines of pyramidal cells are rarely contacted by basket cell axons. A single basket cell can make up to 15 varicosities (presumably presynaptic specializations) on a single pyramidal neuron. In the case of one well filled basket cell, the total number of presumed synaptic boutons was in excess of 10,000 and was estimated to converge onto ~110 pyramidal neurons (Halasy et al., 1996).

Chandelier cells or axo-axonic cells of the dentate gyrus and hippocampus are so named because of the appearance of their axonal arborization. The cell type was first described by Szentagothai and Arbib (1974) in the neocortex and was subsequently found in the hippocampus (Kosaka, 1983; Somogyi et al., 1983a,b). The axons of the stratum pyramidale chandelier cells originate from the soma or primary dendrite and form rows of 2 to 30 boutons throughout the principal cell layers and in the stratum oriens. These rows of boutons are aligned parallel to the axon initial segments of principal cells (pyramidal cells in CA1 or CA3 and granule cells in the dentate gyrus) (Freund and Buzsáki, 1996) and drape the principal cell layer with a termination pattern reminiscent of a chandelier. The axonal arbor occupies an elliptical area of ~600 to 850  $\mu\text{m}$ , elongated in the septo-temporal direction;

and a single chandelier cell is estimated to innervate ~1200 postsynaptic CA1 cells (Li et al., 1992). Interestingly, the number of cells targeted by a single chandelier cell in the CA3 subfield may be almost double that in CA1 (Gulyás et al., 1993b).

Although both fast spiking (PV- or CCK-containing interneurons) and axo-axonic interneurons predominantly innervate the somata, proximal dendrites, and axon initial segments of principal cells, respectively, other interneurons exclusively contact dendritic locations on principal cells. Two examples of dendritic projecting interneurons are the bistratified and the O-LM interneuron populations. These two cell types form an axonal plexus largely complementary to basket and axo-axonic cells. Bistratified cells (PV-positive, somatostatin-positive, CB-positive, neuropeptide Y-positive) have axons that innervate the dendrites of pyramidal cells in both the stratum radiatum and stratum oriens and largely spare the principal cell somata. In one confirmed CB-positive bistratified interneuron (Sik et al., 1995) the area occupied by the axon collaterals was  $1860 \mu\text{m}$  (septotemporal)  $\times 2090 \mu\text{m}$  (mediolateral). The total axon length was  $78,800 \mu\text{m}$ , had 16,600 boutons, and innervated as many as 2500 pyramidal cells. O-LM cells (somatostatin-positive, mGluR1-positive, and to a lesser extent PV-positive) have horizontally oriented cell bodies residing deep within the stratum oriens and send out a largely nonbranching axon, often from a proximal dendrite, which crosses the strata pyramidale and radiatum to form an extensive axonal plexus in the stratum lacunosum moleculare, making synapses onto the distal dendrites of pyramidal cells. In one well-filled O-LM cell from an *in vivo* study (Sik et al., 1995) the axon had a rather limited septotemporal and mediolateral extent of its termination field ( $840 \mu\text{m}$  by  $500 \mu\text{m}$ ). The total axon length of this cell was  $\sim 65,000 \mu\text{m}$ , and the calculated total number of presynaptic boutons was 16,874. Thus, even though the spatial extent of the terminal field was limited, the total number of putative synapses was typically higher than that of basket cells measured in the same study.

### 5.9.6 Resting Membrane Properties

Characterization of the passive membrane properties of inhibitory interneurons has been limited, with only a handful of studies providing reliable data. Given the numerous classes and subpopulations of inhibitory interneurons in the mammalian hippocampus, extrapolation of these numbers between subpopulations is to be avoided. Here, we discuss only those cells in which the anatomy is known and the passive membrane properties have been estimated using patch-clamp recording.

Where studied, inhibitory interneurons have resting membrane potentials that are slightly more depolarized than CA1 and CA3 pyramidal neurons. Estimates of interneuron resting membrane potentials have provided numbers spanning a wide range but typically lie 5 to 10 mV more depolarized than pyramidal neurons.

Inhibitory interneurons located in the CA1 pyramidal cell layer and morphologically identified as basket cells had highly variable input resistances, but on average the  $R_N$  was  $\sim 180 \text{ M}\Omega$  (Thurbon et al., 1994). Estimates of  $R_m$  in this cell population were also highly variable and ranged from 82,000 to  $281,000 \Omega\text{cm}^2$  (mean  $66,200 \Omega\text{cm}^2$ ).  $R_i$  was also highly variable and ranged from 60 to  $> 500 \Omega\text{cm}$  (mean  $\sim 300 \Omega\text{cm}$ ). By combining the physical lengths of the apical and basal dendrites of these cells with their  $R_m$  and  $R_i$ , the electrotonic lengths ( $L$ ) were calculated to be  $\sim 1.0$  and 0.5 for the apical and basal dendrites, respectively. These values highlight an interesting aspect of interneuron physiology. Although the total surface area of the interneurons and the physical length of their dendrites are considerably shorter than for CA1 pyramidal neurons, their electrotonic profiles are often similar. This suggests that neurons with small physical profiles cannot simply be assumed to be more electrotonically compact than larger neurons.

The membrane time constants of both spiny and aspiny stratum lucidum interneurons ( $\tau_m = \sim 40$  and  $\sim 30 \text{ ms}$ , respectively) are slower than that of CA1 pyramidal neurons but faster than that of CA3 pyramidal neurons, suggesting that these cells have  $R_m$  intermediate to both pyramidal neuron types (Spruston et al., 1997). Input resistances ( $R_N = \sim 350$  and  $290 \text{ M}\Omega$ , respectively), however, are typically higher than that of both CA1 and CA3 pyramidal neurons, presumably owing to the smaller somata and dendritic trees in these neurons.

Estimates of passive membrane parameters for a variety of interneuron types throughout all five laminar substrata in CA3 (stratum oriens through stratum lacunosum-moleculare) have also been determined (Chitwood et al., 1999). Although these numbers were not accompanied by a detailed analysis of the corresponding anatomy, the measured parameters provide worthwhile comparisons with other published data. Input resistances were significantly higher than those reported for basket cells but were similar to those obtained from identified stratum lucidum interneurons; on average they were  $\sim 440 \text{ M}\Omega$ . The membrane time constants of CA3 interneurons were also highly variable (27–69 ms) with a mean of  $\sim 60 \text{ ms}$ . Interestingly, no significant differences in  $R_N$ ,  $\tau_m$ ,  $R_m$ , or  $C_m$  were observed for interneurons located across the five substrata despite the marked heterogeneity in cell morphology across all subfields.

### 5.9.7 Voltage-Gated Channels in Inhibitory Interneurons

How an interneuron responds to afferent activity depends on many factors, in particular the synaptic conductance time course and the nature of the intrinsic channel proteins expressed on the cell surface. As was discussed in detail for CA1 pyramidal neurons, the properties, density, and distribution of these conductances determine how synaptic inputs are integrated and converted to unique patterns of action poten-

tial firing. Like most CNS neurons, interneurons differentially express a wide array of conductances with overlapping voltage dependence (e.g., activation by depolarization or hyperpolarization) and kinetics.

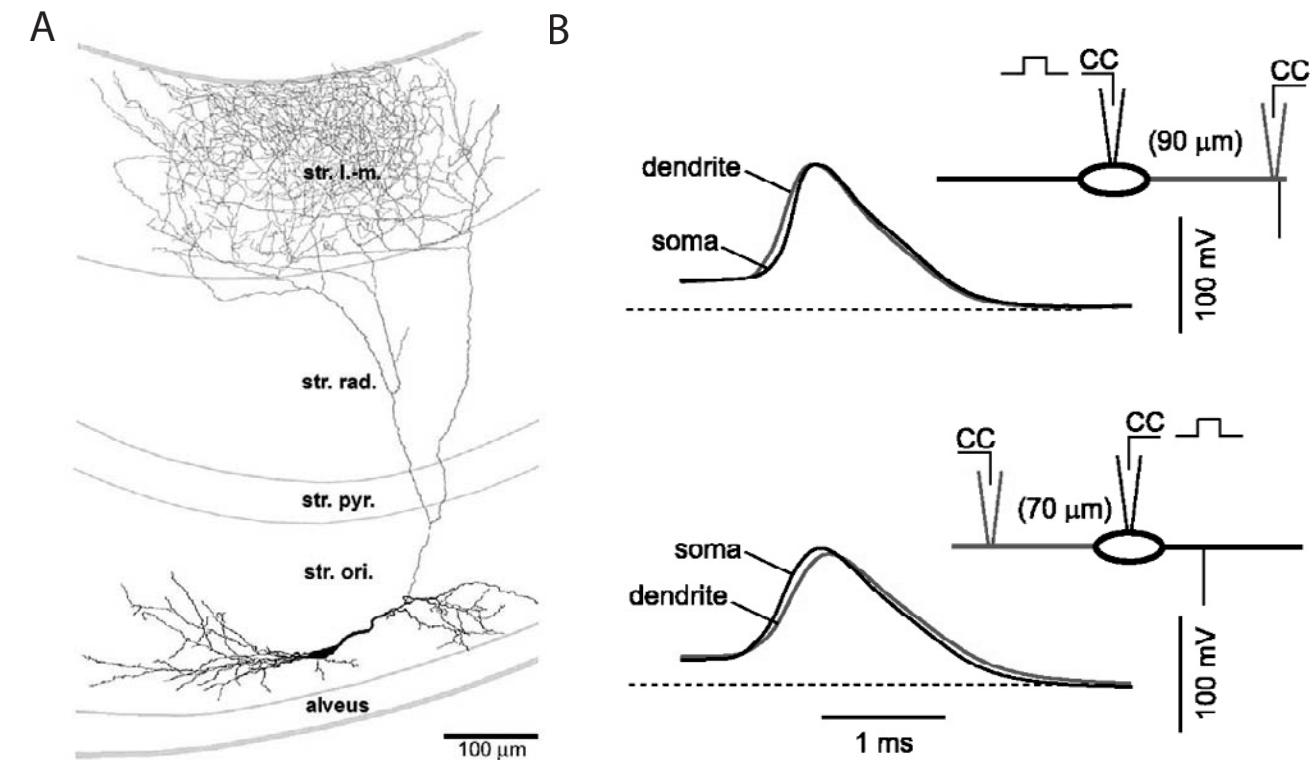

The first clue that interneurons might express voltage-gated ion channels distinct from their principal neuron counterparts came from inspection of action potential waveforms. Many interneurons fire brief action potentials with rapid repolarization, followed by only a simple fast after-hyperpolarization. Responses of interneurons to sustained depolarization are often quite distinct from both CA1 and CA3 pyramidal neurons, with many cell types showing high firing rates, brief interspike intervals, and little action potential accommodation. The most parsimonious explanation for these distinct properties was the presence of voltage-gated channel types unique to interneurons. The demonstration that low-threshold voltage-activated calcium channels conferred burst-firing properties on interneurons of the stratum lacunosum-moleculare provided the first direct evidence that interneurons expressed voltage-gated channels with properties distinct from principal cells (Fraser and MacVicar, 1991). Sodium channels with properties distinct from those of the principal cells have also been described (Martina and Jonas, 1997). Demonstration of the differential expression and func-

tional roles played by voltage-gated potassium channels has arguably provided the best insight into determinants of interneuron function (for review see McBain and Fisahn, 2001). Although attempts to correlate interneuron K<sup>+</sup> channel function with properties of recombinant K<sup>+</sup> channels has been problematic, major differences between principal cell and inhibitory interneuron voltage-gated potassium channels have emerged.

In recombinant systems, the K<sup>+</sup> channel subunits Kv3.1b and Kv3.2 confer currents that activate at highly depolarized potentials, show little inactivation during sustained depolarization, and deactivate rapidly upon repolarization (Rudy and McBain, 2001). Homo-tetramers formed by recombinant Kv3.1b and Kv3.2 have similar biophysical properties, with the notable difference that channels formed by Kv3.2 have a PKA-phosphorylation site that reduces currents through these channels when phosphorylated. In the hippocampus, Kv3.1b and Kv3.2 are expressed in all PV-containing interneurons, and Kv3.2 is also found in ~40% of somatostatin-containing interneurons; both are interneuron subpopulations with fast spiking phenotypes. Outward currents through Kv3 channels act to keep action potentials brief by activating at potentials close to the action potential peak, rapidly repolarizing the membrane potential, and limiting the duration of the after-

**Figure 5–26.** Inhibitory interneuron dendritic excitability. A. Camera lucida reconstruction of a biocytin-filled oriens-alveus interneuron. Soma and dendrites (thick lines) are typically restricted to the strata oriens and alveus. The axon (thin lines) projects across the pyramidal cell layer through the stratum radiatum to ramify extensively throughout the stratum lacunosum-moleculare.

B. Simultaneous current clamp (CC) recordings from a dendrite (gray) and soma (black). In response to long, threshold-level current injections, the action potential occurs first in the axon-bearing dendrite (top). With briefer, stronger-current injections, the action potential occurs first at the site of current injection (bottom). (Source: Data are from Martina et al., 2000.)

hyperpolarization by rapidly deactivating. High firing frequencies can be achieved by the ability of Kv3 channels to facilitate the recovery of both  $\text{Na}^+$  channels and transient A-type potassium channels from inactivation. Of particular interest, PKA phosphorylation of Kv3.2 subunits is triggered by histamine via  $\text{H}_2$  receptor activation, which reduces outward currents, broadens action potentials, and reduces the maximal firing frequency of dentate gyrus interneurons by altering Kv3.2 function.

Although the type of channels expressed by the cells are important determinants of interneuron function, the density and spatial distribution of those channels is also important. The density of both  $\text{Na}^+$  and sustained  $\text{K}^+$  currents are significantly higher and more uniform in dendrites of somato-statin-containing interneurons of the CA1 stratum oriens-alveus than those in the dendrites of neighboring principal cells (Martina et al., 2000). Consequently, action potentials in interneurons are initiated at sites across the dendritic tree and propagate rapidly to and from the soma with little decrement even during high-frequency firing (Fig. 5–26). Action potential initiation can switch between the soma and the axon-bearing dendrite, depending on the nature of the excitatory stimulus. Such organization of voltage-gated channels acts to ensure fast and reliable signaling in interneurons. This channel organization is in marked contrast to channel expression in principal cells, where dendritic action potentials are attenuated by a gradient of dendritic A-type  $\text{K}^+$  channels (Hoffman et al., 1997; however, see Goldberg et al., 2003b) (see Section 5.2.11 for further discussion). Whether such organization of voltage-gated channels and dendritic initiation of action potentials exists in other interneurons remains to be seen, but it highlights another feature of interneuron design important for rapid signaling. Studies of the transcriptional regulation and selective targeting of both ligand- and voltage-gated channels will ultimately provide valuable insight into the molecular events regulating expression of these important membrane proteins.

## ACKNOWLEDGMENTS

The authors thank members of their laboratories for helpful comments and discussion during the preparation of the chapter.

# Synaptic Function

## 6.1 Overview

Ever since Sherrington coined the term “synapse” (from the Greek “hold together”), this organelle has attracted intense interest for several reasons. First, the information passing through the synapses supplied by an individual neuron reflects the outcome of its integrative functions. Second, with some notable exceptions it acts as a one-way “valve,” transmitting information from the pre- to the postsynaptic neuron. Third, plasticity of synaptic transmission is the leading candidate for the cellular substrate of memory formation and storage. This chapter addresses some of the ways that individual synapses in the hippocampus are specialized to transmit signals and encode a history of their recent activity. It also provides the physiological context to Chapter 7, which examines the function of many of the molecules underlying synaptic transmission. The mechanisms of induction and expression of long-term changes in synaptic strength are addressed in Chapter 10.

Although the hippocampus has provided extensive information on the mechanisms by which neurons communicate with one another, many important principles underlying synaptic transmission were originally elucidated at the mammalian or arthropod neuromuscular junction. Indeed, many of the mechanisms underlying the trafficking of presynaptic vesicles are shared with other intracellular membrane-bound compartments and are even present in prokaryotes. We therefore start by summarizing some general features of interneuronal communication that are shared with other systems without going into detail into the experimental basis for these generally agreed upon principles. A detailed treatment of this subject is given in *Synapses* (Cowan et al., 2003). We then examine the various types of hippocampal synapse (classified anatomically) to see how their functional properties differ and how these distinct characteristics shed light on their roles.

For the purpose of this chapter a synapse is taken to represent the specialized structural and functional unit that is composed of one or more contiguous synaptic specializations occurring at the interface between two neurons (the presynaptic and postsynaptic partners). Thus, a single synapse can contain more than one presynaptic active zone (where neurotransmitter molecules are released) and postsynaptic specialization (where receptors detect them). However, a pair of pre- and postsynaptic neurons can also be connected via more than one synapse. Although this definition of a synapse is morphological, it should be borne in mind that major insights into synaptic function have relied principally on electrophysiological, pharmacological, and biochemical methods, often in the absence of histological reconstruction of the underlying elements.

Not all communication between neurons is via synapses: Some neurotransmitters are released from axonal varicosities in the absence of postsynaptic specialization. The fact that receptors are sometimes relatively remote from the site of release of their endogenous ligands (e.g., monoamines, peptides, acetylcholine) has been taken as evidence that two distinct forms of signaling exist: (1) “point-to-point” or “wiring” transmission at synapses and (2) a more diffuse “spillover,” “extrasynaptic,” or “volume” transmission mediated by diffusion of neuroactive substances through the extracellular space (Agnati et al., 1995). As is argued below, the distinction between these concepts is blurred by the existence of numerous types of receptor at variable distances from the release sites of their endogenous agonists. Neurons can also exert effects on their neighbors via mechanisms that do not involve neurotransmitters at all, for instance via field effects (Jefferys, 1995) or gap junctions (Galarreta and Hestrin, 1999; Gibson et al., 1999). These act as relatively low-impedance pathways that permit the passive flow of electrical signals among connected neurons. They can also permit ions to flow down their electrochemical gradients, thereby dissipating their local accu-

mulation and depletion. Preliminary data also imply that axons of neighboring pyramidal neurons may be coupled through electrical contacts (Schmitz et al., 2001b). Moreover, not all hippocampal synapses are formed between neurons: Morphological and electrophysiological evidence supports the existence of excitatory synapses between hippocampal neurons and a subset of oligodendrocyte precursors (Bergles et al., 2000).

## 6.2 General Features of Synaptic Transmission: Structure

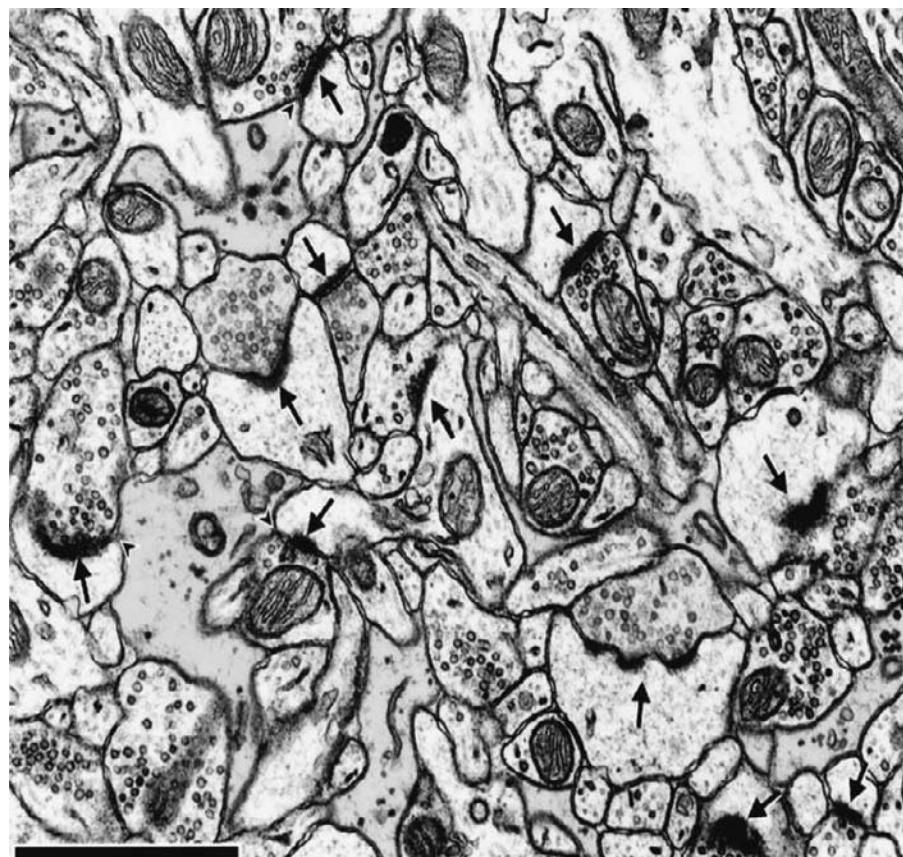

Synaptic transmission can be broken down into neurotransmitter release from a presynaptic specialization, diffusion of the neurotransmitter across the synaptic cleft, and activation of postsynaptic receptors. These phenomena must be understood in the context of the detailed ultrastructure of the synapse.

The electron micrograph shown in Figure 6–1, see color insert illustrates some features of hippocampal synapses. The pre- and postsynaptic elements are separated by a synaptic cleft. This cleft is often narrower than the gap separating non-synaptic membranes and appears relatively dense, reflecting the presence of a “basal substance” containing intercellular adhesion molecules. These molecules, some of which are

described in detail in Chapter 7, are thought to contribute to the formation, stabilization, and plasticity of synapses (see also Chapter 10).

The presynaptic element is readily identified by the presence of vesicles containing neurotransmitter molecules. These vesicles are generally of relatively uniform size and are aggregated near a membrane specialization that is often identified ultrastructurally as a thickening. This is thought to represent the “active zone,” which is the site of exocytosis; and the thickening reflects the presence of membrane proteins necessary for exocytosis. Among them are proteins that interact with vesicular partners (SNARE proteins, see below), as well as voltage-dependent channels that mediate the influx of  $\text{Ca}^{2+}$ , which triggers exocytosis upon action potential invasion. It is almost universally agreed that vesicles are the morphological counterpart of the “quanta,” that make up synaptic signals (see below). In addition, mitochondria are frequently present, reflecting the energetic demands of transmitter release (principally represented by the work required for transmitter synthesis, vesicular packaging, exocytosis, and reuptake) (Shepherd and Harris, 1998).

On the postsynaptic side, there is also an increased density of the membrane. Synapses with obvious postsynaptic thickening are known as asymmetrical, or type I, synapses (Gray, 1959) and were shown to be excitatory by Andersen and colleagues (1966), who examined the ultrastructural consequences of lesioning monosynaptic excitatory pathways. The

**Figure 6–1.** Fine structure of the hippocampal neuropil. Arrows point to individual asymmetrical (glutamatergic) synapses in a section taken from the stratum radiatum of CA1 in the rat. The presynaptic boutons contain numerous vesicles, which are frequently clustered close to membrane specializations (the active zone). A proportion of “docked” vesicles are in contact with the presynaptic membrane and are thought to be ready for exocytosis. The electron-dense area is the postsynaptic density, which distinguishes these synapses from numerically less abundant symmetrical (inhibitory) synapses (see Fig. 6–9). Astrocyte profiles, colored in blue, lacking vesicles and postsynaptic densities, contact the synaptic perimeter in some cases (arrowheads). Bar = 1  $\mu\text{m}$ . (Source: Ventura and Harris, 1999, with permission.)

"postsynaptic density" (PSD) is a relatively detergent-resistant structure containing glutamate receptors and associated macromolecules (Kennedy, 1997) (discussed in Chapter 7). Some synapses lack this specialization and are therefore known as "symmetrical," or type II, synapses (Gray, 1959). They are thought to be principally GABAergic inhibitory synapses (see Chapter 8). Although they represent a small number of synapses in the hippocampus as a whole, they play numerous important roles, including setting the overall excitability of the structure and its rhythms. GABAergic synapses are concentrated around the soma and axonal initial segment of many neurons but are also found on dendrites.

In addition to the pre- and postsynaptic elements that make up a synapse, astrocyte processes commonly occur in close proximity to the synaptic cleft. As is shown below, they play a critical role in clearing neurotransmitter from the extracellular space. They also play an important role in buffering extracellular ion transients and in providing for the energetic demands of synaptic transmission. Although astrocyte processes are often thought of as an obligatory partner, making up the third element of a "tripartite" synapse, their presence at excitatory and inhibitory synapses is much more haphazard in the hippocampus than in other regions of the brain, such as the cerebellar cortex (Spacek, 1985; Lehre et al., 1995; Ventura and Harris, 1999). Indeed, many synapses in the hippocampus are not contacted by an obvious astrocytic process at all (Ventura and Harris, 1999).

### 6.2.1 Transmitter Release and Diffusion

Anatomical, biochemical, and electrophysiological methods have converged on the following general account of transmitter release (Zucker et al., 1998; Chen and Scheller, 2001; Sudhof, 2004) (Fig. 6–2). (Fig. 6–2)

On the presynaptic side, neurotransmitter molecules are translocated from the cytoplasm into vesicles by specific transporters, which exploit a proton gradient formed by vesicular ATPases. The two principal vesicular amino acid neurotransmitters differ slightly in their uptake mechanisms. The gluta-

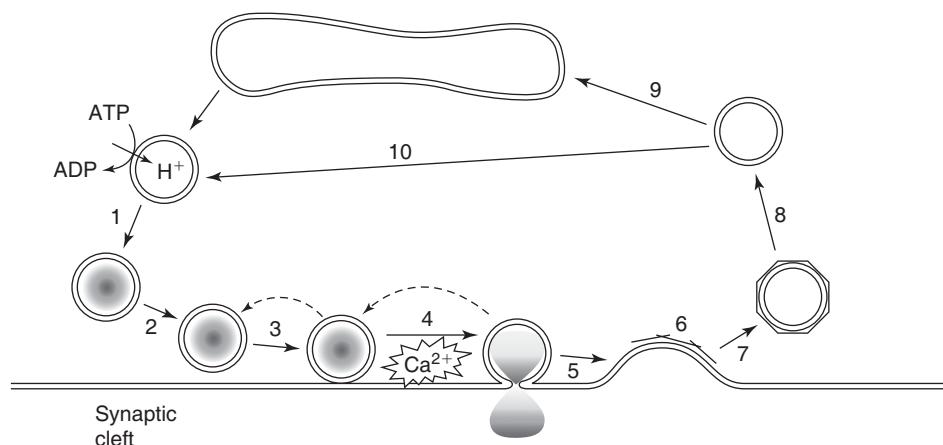

mate anion is driven into vesicles by the vesicle potential gradient formed by the high intraluminal H<sup>+</sup> concentration. A family of proteins that mediate glutamate uptake (VGLUT1-3) has recently been identified (Bellocchio et al., 2000; Takamori et al., 2000). In the case of GABA ( $\gamma$ -aminobutyric acid), in addition to uptake driven by the potential gradient, another mechanism exists: Cl<sup>−</sup> is driven in by the potential gradient, and then exchanged for the GABA anion (Fykse and Fonnum, 1996). The vesicular transporter VGAT appears to be responsible for GABA uptake (McIntire et al., 1997).

Vesicles are reversibly tethered by synapsin molecules to a presynaptic actin scaffold. A subset of vesicles are especially closely apposed to the presynaptic active zone and have been described as being "docked," presumably ready for exocytosis (Harris and Sultan, 1995). These vesicles may correspond to a population of quanta that are available for release on a relatively rapid time scale (defined physiologically as the "readily releasable pool") (Stevens and Tsujimoto, 1995; Rosenmund and Stevens, 1996). Evidence obtained in isolated preparations suggests that vesicle docking may be reversible (Steyer et al., 1997; Murthy and Stevens, 1999), and there may be a further stage of preparation for exocytosis that is not resolved ultrastructurally (named "priming").

Considerable effort has gone into identifying the molecular identity of the proteins that mediate and detect the influx of Ca<sup>2+</sup> and trigger the fusion of the vesicle membrane with the presynaptic neuronal membrane (Augustine, 2001).

Voltage-dependent Ca<sup>2+</sup> channels clearly play a critical role, and it is important to understand their properties to explain use-dependent plasticity and pharmacological modulation of transmitter release. Of the various pharmacologically and biophysically defined classes, P/Q- and N-type channels (also known as Ca<sub>v</sub>2.1 and Ca<sub>v</sub>2.2, respectively) account for most of the Ca<sup>2+</sup> influx that triggers exocytosis (Dunlap et al., 1995). A third class of Ca<sup>2+</sup> channels, R type (Ca<sub>v</sub>2.3), play a relatively small role at most synapses. Because of their high depolarization threshold, all three types are normally kept shut at resting potentials. They open rapidly upon depolarization; but because their closure lags slightly behind action

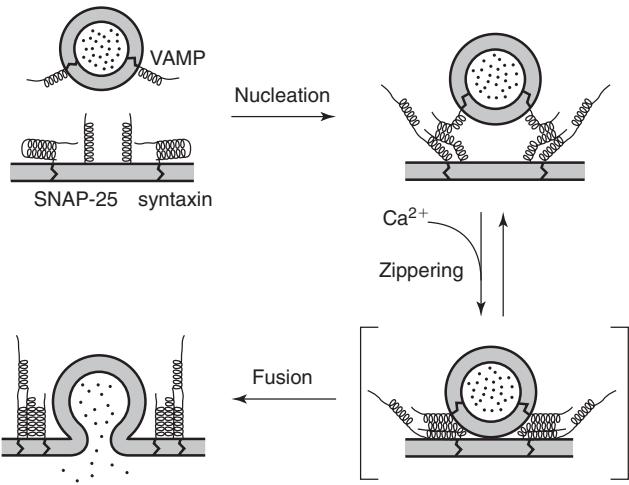

**Figure 6–2.** Stages of the vesicle cycle. 1, Vesicle filling. 2, Trafficking to the release site. 3, Docking/priming. 4, Fusion/release. 5, Membrane flattening. 6, Clathrin coating. 7, Endocytosis. 8, Clathrin uncoating. 9, Merging with endosome. 10, Recycling. Some evidence suggests that docking/priming and fusion/release may be reversible (indicated by broken line arrows).

potential repolarization, they are still able to carry  $\text{Ca}^{2+}$  flux when the presynaptic membrane potential has returned close to the resting value. The bulk of the  $\text{Ca}^{2+}$  influx triggering exocytosis therefore probably occurs during repolarization, because the inward driving force for  $\text{Ca}^{2+}$  ions is maximal at this time point. Interestingly, whereas both N- and P/Q-type channels contribute to triggering glutamate release at individual synapses, many GABAergic terminals appear to fall into two classes: those that rely mainly on N-type channels and those that predominantly use P/Q-type channels (Poncer et al., 1997). It is not known if the  $\text{Ca}^{2+}$  channel identity is somehow tailored to the firing patterns of the presynaptic neurons.

Measurement of the intraterminal spatiotemporal  $\text{Ca}^{2+}$  concentration profile that occurs following action potential invasion is technically difficult in relatively small hippocampal synapses. Nevertheless, it has been estimated that the average concentration of free  $\text{Ca}^{2+}$  in a presynaptic varicosity rises to about 500 nM (Koester and Sakmann, 2000). This underestimates the peak concentration seen by the  $\text{Ca}^{2+}$  sensors responsible for triggering exocytosis. Based on studies at other synapses, the concentration at the site of exocytosis is thought to rise transiently approximately 100-fold, to approach 10  $\mu\text{M}$  (Bollmann et al., 2000; Schneggenburger and Neher, 2000). Estimates of the size of the  $\text{Ca}^{2+}$  ion flux through an individual  $\text{Ca}^{2+}$  channel and the distance separating them from docked vesicles are consistent with the view that relatively few voltage-sensitive  $\text{Ca}^{2+}$  channels (possibly fewer than 100) must open to trigger exocytosis of a single vesicle (Borst and Sakmann, 1996).

Transmitter release shows a steep dependence on the extracellular  $\text{Ca}^{2+}$  concentration. A fourth-power relation has been observed at some synapses (Dodge and Rahamimoff, 1967), although this saturates at supraphysiological concentrations so the curve relating transmitter release to  $\text{Ca}^{2+}$  concentration is actually sigmoid. Several possible explanations exist for the steep  $\text{Ca}^{2+}$  dependence, including summation of  $\text{Ca}^{2+}$  influx via multiple channels, saturation of buffers, and cooperativity of  $\text{Ca}^{2+}$  sensors, in particular the vesicle-associated protein synaptotagmin I (Fernandez-Chacon et al., 2001). Synaptotagmin I contains two  $\text{Ca}^{2+}$ -binding domains, and genetic deletion of this protein severely disrupts fast  $\text{Ca}^{2+}$ -dependent exocytosis, making it a strong candidate for the  $\text{Ca}^{2+}$  sensor responsible for triggering transmitter release (Geppert et al., 1994).  $\text{Ca}^{2+}$  binding is thought to trigger a conformational change in a macromolecular complex consisting of three groups of proteins: vesicular, target membrane-associated, and soluble proteins (Chen and Scheller, 2001). The membrane-associated proteins are known as the SNAREs, from “SNAP-receptors” (SNAP: synaptosomal-associated proteins). The vesicular SNAREs (v-SNAREs) include VAMP (vesicle-associated membrane protein, also known as synaptobrevin); and the target membrane SNAREs (t-SNAREs) include SNAP-25 and syntaxin. These key proteins form a complex consisting of four helices (one  $\alpha$  helix contributed by each of VAMP/synaptobrevin and syntaxin, and two  $\alpha$  helices contributed by SNAP-25). Each of these proteins can be

**Figure 6-3.** Proposed mechanism of SNARE-mediated exocytosis. Assembly of the core complex (VAMP/synaptobrevin, syntaxin, SNAP-25) is seen as a “nucleation” event necessary to prepare the vesicle for exocytosis.  $\text{Ca}^{2+}$  influx induces a conformational change of the core complex (“zippering”), which brings the vesicle and plasma membranes into contact, followed by transmitter release. (Source: Lin and Scheller, 2000, with permission.)

cleaved by at least one clostridial toxin (botulinum toxins A–G and tetanus toxin), which results in blockade of neurotransmitter release.

A compelling suggestion for the role of the core complex formed by VAMP/synaptobrevin, syntaxin, and SNAP-25 is that it forces together the vesicular and target membranes in preparation for their fusion. Nevertheless, the precise sequence of events that leads up to the conformational change underlying exocytosis is incompletely understood. In particular, it remains unclear precisely how synaptotagmin interacts with the SNARE complex and how the cascade overcomes the steep energy barrier to fusion of the vesicular and target membrane bilayers. Ultimately, the transmitter is released into the synaptic cleft. An outline of this cascade is summarized in Figure 6-3.

Before considering the consequence of transmitter release into the synaptic cleft, it is worth examining the fate of  $\text{Ca}^{2+}$  ions. Powerful presynaptic  $\text{Ca}^{2+}$  buffers exist in the form of proteins and mitochondria (Klingauf and Neher, 1997; Tang and Zucker, 1997). These, together with  $\text{Ca}^{2+}$  extrusion mechanisms, contribute to terminating the  $\text{Ca}^{2+}$  transient in such a way that the system is returned to the resting state. Nevertheless, it may take several minutes for this to be achieved, during which time successive action potentials may become increasingly effective in triggering transmitter release (Kamiya and Zucker, 1994; Zucker and Regehr, 2002). Genetic manipulation of  $\text{Ca}^{2+}$ -buffering proteins can alter the dependence of synaptic strength on the recent history of activity, underlining the importance of this phenomenon (Caillard et al., 2000). However, this is only one of several mechanisms that contribute to short-term use-dependent plasticity of synaptic transmission (see below).

It remains unclear whether exocytosis always involves complete fusion of the vesicle, flattening and merging with the presynaptic membrane, or can occur through the reversible opening of a “fusion pore,” allowing the escape of all or part of the vesicle contents. Early reports of incomplete exocytosis came from ultrastructural studies at the neuromuscular junction and from two types of electrophysiological measurement that offer very good temporal resolution: voltammetric recordings of monoamine release (Chow et al., 1992; Bruns and Jahn, 1995) and capacitance measurements of the release of secretory granules (Breckenridge and Almers, 1987). None of these measurements was obtained at hippocampal synapses, so their relevance to this structure remains indirect. However, recent optical measurements of dyes taken up by presynaptic vesicles in hippocampal neurons in culture have suggested that individual vesicles can retain their identity through the cycle of release and reuptake (Murthy and Stevens, 1998), consistent with the proposal that they discharge their contents without completely fusing with the presynaptic membrane. This behavior raises the possibility that a vesicle may release less than its entire contents (so-called kiss-and-run release) before separating from the presynaptic membrane and mixing with a pool of vesicles in the terminal. Electrophysiological evidence has also been reported from hippocampal neurons in culture suggesting that glutamate can be released through two interchangeable modes, corresponding to full exocytosis or escape through a fusion pore (Renger et al., 2001).

Once fusion has occurred, the SNARE proteins must be dissociated and made available for another round of exocytosis. This step involves the soluble ATPase NSF (*N*-ethylmaleimide-sensitive factor) and  $\alpha$ -SNAP (soluble NSF attachment protein). The requirement for ATP hydrolysis probably reflects the energetically unfavorable reversal of the formation of the core complex (Chen and Scheller, 2001; Jahn et al., 2003). The vesicle membrane, together with the membrane-associated proteins (including the vesicular ATPase and transporters, v-SNAREs, and synaptotagmin) must also be endocytosed if full fusion has occurred. This retrieval proceeds by formation of a lattice of clathrin molecules on the cytoplasmic face of the vesicle membrane. This lattice imposes a concavity on the membrane that is eventually pinched off by the action of dynamin, following which the recycled vesicle reenters the presynaptic pool (Cremona and De Camilli, 1997). Whether the vesicle merges immediately with the pool available to be released or is targeted specifically to an intermediate endosomal compartment is unclear.

Numerous mechanisms regulate the availability of vesicles for release. Among them is ATP-dependent mobilization of vesicles tethered to presynaptic microfilaments by synapsins (Rosahl et al., 1995). Rab3A is a GTP-binding protein that reversibly associates with vesicles as they go through the exocytosis–endocytosis cycle. Genetic deletion of Rab3A interferes with the expression of long-term potentiation at mossy fibers (see below) (Castillo et al., 1997a), suggesting a regulatory role; but its precise function in the vesicle cycle is unclear.

It is known to interact with two other proteins, rabphilin and RIM (Rab-interacting molecule), that contain putative  $\text{Ca}^{2+}$ -binding domains. There may also be a mechanism that regulates vesicle trafficking as a function of the neurotransmitter contents: Interfering with vesicular ATPase has been reported not to reduce the quantal amplitude but only to reduce the number of quanta available for release (Zhou et al., 2000). This observation suggests that a form of quality control exists to prevent underfilled vesicles from docking and/or releasing.

Following release, neurotransmitter molecules diffuse across the cleft to activate postsynaptic receptors. Because the synaptic cleft spans only approximately 20 nm, the time taken by neurotransmitter molecules to reach the nearest possible postsynaptic receptors is negligible: Assuming that neurotransmitter molecules diffuse readily in the extracellular space, they should reach most of the receptors in the synaptic cleft within 100  $\mu\text{s}$ . However, although many receptors occur in the postsynaptic membrane opposite the active zone, others are farther away. Several classes of receptors (considered in detail below) show distinct patterns of localization: in the presynaptic membrane within the synaptic cleft or in a perisynaptic halo around the synapse, either pre- or postsynaptically (Takumi et al., 1998). Some receptors are even found in the axonal membrane relatively far from the synaptic cleft (Yokoi et al., 1996). To assess the functional role of these types of receptor, it is important to understand how the endogenous ligands reach them following release from presynaptic varicosities. The factors that determine the activation of these receptors are as follows.

- Amount of neurotransmitter released
- Temporal profile of release
- Distance from release site to receptors
- Diffusion coefficient (or diffusivity) of the neurotransmitter in the cleft and in the extracellular medium
- Diffusional obstacles
- Neurotransmitter transporters, their affinity and kinetics, and other binding sites
- Kinetics of the receptors

Astrocytes play an important role in determining receptor activation because they frequently extend processes that contact the perimeter of the synaptic cleft and because they express transporters and receptors on their surface, which buffer and/or sequester the neurotransmitter molecules. A further role played by astrocytes in the case of glutamate, is to convert it enzymatically to glutamine (see below).

### 6.2.2 Receptors and Receptor Activation

Receptors fall into two distinct classes. Ionotropic receptors, also known as ligand-gated ion channels, contain binding sites for neurotransmitters. Binding of the transmitter molecules causes the channel to open, allowing charged ions to travel down their chemical and electrical gradients. The biophysical principles and molecular mechanisms underlying ion selectiv-

ity and permeation are described in detail in *Ion Channels of Excitable Membranes* (Hille, 2001). With the other type, known as metabotropic receptors, ligand binding triggers an intracellular biochemical cascade beginning with dissociation of GTP-binding proteins (G proteins).

Ionotropic receptors generally occur postsynaptically, although they can also occur presynaptically in some areas of the brain (MacDermott et al., 1999), and mediate depolarizing or hyperpolarizing synaptic signals that activate within milliseconds. Depolarizing signals mediated by glutamate receptors take the form principally of an influx of  $\text{Na}^+$  ions, accompanied by variable amounts of  $\text{Ca}^{2+}$  influx. Other excitatory ionotropic receptors (purinergic P2x receptors, nicotinic acetylcholine receptors, and serotonergic 5HT<sub>3</sub> receptors) are present in far smaller numbers. The ion flux constitutes the excitatory postsynaptic current (EPSC), whose size is determined by the membrane potential, the reversal potential for each ion species, its permeability through the receptor, and the mean number of receptor channels opening. The EPSC depolarizes the postsynaptic membrane, and gives rise to an excitatory postsynaptic potential (EPSP), which if it is sufficiently large and/or sums with other EPSPs can activate regenerative currents. Such currents can reach threshold to trigger an action potential in the axon initial segment, although under some conditions an action potential can also arise in the parent dendrite (see Chapter 5). Box 6–1 summarizes some principles underlying voltage-clamp recording techniques, which have shed much light on the mechanisms underlying the generation of synaptic signals.

Conversely, inhibitory ionotropic signals are mediated principally by GABA<sub>A</sub> receptors. Although glycine receptors also contribute to inhibition in spinal and brain stem neurons, they are not known to play an important role in the hippocampus. Inhibitory postsynaptic currents (IPSCs) are carried by  $\text{Cl}^-$  and  $\text{HCO}_3^-$  ions flowing down their electrochemical gradients. Because the permeability of GABA<sub>A</sub> receptors for  $\text{Cl}^-$  is greater than that for  $\text{HCO}_3^-$  and the equilibrium potential for  $\text{Cl}^-$  is relatively negative, the IPSC generally hyperpolarizes the neuron, giving rise to an inhibitory postsynaptic potential (IPSP). Synaptic inhibition has two effects on neuronal excitability. First, it drives the membrane potential farther away from the threshold for activating regenerative depolarizing currents; and, second, by lowering the membrane resistivity it shunts EPSCs that would normally depolarize the neuron.

Although IPSPs and EPSPs contribute to the excitability of the neuron, they do not sum linearly because of several factors addressed in Chapter 5. Briefly, voltage- and time-dependent electrical properties of dendrites cause synaptic currents to dissipate or amplify as they propagate, the results of which depend strongly on the initial spatial profile of the membrane voltage, on the geometric distribution of active synapses, and on the density and kinetics of a set of voltage-gated ion channels.

Metabotropic receptors occur both pre- and postsynaptically, although different types, which have distinct pharmacological profiles, have specific patterns of distribution. Most such receptors exert their actions over a slower time scale, lasting up to seconds. As a general principle, presynaptic metabotropic receptors depress transmitter release (Pin and Duvoisin, 1995; Schoepp, 2002). This effect is mediated partly through G protein regulation of presynaptic  $\text{Ca}^{2+}$  channels.

### Box 6–1

#### Voltage-Clamp Techniques

Early studies of ion channels in neurons relied on measuring the effects of drugs and stimuli on the membrane potential. However, an ion flux through a population of channels can itself alter the membrane potential. This has two consequences: It alters the driving force for further ion flux and can cause voltage-sensitive channels to open or close, thereby potentially setting off regenerative currents. Thus, it is difficult to characterize the properties of different types of receptors on the basis of voltage recordings alone. The voltage-clamp method circumvents this problem by keeping the membrane potential at a fixed value and estimating the current flowing through the membrane. The method relies on a feedback circuit that pumps enough current back into the neuron to clamp its voltage at the desired level. The amplitude and time course of this current in relation to various stimuli (for instance, synaptic release or exogenous application of neurotransmitters or changes in the command voltage itself) then give an indication of the properties of the ion channels. As originally developed to study muscle fibers and axons, the method required separate electrodes to detect the membrane potential and to pass the current. This was not feasible in any but the largest cells. The patch-clamp method overcomes this difficulty by using the same low-resistance electrode to detect the membrane potential *and* pass the current. It relies on the finding that a glass pipette applied to the surface of a neuron can make a very high resistance seal with the plasmalemma. The method can work in various configurations.

1. Currents passing through individual ion channels under the membrane can be recorded in the “cell attached” mode.
2. The membrane under the pipette can be ruptured to allow the entire neuron to be voltage-clamped (“whole cell” mode—the most versatile method for recording synaptic currents).
3. Another way to access the entire cell electrically while minimizing the perturbation of its biochemical milieu is to add an ionophore to the pipette solution while remaining in the cell attached mode. This is the “perforated patch” technique.
4. In the whole cell configuration, slowly withdrawing the pipette causes a patch of membrane to seal over the pipette mouth (“outside-out configuration”). This allows the effects of brief pulses of agonists on small numbers of receptors to be studied in great detail.
5. It is also possible to rupture a vesicle of membrane in such a way that the cytoplasmic face is exposed to the bath (“inside-out configuration”). This is useful for studying the regulation of ion channels by second messengers.

N-type  $\text{Ca}^{2+}$  channels in particular are directly modulated by the G protein subunit  $G_{\beta\gamma}$  (Zhang et al., 1996; Dolphin, 1998); but in addition, some metabotropic receptors affect transmitter release indirectly via inactivation of adenylate cyclase (Tzounopoulos et al., 1998). Some metabotropic receptors may decrease transmitter release separately from an effect on  $\text{Ca}^{2+}$  influx (Scanziani et al., 1995; Blackmer et al., 2001).

On the postsynaptic side, metabotropic receptors have more diverse actions, although again most of these effects involve G proteins. The effector mechanisms include opening of  $K^+$  channels, giving rise to a slow hyperpolarization (Pin and Duvoisin, 1995; Luscher et al., 1997). Some metabotropic glutamate receptors in contrast trigger the closure of specific  $K^+$  channel subtypes, leading to depolarization or a change in the temporal profile of repetitive action potentials. Activation of yet other metabotropic receptors can lead to a depolarizing current by opening a cation channel with high permeability to  $\text{Na}^+$  (Heuss et al., 1999). Other effects of metabotropic receptor activation include activation of phospholipase C, generating inositol trisphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). IP<sub>3</sub> is intimately involved in regulating the release of  $\text{Ca}^{2+}$  from internal stores, which may lead to triggering regenerative  $\text{Ca}^{2+}$  release and more remote effects such as modulation of gene transcription.

Receptor activation must eventually terminate. The most important mechanism that underlies this is rapid dissipation of the neurotransmitter pulse by diffusion into the large extracellular space, which can drop the concentration 100-fold within a few milliseconds. This phenomenon, on its own, thus causes a rapid decrease in ligand concentration to levels that may fall below those required to activate receptors. Nevertheless, some receptors remain bound for several hundred milliseconds because they have very high affinity (Lester et al., 1990). Uptake also plays a major role in the clearance of neurotransmitter through both the rapid quenching of neurotransmitter molecules binding to unoccupied transporters and their translocation into the cytoplasm. A third mechanism that can underlie the termination of receptor activation is desensitization: In the continued presence of agonist molecules, ionotropic receptors generally enter a state that is no longer able to open. (Much less is known about the desensitization mechanisms of metabotropic receptors.) The relative importance of diffusion, uptake, and desensitization in terminating activation may vary among receptors and even among synapses. However, even if uptake plays little role in the rapid termination of receptor activation, the neurotransmitters must eventually be cleared from the extracellular space by active transport because, apart from acetylcholine, ATP, and some neuroactive peptides, there are no extracellular mechanisms to break them down.

### 6.2.3 Quantal Transmission

The conventional view of synaptic function—originating from studies by Katz and coworkers at the neuromuscular junction—is that transmission is quantized; that is, repeated

presynaptic action potentials give rise to postsynaptic signals that fluctuate from trial to trial among discrete levels (Katz, 1969; Zucker et al., 1998). These discrete levels occur at integral multiples (0, 1, 2, ...) of an underlying unit, the “quantum.” This model of transmission has received only partial support from studies in the central nervous system (CNS). As already hinted above, if exocytosis is incomplete or the neurotransmitter is discharged slowly, a single vesicle may give a graded postsynaptic effect, even if it originally contained a fixed amount of neurotransmitter. Moreover, nonuniformities in the distribution of receptors available to detect transmitter released at different synapses or in the degree of distortion that the postsynaptic signals undergo as they propagate to the cell body are likely to conceal any quantal “structure” in the amplitude fluctuations of postsynaptic signal recorded at the soma. Finally, unlike the neuromuscular junction, where a single presynaptic end-plate has a large number of relatively uniform, well separated release sites, most hippocampal synapses probably contain only one or a few release sites (Schikorski and Stevens, 1997), which probably interact nonlinearly. Nevertheless, recordings of synaptic signals have reported large trial-to-trial fluctuations in the size of the postsynaptic response to activation of a single or a small number of presynaptic axons. In some cases, it has even been possible to discern clustering of postsynaptic response amplitudes at integral multiples of the unit value, perhaps reflecting the fortuitous case where underlying release events gave similar responses, and where they summed relatively linearly across the various active synapses or release sites (e.g., Kullmann and Nicoll, 1992). These cases probably represent only a small number of recordings but have helped shed light on the parameters that underlie transmission. Box 6–2 summarizes the principles of “quantal analysis” (Zucker et al., 1998).

The more general finding is that although transmission is stochastic and can even fail on occasion EPSCs, EPSPs, IPSCs, and IPSPs tend not to cluster systematically at preferred amplitudes (Raastad, 1995). It has nevertheless been possible to extract some information on the mechanisms of modulation of synaptic strength from examining the trial-to-trial variability of such signals. This application of quantal analysis relies on making a few assumptions, but some of them have been found to be reasonably robust. For instance, if it is assumed that failures of transmission reflect cases where the presynaptic action potential did not trigger exocytosis, it may be possible to use the frequency of such failures as an indirect witness of the state of the presynaptic terminal. That is, if a physiological or pharmacological event decreases the rate at which presynaptic action potentials elicit postsynaptic responses, it may be inferred that the presynaptic release probability has decreased. Other approaches rely on estimating the coefficient of variation of the postsynaptic signal (see Box 6–2). These approaches, however, must be used with caution. They have been at the center of a controversy surrounding the mechanisms of expression of long-term potentiation (see Chapter 10), and some of the disagreements

**Box 6-2**  
**Quantal Analysis**

Chemical synaptic transmission occurs via the presynaptic release of packages of neurotransmitter, which diffuse to and act upon postsynaptic receptors. This phenomenon was originally elucidated at the neuromuscular junction on the basis of electrophysiological recordings from the postsynaptic muscle cells. Under certain conditions, the size of the postsynaptic response to presynaptic stimulation fluctuates from stimulus to stimulus among discrete levels, reflecting 0, 1, 2... quanta released. These levels correspond to integral multiples of an underlying unit, which coincide with the size of a spontaneous event arising from the spontaneous release of a single package of neurotransmitter. From a wealth of other data, it has been established that the quantum corresponds to the postsynaptic response to the neurotransmitter packaged in an individual vesicle. The quantal description of neurotransmission not only gives a powerful insight into the biophysics of transmitter release and receptor activation, it provides a shortcut for investigating the mechanisms of synaptic signaling modulation. Thus, factors that reduce or increase the presynaptic release of transmitter almost universally affect the average number of quanta released across a population of release sites (the quantal content  $m$ , which is the product of the number of available quanta  $n$ , and their average release probability  $p$ ). Factors that modulate the state of the postsynaptic receptors alter the size of the response to an individual package of neurotransmitter (the quantal amplitude  $Q$ ).

Extrapolation of the quantal model to the central nervous system (CNS) has uncovered some subtle but important differences. Unlike the neuromuscular junction—which is often a long ribbon-like structure with numerous vesicles available to be released—active zones in the CNS tend to be small structures with only a few vesicles in close apposition to the presynaptic membrane (“docked” vesicles). Correspondingly, postsynaptic signals often fluctuate between failures and an amplitude that may reflect the release of only one vesicle (0 or 1 quantum). Moreover, because the peak occupancy of postsynaptic receptors in response to release of a single vesicle may be high (> 50%), release of two vesicles may not yield a signal whose amplitude is twice as large. Nevertheless, some synapses (such as mossy fiber synapses on CA3 pyramidal neurons) have numerous active zones and postsynaptic densities; and at these synapses, multi-quantal release can be detected. Another difference between quantal transmission in the CNS and neuromuscular junction is that different synapses are probably not electrically equivalent: Differences in the number of receptors and degrees of electrotonic attenuation at distinct synapses may conceal any clear quantal increments in the distribution of amplitudes of the postsynaptic signal obtained by repeatedly sampling the connections between pre- and postsynaptic neurons.

Despite the differences in quantal neurotransmission between the CNS and neuromuscular junction, measuring the trial-to-trial fluctuations in the amplitudes of postsynaptic currents or potentials yields a powerful insight into the loci of alterations in synaptic strength. In particular, a change in the fraction of presynaptic stimuli evoking failure of transmission implies an alteration in  $p$  or  $n$ . A more indirect method relies on measuring the trial-to-trial variability of the signal, as estimated by the coefficient of variation (CV: standard deviation/mean). Although the evidence is more circumstantial, changes in CV are again generally associated with alterations in  $p$  or  $n$ . Conversely, if the average size of the postsynaptic response is not associated with a change in either the failure rate or the CV, the simplest inference is that it is mediated by a change in  $Q$ . An important application of quantal analysis is for understanding the mechanisms of the expression of synaptic plasticity, and some of the results and pitfalls of this approach are discussed in Chapter 10.

can be attributed to unjustified assumptions about the underlying mechanisms.

#### 6.2.4 Short-term Plasticity

Implicit in the outline of quantal transmission given above is the assumption that action potentials repeatedly invading a presynaptic terminal trigger neurotransmitter release with a constant probability. In fact, synapses show numerous forms of memory of their activation history. Some of the most inter-

esting forms of synaptic plasticity (long-term potentiation and depression, LTP and LTD, respectively) persist for hours if not longer and are considered in detail in Chapter 10. There are, however, other forms of use-dependent plasticity that last up to a few minutes and that may play an equally important role in the second-to-second traffic of information through synapses. Phenomenologically, they are divided into increases and decreases in transmission: facilitation, augmentation, and potentiation on the one hand and depression on the other (Zucker and Regehr, 2002). There is some redundancy in these

terms. Facilitation describes the enhancement of transmission frequently seen following a preceding action potential. If the synapse is stimulated twice in rapid succession and the second response is larger than the first, the phenomenon is often referred to as “paired pulse facilitation.” Augmentation refers to a gradual increase in synaptic strength with repeated stimulation. Potentiation (often referred to as post-tetanic potentiation to distinguish it from long-term potentiation) requires a high-frequency train of stimuli for its induction and persists for up to a few minutes after the end of the train. Many synapses do not show these phenomena and, instead, depress when repeatedly stimulated. At some hippocampal synapses early facilitation gives way to later depression with prolonged trains of stimulation.

These distinct patterns of short-term plasticity result from a large number of processes occurring principally in the presynaptic terminals (Thomson, 2000; Zucker and Regehr, 2002). The following is an incomplete list of events that contribute to short-term plasticity.

#### 1. Facilitation/augmentation/potentiation

- If the presynaptic free  $\text{Ca}^{2+}$  concentration has not returned to baseline levels or if the occupancy of  $\text{Ca}^{2+}$  buffers is high, successive action potentials may give rise to larger increments of  $\text{Ca}^{2+}$ , thereby enhancing exocytosis.
- High-affinity  $\text{Ca}^{2+}$  sensors detect a slow build-up of  $\text{Ca}^{2+}$  in the presynaptic varicosity and contribute to triggering exocytosis.
- Some presynaptic protein kinases activated with repeated  $\text{Ca}^{2+}$  influx may phosphorylate proteins involved in making vesicles available for exocytosis or in triggering exocytosis itself.

#### 2. Depression

- The readily releasable pool of quanta (possibly equivalent to docked vesicles) may become depleted.
- Repeated depolarizing pulses inactivate presynaptic voltage-dependent  $\text{Ca}^{2+}$  channels, reducing the amount of  $\text{Ca}^{2+}$  entry following successive action potentials.
- Depletion of extracellular  $\text{Ca}^{2+}$  from the restricted synaptic cleft may reduce its availability for the presynaptic terminal.
- Presynaptic autoreceptors activated by released neurotransmitters decrease further transmitter release during subsequent action potentials.

The above list focuses on presynaptic mechanisms that contribute to short-term plasticity. However, postsynaptic mechanisms also contribute. In particular, depolarizing synaptic potentials can summate, leading to activation of regenerative currents in the postsynaptic dendrite. Interactions with dendritic action potentials further complicate the relation between voltage signals measured at the soma and presynaptic transmitter release: Orthodromically or antidromically propagating action potentials can either amplify or shunt synaptic potentials, depending on many

variables, such as their temporal relation and the distribution of voltage-gated channels (Johnston et al., 1996; Larkum et al., 1999; Häusser et al., 2001; Stuart and Häusser, 2001). Nonlinearities in the secondary message cascade may also amplify metabotropic receptor-mediated signals. Another postsynaptic mechanism contributing to the facilitation of some glutamatergic signals is relief from voltage-dependent block of the ion channel by polyamines (Rozov and Burnashev, 1999). Conversely, at some synapses desensitization of receptors can contribute to use-dependent depression of neurotransmission (Brenowitz and Trussell, 2001).

Because principal neurons frequently discharge in bursts of action potentials, the degree of postsynaptic facilitation or depression during such bursts may contain much of the information transmitted through the network. Indeed, it has been argued that lasting changes in short-term plasticity are of greater importance for information encoding than synaptic strength per se (defined as the size of an EPSP or IPSP evoked after an interval sufficiently long for short-term plasticity phenomena to have dissipated) (Markram and Tsodyks, 1996). However, because short-term plasticity is mediated predominantly through use-dependent alteration in release probability, the information contained in a facilitating or depressing burst is inevitably corrupted by the stochastic nature of transmitter release. That is, the degree of facilitation or depression at a synapse can be reliably detected by the network only by averaging out the response to a stereotyped sequence of action potentials repeatedly delivered to the presynaptic neuron. This has led to an almost diametrically opposite view of the importance of bursts: Because high-probability synapses often depress and low-probability synapses often facilitate, the function of bursts is to cancel out the effects of the initial release probability and minimize the sampling error arising from stochastic release. Thus, it is argued that the most important modifiable parameter relevant to information transmission is the quantal amplitude (Lisman, 1997). Against this background, there has recently been considerable interest in the long-term consequences of particular timing patterns of pre- and postsynaptic action potentials. Notably, it has been reported at several cortical synapses that if presynaptic glutamate release occurs shortly before a postsynaptic action potential it can lead to persistent enhancement of transmission. If, on the other hand, the presynaptic stimulus lags behind the postsynaptic action potential, it can be followed by depression of transmission (Bi and Poo, 2001). The mechanisms underlying these phenomena and their relevance to learning are further considered in Chapter 10.

### 6.3 Glutamatergic Synaptic Transmission

The main excitatory transmitter in the hippocampus, as elsewhere in the mammalian CNS, is glutamate. Although the earliest evidence for this was principally obtained in the spinal cord, many important insights have come from work on

rodent hippocampal tissue: Glutamate depolarizes hippocampal neurons (Biscoe and Straughan, 1966), and tritiated glutamate is avidly taken up by areas enriched in synapses (Storm-Mathisen and Iversen, 1979). Moreover, electrical stimulation evokes glutamate release (Dolphin et al., 1982; Walker et al., 1995), and antibodies raised against glutamate stain presynaptic terminals at asymmetrical synapses (Ottersen et al., 1990). Importantly, glutamate activates the three principal types of receptors that mediate ionotropic excitatory transmission:  $\alpha$ -amino-3-hydroxy-5-methyl-isoxazole-propionic acid (AMPA), kainate, and *N*-methyl-D-aspartate (NMDA). Finally, a vesicular glutamate transporter has recently been identified (Bellocchio et al., 2000; Takamori et al., 2000).

Although there is abundant evidence that glutamate mediates fast excitatory transmission at “glutamatergic” synapses, there are persistent reports that aspartate also can be released from hippocampal slices in an activity-dependent manner (Szerb, 1988; Nadler et al., 1990). Aspartate immunoreactivity has also been found in certain presynaptic glutamate-releasing terminals, and the abundance of this signal decreases following intense synaptic activity (Gundersen et al., 1998). Because aspartate is a weak agonist at NMDA receptors (although inactive at AMPA or kainate receptors), these observations raise the possibility that it may be co-released with glutamate. However, aspartate is not taken up effectively by isolated vesi-

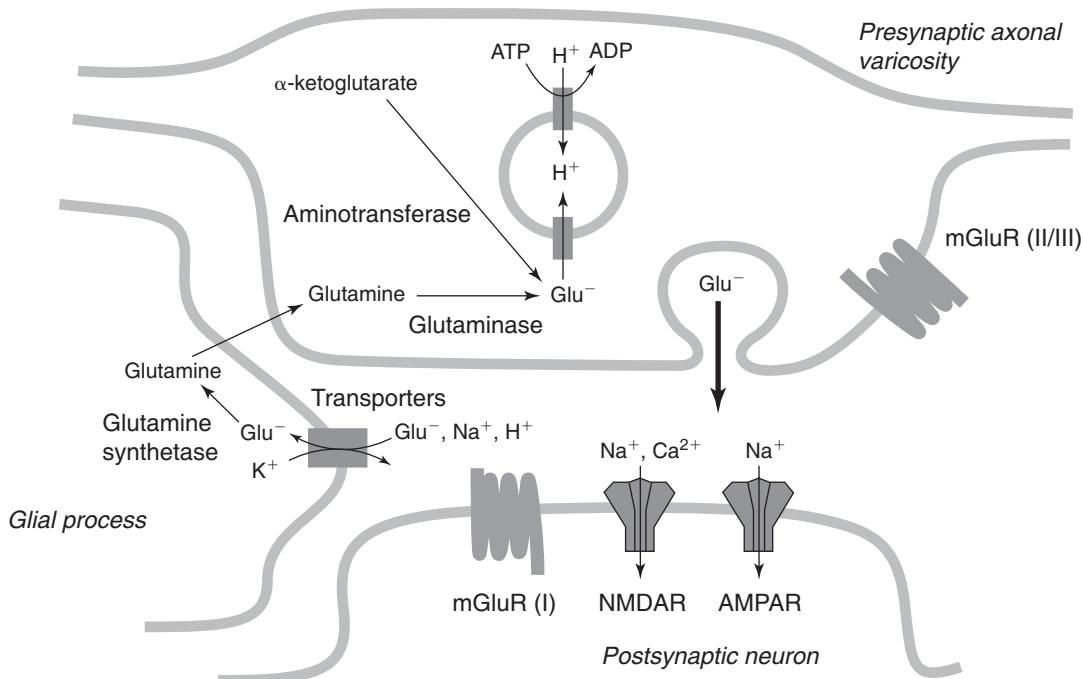

cles, so it is unclear how it could be packaged appropriately to fulfill a role as a fast neurotransmitter.

Following release, glutamate is taken up into neurons and glia, although this process takes place at a much slower rate than passive diffusion away from the release site (see below). Of the cloned glutamate transporters, the most abundant in the rodent hippocampus is GLT (also known as EAAT2), followed by GLAST (EAAT1) and EAAC1 (EAAT3) (Danbolt, 2001). In the hippocampus, GLT and GLAST are almost exclusively expressed in astrocytes. EAAC1 is principally expressed in neurons although at a relatively low level, so it probably contributes relatively little to clearing glutamate following exocytosis. However, it has been proposed to supply glutamate for GABA synthesis in inhibitory boutons (Sepkuty et al., 2002; Mathews and Diamond, 2003).

Glutamate taken up into astrocytes is decarboxylated by glutamine synthetase (Fig. 6–4). The intracellular concentration of glutamate in astrocytes is thereby kept low, which is necessary to make continued uptake of glutamate energetically favorable. The energy required for uptake of glutamate comes from the co-transport of three  $\text{Na}^+$  ions down their electrochemical gradient. In addition, flux measurements have shown that one  $\text{H}^+$  ion accompanies glutamate, and one  $\text{K}^+$  ion is countertransported (Zerangue and Kavanaugh, 1996). Because the net movement of glutamate is dictated by the electrochemical gradients for these other species, it is pos-

**Figure 6–4.** Glutamate–glutamine cycle. The excitatory neurotransmitter glutamate is synthesized from  $\alpha$ -ketoglutarate, which is produced by the Krebs cycle, and recycled from glutamine. Following release, glutamate is taken up by glial cells, where it is rapidly decarboxylated to form glutamine. Glutamine can diffuse across the extracellular space back to presynaptic varicosities. The diagram

also shows the arrangement of several types of glutamate receptors: AMPA and NMDA receptors tend to be located opposite release sites, and group I metabotropic receptors [mGluR (I)] tend to be located in a perisynaptic distribution. Group II and III metabotropic receptors tend to be located presynaptically.

sible to reverse uptake; moreover, evidence exists that such reversed uptake can take place during ischemia, when extracellular  $K^+$  builds up and cells become depolarized because of ATP depletion (Rossi et al., 2000). Because the extracellular accumulation of glutamate can exacerbate depolarization of neurons by acting at glutamate receptors, there is the possibility of triggering a positive feedback loop. This cascade may underlie part of the “excitotoxic” role of glutamate in stroke.

Astrocytic glutamine, formed from decarboxylation of glutamate, can enter metabolic pathways in astrocytes; but it can also diffuse passively down its concentration gradient into the extracellular space, a phenomenon facilitated by several transporters. From here it is taken up into presynaptic terminals, where it can be converted back to glutamate and repackaged into vesicles.

The three major classes of ionotropic glutamate receptors (Table 6–1) take their names from agonists that activate them in a relatively selective fashion (Watkins and Evans, 1981; Nakanishi et al., 1998; Ozawa et al., 1998). These agonists do not normally exist in the brain. At most excitatory hippocampal synapses, EPSCs are mediated by AMPA and NMDA receptors, which have strikingly different biophysical and pharmacological properties. Kainate receptors play a relatively poorly understood role in synaptic transmission. All three receptor types are heteromultimeric structures probably made up of four pore-forming subunits. These subunits are coded for by several genes that show considerable homology and exist in several splice variants, which contribute to defining their kinetic properties. The importance of the molecular variability of the subunits making up each class of receptors is considered further in Chapter 7. Here, we concentrate on the major pharmacological and biophysical differences that exist among the various receptors. Much of the information summarized here has been obtained by studying the behavior of small numbers of receptors present in membrane patches exposed to brief pulses of glutamate and studied with voltage-clamp methods. These patches are taken from the somata of neurons in acute hippocampal slices or in cultures (reflecting

the properties of native, although not necessarily synaptic, receptors) or from cells expressing recombinant receptors.

### 6.3.1 AMPA Receptors

AMPA receptors are composed of different combinations of four subunits (GluR1-4, also known as GluRA-B) (Hollmann et al., 1989; Keinanen et al., 1990; Hollmann and Heinemann, 1994; Nakanishi et al., 1998; Ozawa et al., 1998). They occur at almost all excitatory synapses in the hippocampus and gate a cation-selective channel. At resting membrane potentials,  $Na^+$  influx accounts for most of the current, but the channel is also permeant to other small monovalent cations, so  $K^+$  efflux can also occur at depolarized potentials. Most AMPA receptors in pyramidal neurons of the adult hippocampus (at least in rodents) are thought to be GluR1-2 or GluR2-3 tetramers (Wenthold et al., 1996).

AMPA receptors require a rapid pulse of glutamate in excess of approximately 100  $\mu M$  to open. When a membrane patch taken from the soma or proximal dendrite of a hippocampal neuron is exposed to a pulse of 1 mM glutamate (roughly corresponding to the synaptic glutamate transient; see below) a current is generated with a rapid rise time (100–600  $\mu s$  at physiological temperature). This reflects both very fast binding kinetics and a high opening probability: the peak probability that a bound receptor is in the open state has been estimated at approximately 0.6 (Jonas et al., 1993).

Native AMPA receptors deactivate rapidly following clearance of synaptic glutamate (with a time constant of 2.3–3.0 ms) (Colquhoun et al., 1992). Deactivation is probably sufficient to explain the termination of AMPA receptor-mediated EPSCs on the grounds that glutamate is cleared from the synaptic cleft faster than this. If glutamate is not cleared, however, AMPA receptors close rapidly and enter a desensitized state from which they recover relatively slowly. The time course of desensitization depends on the subunit composition of the receptors and is affected by alternative splicing of the subunit mRNA (so-called flip and flop variants; see

**Table 6–1.**  
**Ionotropic Glutamate Receptors**

Receptor type	Agonists	Subunits	Permeant ions	Examples of antagonists
AMPA ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid)	Glutamate (endogenous), AMPA, kainate	GluR1-4 (GluRA-D)	$Na^+, K^+$ ( $Ca^{2+}$ )	Kynurenic acid 6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX) GYKI53655
Kainate	Glutamate (endogenous), kainate	Glur5-7, KA1,2	$Na^+, K^+$ ( $Ca^{2+}$ )	Kynurenic acid CNQX LY382884 (GluR5-specific)
NMDA ( $N$ -methyl-D-aspartic acid)	Glutamate, glycine, D-serine (endogenous co-agonists), NMDA	NR1, NR2A-D	$Na^+, K^+,$ $Ca^{2+}$	Kynurenic acid D-Aminophosphonovalerate (D-AP5) 3-[(RS)-2-carboxypiperazine-4-yl]-propyl-1-phosphonate (CPP)

Chapter 7), but it usually proceeds with a decay time constant of the order of 5–10 ms) (Mosbacher et al., 1994). AMPA receptors can even desensitize in the presence of glutamate concentrations that are insufficient to open them or if the glutamate concentration rises sufficiently slowly. This form of desensitization may be an adaptation that prevents excessive receptor activation under pathological conditions where extracellular glutamate accumulates. Desensitization may also occur with extremely brief (millisecond) exposure to the agonist, so if a second pulse is applied a smaller response is obtained. However, this phenomenon does not contribute appreciably to frequency-dependent plasticity of transmission in the hippocampus (Hjelmstad et al., 1999).

Depending on their subunit composition, AMPA receptors can also show significant permeability to  $\text{Ca}^{2+}$  ions. This permeability is determined by the presence or absence of a critical amino acid (arginine, R) in a pore-lining segment of the GluR2 subunit. This subunit undergoes post-transcriptional RNA editing resulting in a change of the amino acid at this position from glutamine (Q), encoded by the genomic sequence, to arginine (Sommer et al., 1991). The presence of the edited form of GluR2 ensures that the receptor is impermeable to  $\text{Ca}^{2+}$ , which is the case for most of the glutamate receptors in principal cells. If the GluR2 subunit is absent, the receptor has significant  $\text{Ca}^{2+}$  permeability. Such receptors are present in some hippocampal interneurons (Geiger et al., 1995). In addition, some fetal GluR2 subunits are not edited.

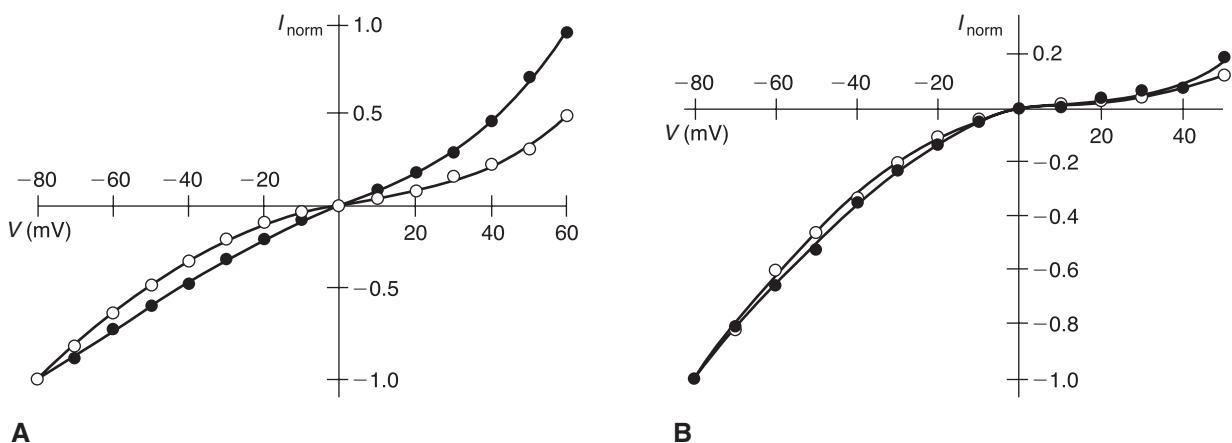

“Q/R editing” has several other consequences for AMPA receptor function (Swanson et al., 1997). If the edited (R)

form of GluR2 is present in the receptor, its conductance is relatively small and is independent of the transmembrane voltage. If the unedited GluR2 is absent from the receptor, the current–voltage relation becomes highly nonlinear (Fig. 6–5). That is, the receptor functions as a rectifier, with a conductance that increases with the transmembrane potential difference. This transition between low- and high-conductance states is due to blockade of the receptor by polyamine molecules, which enter the ion channel but can be expelled in a voltage-dependent manner (Bowie and Mayer, 1995; Donevan and Rogawski, 1995; Kamboj et al., 1995; Koh et al., 1995).

The single-channel conductance of native receptors varies broadly from < 1 pS to approximately 30 pS, depending not only on the presence of GluR2 but also on the identity of other subunits (Swanson et al., 1997). Bound receptors do not remain open continuously. In common with other ligand-gated ion channels, they flicker between open and closed states; and even in their open state they fluctuate among distinct preferred conductance levels. Although most kinetic schemes assume that two glutamate molecules must bind for the receptor to open (Jonas et al., 1993; Diamond and Jahr, 1997), there is little direct experimental data to support this assumption. Indeed, it has been proposed that four binding steps to a tetrameric receptor take place, and that the conductance level of an individual channel increases with the number of glutamate molecules bound (Rosenmund et al., 1998). Both the opening probability and the conductance of the channel can be modulated by phosphorylation (Derkach et al., 1999; Banke et al., 2000), phenomena that may play an important role in synaptic plasticity (see Chapter 10).

**Figure 6–5.** Rectification of unedited GluR2-containing AMPA receptors. A, Current (I)–voltage (V) relationships of glutamate-evoked currents obtained in a cell expressing  $\text{Ca}^{2+}$ -permeable unedited GluR2 (GluRB) subunits. The open circles show a nonlinear, rectifying, I–V relation 1 minute after beginning whole-cell recording. This is explained by a blockade of the ion pore by endogenous polyamines, which is relieved by increasing the voltage gradient across the membrane. Fifteen minutes after beginning the

recording with an intracellular solution devoid of polyamines (filled symbols) the I–V relation becomes more linear, explained by washout of endogenous polyamines from the cytoplasm. B, I–V relation measured with a pipette solution containing 25  $\mu\text{M}$  spermine, an endogenous polyamine. The rectification is more marked and persists despite prolonged recording. (Source: Rozov et al., 1998, with permission.)

### 6.3.2 Kainate Receptors

Kainate receptors share many features with AMPA receptors (Lerma et al., 1997, 2001; Bleakman, 1999; Chittajallu et al., 1999; Ben-Ari and Cossart, 2000; Frerking and Nicoll, 2000; Kullmann, 2001). They too are heteromultimeric, made up of different combinations of five subunits: GluR5-7 and KA1-2. However, not all of these subunits have the same status because receptors made up of KA1 or KA2 alone are nonfunctional. GluR5-6 undergo Q/R editing with similar consequences as for GluR2, although the proportion of edited subunits falls considerably below 100%. This means that the  $\text{Ca}^{2+}$  permeability, single-channel conductance, and rectification of the receptor cannot be inferred easily from the subunit composition.

The biophysical properties of recombinant kainate receptors are similar to those of AMPA receptors. That is, they open and desensitize rapidly, and they have single-channel conductances, rectification properties, and  $\text{Ca}^{2+}$  permeabilities that depend on Q/R editing (Bowie and Mayer, 1995; Kamboj et al., 1995). However, there are some unexplained discrepancies between the relatively low affinity and rapid kinetics of kainate receptors studied in isolated cells and the finding that synaptic kainate receptor-mediated signals exhibit very slow kinetics (Castillo et al., 1997b; Lerma et al., 1997, 2001; Vignes and Collingridge, 1997; Cossart et al., 1998; Frerking et al., 1998). Some kainate receptor-mediated EPSCs can last more than 100 ms, at which time they would have been expected to have deactivated following clearance of glutamate or desensitized if glutamate persisted. Several explanations have been proposed for this discrepancy, including the possibility that synaptic kainate receptors differ from nonsynaptic receptors in their subunit composition because of the actions of accessory proteins or because of site-specific phosphorylation (Garcia et al., 1998). Among other possible explanations for the slow kinetics of kainate receptor-mediated EPSCs is that glutamate needs to diffuse a long distance to reach the receptors, perhaps because they are relatively remote from the site of exocytosis. Finally, synaptic co-release of a modulatory substance might alter the response of kainate receptors to glutamate. Another puzzle is that, although kainate receptors are abundant in the hippocampus, synaptic responses mediated by them are very small and generally require trains of high-frequency stimuli to be detected. Recently, however, relatively fast, apparently monoquantal kainate receptor-mediated EPSCs have been described in interneurons and CA3 pyramidal neurons (Cossart et al., 2002). Why such currents have been overlooked previously is unclear.

Evidence has emerged for a major role of presynaptic kainate receptors in modulating transmitter release (Chittajallu et al., 1996; Rodriguez-Moreno et al., 1997; Vignes et al., 1998; Kamiya and Ozawa, 2000; Cossart et al., 2001; Jiang et al., 2001; Schmitz et al., 2001a), axon excitability (Semyanov and Kullmann, 2001), and synaptic plasticity (Contractor et al., 2001; Lauri et al., 2001). Surprisingly,

kainate receptors at various synapses, activated by different concentrations of agonists, either enhance or depress transmitter release. The mechanisms underlying these phenomena are incompletely understood (Kullmann, 2001) and may include depolarization,  $\text{Ca}^{2+}$  influx via permeable receptors, and coupling to a metabotropic cascade (Rodriguez-Moreno and Lerma, 1998). Controversy also surrounds the subunit composition of the kainate receptors mediating postsynaptic and presynaptic kainate receptor-mediated signaling. Some pharmacological data suggest a major role for GluR5-containing receptors at mossy fibers (Bortolotto et al., 1999; Lauri et al., 2001). However, the results of genetic deletion experiments are more consistent with a role for GluR6-containing receptors at mossy fibers and GluR5-containing receptors on interneurons (Contractor et al., 2000, 2001; Mulle et al., 2000). Although presynaptic kainate receptors exert a powerful influence on synaptic function, the adaptive significance of the enhancement and depression of transmitter release remains a subject of speculation.

### 6.3.3 NMDA Receptors

NMDA receptors consist of subunits belonging to two relatively distinct subtypes (McBain and Mayer, 1994); they exist as heteromultimers of NR1 and NR2A-D subunits. (A recently described NR3 subunit does not appear to play an important role in the hippocampus.) The NR1 subunit is encoded by one gene but exists in several alternatively spliced isoforms. It does not bind glutamate but, instead, contains an important binding site for another amino acid, glycine or D-serine, which acts as a co-agonist (see below). The NR2A-D subunits, on the other hand, contain the glutamate-binding site (Laube et al., 1997). They are encoded by four genes and are variably expressed in different regions of the brain and at different stages of development (see Chapter 7).

NMDA receptors show many striking properties that mark them out as quite different from AMPA and kainate receptors. Notably, they have very slow kinetics and can continue to mediate an ion flux for several hundreds of milliseconds after the glutamate pulse has terminated (activation time constant is approximately 7 ms; deactivation time constants are approximately 200 ms and 1–3 s). The slow kinetics are explained by an extremely slow receptor unbinding rate (Lester et al., 1990). That is, once glutamate molecules have become bound to NMDA receptors, they remain bound for a long time, during which time the ionophore can undergo repeated opening. The maximal probability that a bound receptor is in the open state has been estimated at between 0.05 and 0.3, which is lower than the corresponding probability for AMPA receptors (Jahr, 1992; Rosenmund et al., 1995). The range of estimates reflects alterations in NMDA receptor kinetics as a function of intracellular factors, including  $\text{Ca}^{2+}$  ions. Reflecting the very slow dissociation rate, the apparent affinity of NMDA receptors under steady-state conditions is much higher than that of AMPA receptors (the  $\text{EC}_{50}$  is in the

range of 1–10  $\mu\text{M}$ , instead of 100–500  $\mu\text{M}$ ) (Patneau and Mayer, 1990). This distinction may explain several striking properties of glutamatergic EPSCs (discussed further below). In addition to their slow kinetics, NMDA receptors have three other important features.

First, a second agonist-binding site (the “strychnine-insensitive glycine site”) must be occupied before glutamate is able to activate them (Johnson and Ascher, 1987; Kleckner and Dingledine, 1988). However, some estimates of the tonic extracellular glycine concentration in the brain suggest that the glycine-binding site is normally occupied. Alternatively, D-serine can substitute for glycine, and it has been proposed that this amino acid plays a physiological role in regulating NMDA receptor function (Schell et al., 1995; Baranano et al., 2001).

Second, they are highly permeable to  $\text{Ca}^{2+}$  ions and monovalent cations (Ascher and Nowak, 1988).  $\text{Ca}^{2+}$  influx via NMDA receptors plays a central role in several forms of long-term synaptic plasticity (see Chapter 10).  $\text{Ca}^{2+}$  ions are actually ubiquitous secondary messengers, and NMDA receptor activation has been shown to trigger further release of  $\text{Ca}^{2+}$  from intracellular stores (Emptage et al., 1999). Accompanying the high  $\text{Ca}^{2+}$  permeability of NMDA receptors is a relatively high single-channel conductance (40–50 pS), which is greater than that of most AMPA receptors (Jahr and Stevens, 1987; Gibb and Colquhoun, 1992).

Third,  $\text{Mg}^{2+}$  ions block the ionophore in a voltage-dependent manner (Mayer et al., 1984; Nowak et al., 1984). Thus, at resting membrane potentials (more negative than approximately  $-50$  mV), NMDA receptors are unable to mediate an EPSC even if glutamate and glycine (or D-serine) are present. They mediate an ion flux only when the membrane is depolarized.

The  $\text{Ca}^{2+}$  permeability and  $\text{Mg}^{2+}$  blockade of NMDA receptors explain their role as synaptic coincidence detectors:  $\text{Ca}^{2+}$  influx occurs only if there is a conjunction of presynaptic glutamate release and postsynaptic depolarization, a situation that arises when pre- and postsynaptic activity occur together (Wigstrom and Gustafsson, 1986). The significance of this phenomenon for long-term modification of synaptic strength is addressed in Chapter 10.

#### 6.3.4 Co-localization of Glutamate Receptors

Both AMPA and NMDA receptors are present at a roughly 100-fold higher density at synapses than in extrasynaptic membranes (Bekkers and Stevens, 1989; Nusser et al., 1998; Bolton et al., 2000). However, some synapses may be devoid of AMPA receptors, especially early in postnatal development (Nusser et al., 1998; Takumi et al., 1998; Petralia et al., 1999). Less is known about the subcellular location of kainate receptors because adequate antibodies have not been developed.

Reflecting the co-localization of AMPA and NMDA (and possibly kainate) receptors, EPSCs generally show several pharmacologically, electrophysiologically, and kinetically distinct components (Forsythe and Westbrook, 1988; Hestrin et al., 1990). At most hippocampal synapses, at negative mem-

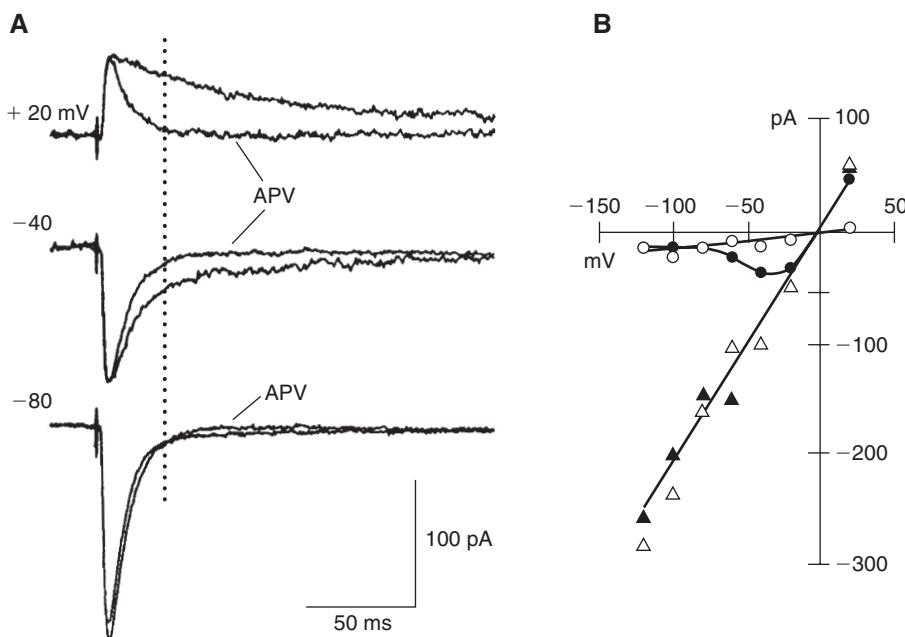

brane potentials, the EPSC has fast kinetics and is blocked by the AMPA/kainate receptor blocker 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). Subsequent studies, taking advantage of more selective AMPA receptor antagonists (in particular the 2,3-benzodiazepine GYKI53655), have established that AMPA receptors account for the fast EPSC at negative potentials. This EPSC is analogous to the fast synaptic current carried by acetylcholine receptors at the neuromuscular junction, which “short-circuits” the transmembrane potential difference. At depolarized membrane potentials, a slower component of the EPSC emerges that is blocked by the NMDA receptor antagonist D-amino-5-phosphonovalerate (APV). This NMDA receptor-mediated current accounts for most of the charge transfer because of the very slow receptor kinetics. Both AMPA and NMDA receptor-mediated components disappear near 0 mV because this represents the reversal potential for the mixture of monovalent cations that account for the bulk of the current. However, a small  $\text{Ca}^{2+}$  influx still occurs at this membrane potential because the reversal potential for  $\text{Ca}^{2+}$  is positive. If the neuron is held at a positive membrane potential, the dual-component EPSC appears again, although it is now an outward current (Fig. 6–6).

Kainate receptors generally do not contribute appreciably to the fast EPSC recorded in principal neurons. However, a low-amplitude kainate receptor-mediated current can be detected in some neurons in response to high-frequency trains of action potentials (especially in CA3 pyramidal neurons in response to mossy fiber stimulation and in some interneurons) (Castillo et al., 1997a; Vignes and Collingridge, 1997; Cossart et al., 1998, 2002). Because it has very slow kinetics, it may account for a sizable fraction of the total charge injected. Although kainate receptor-mediated EPSCs have been described as “synaptic,” it remains to be determined whether they arise from the activation of kainate receptors in synapses rather than by spillover of glutamate onto more remote extrasynaptic receptors.

#### 6.3.5 Metabotropic Glutamate Receptors

Metabotropic receptors contain seven transmembrane segments and are coupled to nucleotide-binding G proteins, which mediate most of their actions. They assemble as dimers, which are thought to be in a dynamic equilibrium between two conformations: Binding of a glutamate molecule stabilizes them in the active state (Kunishima et al., 2000). Metabotropic glutamate receptors fall into three classes, although eight genes have been identified (Pin and Duvoisin, 1995; Ozawa et al., 1998; Schoepp, 2002) (Table 6–2).

Group I receptors ( $\text{mGluR1}$  and 5) are generally localized to postsynaptic membranes and tend to occur in a halo around the synaptic cleft (Baude et al., 1993). They are coupled via G proteins to phospholipase C, and their activation leads to an increase in both inositol trisphosphate and diacylglycerol (Fagni et al., 2000). Activation of these receptors at mossy fiber synapses can elicit a slow EPSP mediated by cation-selective conductance and can trigger  $\text{Ca}^{2+}$  release from intracellular stores (Heuss et al., 1999; Yeckel et al.,

**Figure 6-6.** Dual-component glutamatergic transmission at hippocampal synapses. *A*, EPSCs recorded in a pyramidal neuron at various voltages. As the postsynaptic cell is depolarized, a slow component appears. This slow current is abolished by the NMDA receptor blocker traces marked APV. *B*, Current-voltage (I–V) relation is plotted for the peak of the EPSCs (triangles) and for a later time point indicated by the vertical dotted line in *A*. Filled symbols, control conditions; open symbols, in the presence of APV. The I–V rela-

tion of the APV-sensitive component (circles, measured at a time shown by the dotted line in *A*) shows a region of negative slope (that is, increasing conductance as the cell is depolarized) characteristic of voltage-dependent relief of blockade of NMDA receptors by  $Mg^{2+}$  ions. In contrast, the peak of the EPSC (triangles) has an approximately linear I–V relation because the AMPA receptors in pyramidal neurons mainly contain edited GluR2 subunits. (Source: Hestrin et al., 1990 with permission).

1999). Some responses appear not to involve G proteins, implying that group I receptors may be coupled to other second messenger cascades (Heuss et al., 1999).

Group II (mGluR 2, 3) and group III (mGluR4, 6, 7, 8) receptors tend to be located in presynaptic membranes. At mossy fibers, mGluR2 receptors are located relatively far from glutamate release sites—in axonal membranes—implying that they detect only glutamate molecules that have escaped from the synaptic cleft (Yokoi et al., 1996).

Several group III receptors, on the other hand, tend to be located in synapses, that is, very close to or even within active zones (Shigemoto et al., 1996, 1997). Both types are negatively

coupled to adenylate cyclase via G proteins. The distinction between group II and group III receptors is pharmacological: L-AP4 is a selective agonist at group III, but not group II, receptors. However, the  $EC_{50}$  for L-AP4 differs markedly between the individual receptors in group III, so this classification is somewhat arbitrary (Wu et al., 1998).

The physiological roles of metabotropic receptors are not fully understood. The perisynaptic postsynaptic group I receptors may preferentially respond to trains of action potentials that result in the prolonged presence of glutamate in their vicinity. Indeed, such stimulus patterns have been used to evoke postsynaptic currents and  $Ca^{2+}$  signals mediated by

**Table 6-2.**  
**Metabotropic Glutamate Receptors**

Group	Subtypes	Transduction mechanisms	Agonists	Examples of antagonists
I	mGluR1,5	Phospholipase C ↑	Glutamate, (S)-3,5-dihydroxyphenylglycine (DHPG) 1S,3R-1-aminocyclopentane-1, 3-dicarboxylic acid (1S,3R-ACPD)	3,5-Methyl-4-carboxyphenylglycine (MCPG)
II	mGluR2,3	Adenyl cyclase ↓	Glutamate 1S,3R-ACPD (2S,2'R,3'R)-2-(2',3'-dicarboxycyclopropyl) glycine (DCG-IV)	MCPG LY341495
III	mGluR4,6-8	Adenyl cyclase ↓	Glutamate L-Amino-phosphonobutyrate (L-AP4)	Methylserine-O-phosphate (MSOP)

group I receptors (Heuss et al., 1999; Yeckel et al., 1999). As for group II receptors, their predominantly extrasynaptic presynaptic location implies that they detect the extracellular buildup of glutamate and that they therefore act as autoreceptors that regulate neurotransmitter release as a function of the volume-averaged excitatory traffic (Scanziani et al., 1997). The intrasynaptic presynaptic location of some group III receptors prompts the speculation that they act as autoreceptors on a smaller spatial scale. However, they are also present at some GABAergic terminals (Shigemoto et al., 1997), which are not known to release glutamate. There is evidence that they detect glutamate released from neighboring synapses (Semyanov and Kullmann, 2000), so their role may be akin to that of group II receptors.

### 6.3.6 Receptor Targeting and Anchoring

A major challenge is to understand how receptors are targeted and anchored to postsynaptic densities and how they are trafficked to and from the synapse. These issues are considered from a molecular perspective in Chapter 7. AMPA receptor insertion plays a major role in synapse maturation and long-term potentiation (further considered in Chapter 10). Briefly, considerable evidence is emerging for two types of interaction between AMPA receptor subunits and intracellular proteins involved in trafficking (Shi et al., 2001). One process is mediated by an interaction between the cytoplasmic C-termini of GluR1 (and possibly GluR4) subunits with protein(s) containing a consensus motif known as a PDZ domain (see Chapter 7). This process is triggered by activation of  $\text{Ca}^{2+}$ -calmodulin-dependent protein kinase II (CaMKII) and contributes to long-term potentiation. Another process involves an interaction between the C-terminus of GluR2 subunits and both NSF (the ATPase involved in dissociating the SNARE core complex; see above) and PDZ proteins.

NMDA receptors are anchored to a large number of scaffolding, signaling, and transduction proteins (Husi et al., 2000; Sheng and Sala, 2001). This anchoring is mediated via an interaction between the C-termini of NR2 subunits and several PDZ domain proteins, in particular PSD-95 and SAP97. Some group I metabotropic glutamate receptors are also anchored via a PDZ domain protein, Homer (Brakeman et al., 1997). Relatively less is known of the mechanisms that target and/or anchor other metabotropic receptors: One splice variant of mGluR7 interacts with another intracellular protein, PICK1 (Perroy et al., 2002), but how other receptors are localized to presynaptic terminals is unclear.

## 6.4 GABAergic Synaptic Transmission

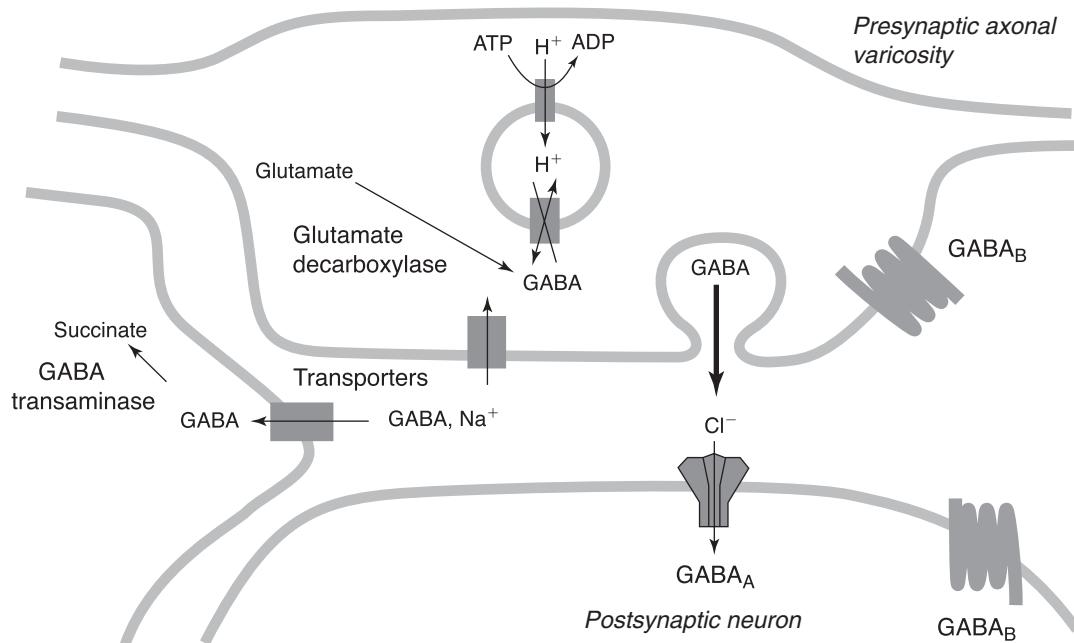

The major inhibitory transmitter GABA is synthesized by decarboxylation of glutamate. Two isoforms of glutamic acid decarboxylase exist. GAD67 is widespread in the cytoplasm, whereas GAD65 is more closely associated with presynaptic

terminals of GABAergic neurons. Its expression varies in response to changes in neuronal activity, implying that it may play a regulatory role in GABAergic transmission (Soghomonian and Martin, 1998). Uptake into vesicles is facilitated by the vesicular GABA transporter VGAT, which can also mediate vesicular glycine transport, although this enzyme may not be essential for vesicular GABA accumulation because it is absent from a subset of GABAergic terminals (Chaudhry et al., 1998). Following exocytosis, GABA diffuses out of the synaptic cleft and is taken up by a family of four transporters: GAT1-4 (Schousboe, 2000) (Fig. 6–7). These transporters are located not only in astrocytes but also in interneurons and principal cells. GABA uptake is electrogenic; that is, the amino acid is transported together with two  $\text{Na}^+$  ions (and possibly one  $\text{Cl}^-$  ion) (Kavanaugh et al., 1992; Cammack et al., 1994). This stoichiometry normally ensures that GABA is taken up into cells because the driving force provided by the  $\text{Na}^+$  electrochemical gradient is sufficient to overcome the gradient for GABA. However, because the transport stoichiometry is less electrogenic than for glutamate, it has been suggested that GABA uptake can be reversed when cells are depolarized (Richerson and Wu, 2003). The various GABA transporters show some differences in localization and substrate specificity: For instance, GAT1 is relatively abundant in neurons and is relatively insensitive to  $\beta$ -alanine compared to the other major transporter GAT3. Although GABA transport shows many similarities with glutamate uptake, there are suggestions that it may be less efficient, either because individual transporters function more slowly or because they are present in a lower concentration. In particular, synaptically released GABA appears to exert actions at high-affinity, remotely located receptors; and GABA escaping from the synaptic cleft can even be detected by recording from a membrane patch containing  $\text{GABA}_A$  receptors positioned on the surface of a slice (Isaacson et al., 1993). In contrast, although glutamate also exerts extrasynaptic actions, they are spatially much more restricted (see below).

GABA receptors are divided into ionotropic ( $\text{GABA}_A$ ) and metabotropic ( $\text{GABA}_B$ ) receptors (Table 6–3).  $\text{GABA}_C$  receptors are ionotropic receptors with an unusual pharmacological profile and are made up of  $\rho$  subunits. They are arguably a variant of  $\text{GABA}_A$  receptors (Barnard et al., 1998; Bormann, 2000). Because they are not known to play a major role in the hippocampus, they are not considered here.

### 6.4.1 $\text{GABA}_A$ Receptors

$\text{GABA}_A$  receptors are heteropentameric, and consist of subunits drawn from at least 7 different families:  $\alpha_{1-6}$ ,  $\beta_{1-3}$ ,  $\gamma_{1-3}$ ,  $\delta$ ,  $\epsilon$ ,  $\pi$ , and  $\theta$  (Mehta and Ticku, 1999). Of these,  $\alpha_6$ ,  $\epsilon$ ,  $\pi$ , and  $\theta$  appear to be excluded from the rodent hippocampus or to occur at very low levels. The remaining subunits show differential distributions at a macroscopic level. Thus,  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_4$ ,  $\beta_3$ ,  $\gamma_2$ , and  $\delta$  are present in the dentate gyrus. In the hippocampus proper, the principal subunits are  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_5$ ,  $\beta_3$ , and  $\gamma_2$ , with relatively lower levels of  $\alpha_4$ ,  $\beta_1$ ,  $\beta_2$ ,  $\gamma_3$ , and  $\delta$ ;  $\alpha_3$  and  $\gamma_1$  are

**Figure 6–7.** GABA cycle. The inhibitory neurotransmitter GABA is synthesized from glutamate via the action of two enzymes, GAD-65 and GAD-67. Following release, GABA is taken up by both neurons and glial cells. GABA can be converted back to glutamate or to succinate by the mitochondrial enzyme GABA transaminase. The dia-

gram also shows the arrangement of GABA<sub>A</sub> and GABA<sub>B</sub> receptors. Ionotropic GABA<sub>A</sub> receptors tend to be located opposite release sites, although extrasynaptic receptors also occur in dentate granule cells. GABA<sub>B</sub> receptors occur both pre- and postsynaptically.

present only at very low levels (Sperk et al., 1997). Most hippocampal GABA<sub>A</sub> receptors probably contain two  $\alpha$  subunits and two  $\beta$  subunits, together with either a  $\gamma$  subunit or the  $\delta$  subunit but not both (Chang et al., 1996; Farrar et al., 1999; Whiting et al., 1999). The  $\alpha$  subunits in particular play important roles in determining the affinity for GABA and the sensitivity to numerous modulatory agents such as Zn<sup>2+</sup> ions, steroids, ethanol, and exogenous pharmacological agents such as benzodiazepines, barbiturates, and general anesthetics (Barnard et al., 1998). The  $\gamma$  subunits also affect several of these parameters and, in addition, mediate anchoring of GABA<sub>A</sub> receptors to synapses via an indirect interaction with gephyrin, a scaffolding protein that plays an important role in the formation and stabilization of both GABAergic and glycinergic synapses (Essrich et al., 1998). The  $\delta$ -containing

receptors tend not to be confined to synapses but have a high affinity for GABA and are relatively insensitive to benzodiazepines. These  $\delta$ -containing receptors are strong candidates for mediating a GABA<sub>A</sub> receptor-dependent tonic inhibition in dentate granule cells (Overstreet and Westbrook, 2001; Nusser and Mody, 2002). The  $\alpha_4\beta_2\delta$  receptors have recently been shown to be strongly potentiated by ethanol at low concentrations, making them a candidate for some of the psychotropic properties of this drug (Sundstrom-Poromaa et al., 2002).

GABA<sub>A</sub> receptor-mediated IPSCs have a fast onset, although their decay is generally slower than that of AMPA receptor-mediated EPSCs. Their single-channel conductance is highly variable, ranging from < 1 to > 30 pS, depending on their subunit composition.

**Table 6–3.**  
**GABA receptors**

Receptor type	Subunits	Ions	Agonists	Antagonists	Modulators
GABA <sub>A</sub>	$\alpha_{1-6}$ , $\beta_{1-3}$ , $\gamma_{1-3}$ , $\delta$ , $\epsilon$ , $\pi$ , $\theta$	Cl <sup>-</sup> , HCO <sub>3</sub> <sup>-</sup> (ion channel)	GABA Muscimol	Picrotoxin Bicuculline SR 95531	Benzodiazepines, barbiturates, Zn <sup>2+</sup> , ethanol, neurosteroids
GABA <sub>B</sub>	GBR1 GBR2	G protein-gated inward rectifying K <sup>+</sup> (GIRK) channels ↑ Ca <sup>2+</sup> channels ↓	GABA Baclofen	Saclofen CGP35348	

Depending on the subunit composition, benzodiazepines enhance the affinity of GABA<sub>A</sub> receptors for the agonist. This causes prolongation of the IPSC and also usually increases the peak amplitude, implying that the occupancy of the receptors is normally incomplete (Perrais and Ropert, 1999; Hajos et al., 2000). However, because benzodiazepines can, in addition, increase single-channel conductance (Eghbali et al., 1997), estimating the occupancy of receptors from their effects on IPSC amplitude is problematic. Barbiturates, on the other hand, enhance and prolong the IPSC by increasing the proportion of the time that GABA-ligated channels remain open (Study and Barker, 1981). Both these classes of drugs have the effect of potentiating GABAergic transmission, possibly accounting for their usefulness as sedative, anxiolytic, and antiepileptic agents. Combined genetic and pharmacological manipulation of the receptors has suggested that  $\alpha_1$ -containing receptors preferentially mediate the sedative, but not the anxiolytic, effects of systemic benzodiazepines (Rudolph et al., 1999), although whether and how the hippocampal formation contributes to these phenomena remains to be determined.

GABA<sub>A</sub> receptors are permeable only to anions. The current is carried overwhelmingly by Cl<sup>-</sup> ions, but receptors are also permeable to HCO<sub>3</sub><sup>-</sup> ions (Kaila, 1994). Because neurons are normally depolarized relative to the Cl<sup>-</sup> reversal potential, GABA<sub>A</sub> receptor-mediated IPSCs are generally hyperpolarizing. The situation is different in neurons at early stages of development (Ben-Ari et al., 1989). The intracellular Cl<sup>-</sup> concentration is relatively high because the principal extrusion mechanism (the K<sup>+</sup>/Cl<sup>-</sup> co-transporter KCC2) is not expressed abundantly (Rivera et al., 1999). The electrochemical gradient then dictates that Cl<sup>-</sup> ions flow out of the cell, making the current depolarizing. Somewhat confusingly, this is sometimes referred to as a “depolarizing IPSC.” Such depolarizing GABAergic signals can bring neurons to firing threshold and trigger Ca<sup>2+</sup> influx, and they may play an important role in the early stages of neural circuit formation (Ben-Ari et al., 1997). An analogous depolarizing response to GABA has also been observed in response to exogenous agonist application to the dendrites of pyramidal neurons in acute slices taken from adult brains (Andersen et al., 1980a). A major mechanism underlying this phenomenon is that prolonged and intense activation of GABA<sub>A</sub> receptors results in accumulation of intracellular Cl<sup>-</sup>, which eventually alters the reversal potential for the receptors (Staley et al., 1995). In addition, because GABA<sub>A</sub> receptors have a significant permeability to HCO<sub>3</sub><sup>-</sup>, alterations in the electrochemical gradient for this anion can contribute to the phenomenon. Extracellular K<sup>+</sup> also accumulates through the action of KCC2, further contributing to neuronal depolarization (Kaila et al., 1997). Although depolarizing responses can be achieved by iontophoretic application of GABA and possibly during seizures (Bracci et al., 2001), it is not clear that they occur with synaptic activity under physiological conditions in adult animals, which generally activates only a small proportion of the receptors on a neuron and for a short time.

#### 6.4.2 GABA<sub>B</sub> Receptors

Metabotropic GABA<sub>B</sub> receptors occur as heterodimers composed of GBR<sub>1</sub> and GBR<sub>2</sub> (Jones et al., 1998), both of which can undergo alternative splicing (Kuner et al., 1999). GABA<sub>B</sub> receptors are widespread at both pre- and postsynaptic elements of synapses and also in extrasynaptic membranes (Fritschy et al., 1999). The GABA<sub>B</sub> receptor agonist baclofen powerfully depresses the synaptic release of both glutamate and GABA, so the presynaptic targeting of GABA<sub>B</sub> receptors and/or their linkage to effector mechanisms is presumably not confined to GABAergic terminals. Conversely, some GABAergic terminals appear to be insensitive to baclofen (Lambert and Wilson, 1993). Among possible explanations for this finding are the absence of receptors at some terminals and heterogeneity in the identity of the presynaptic Ca<sup>2+</sup> channels (see above).

GABA<sub>B</sub> receptors in the presynaptic membrane are negatively coupled to N- and P/Q-type Ca<sup>2+</sup> channels via a G-protein cascade (Anwyl, 1991; Mintz and Bean, 1993), although this may not account entirely for their effect on transmitter release (Capogna et al., 1996). On the postsynaptic side, the GABA<sub>B</sub>-triggered cascade leads to the opening of G protein-gated inward-rectifying K<sup>+</sup> (GIRK) channels (Andrade et al., 1986; Misgeld et al., 1995). Activation of these channels causes a slow IPSP, lasting several hundred milliseconds. This is easily distinguished from the GABA<sub>A</sub> receptor-mediated IPSP, not only because of its slow kinetics but also because it is independent of the Cl<sup>-</sup> reversal potential.

In contrast to GABA<sub>A</sub> receptor-mediated IPSCs, it has proved difficult to elicit GABA<sub>B</sub> receptor-mediated synaptic responses by activating individual presynaptic neurons. This observation is difficult to reconcile with data that GABA<sub>B</sub> receptors generally have a higher affinity for GABA than do GABA<sub>A</sub> receptors. A possible resolution of the paradox is that the receptors are principally extrasynaptic, and that GABA released from multiple presynaptic terminals must accumulate to activate them (Destexhe and Sejnowski, 1995; Scanziani, 2000). This argument suggests that uptake mechanisms are insufficient to isolate GABAergic terminals functionally from one another, at least as far as high affinity GABA<sub>B</sub> receptors are concerned.

#### 6.5 Other Neurotransmitters

In comparison with glutamate and GABA, other neurotransmitters are present at far fewer synapses. Some of them appear to carry a diffuse signal in the extracellular space and may therefore play extensive roles in determining the overall state of the hippocampal circuitry. Relatively little is known about the mechanisms underlying their release and postsynaptic actions.

ATP is thought to be co-released with other neurotransmitters, and activates ionotropic P<sub>2X</sub> receptors linked to a

cation-selective channel. In the presence of broad-spectrum antagonists of amino acid receptors, a fast depolarizing purinergic postsynaptic current has been reported in hippocampal neurons (Pankratov et al., 1998; Mori et al., 2001). However, to detect such a current it is often necessary to stimulate many presynaptic fibers synchronously, implying that the receptors are present in very low density or that little ATP is released. The physiological or pathological role of this class of receptors is not known. ATP undergoes extracellular enzymatic degradation, which eventually results in the formation of adenosine. Adenosine is probably also released by neurons directly, and extracellular adenosine accumulation occurs under conditions of metabolic stress. Presynaptic adenosine receptors (mainly A<sub>1</sub> in the hippocampus) are widespread on excitatory terminals, where they depress glutamate release via a G protein-dependent mechanism (Wu and Saggau, 1994). This phenomenon contributes to the potent depressant effect of hypoxia on excitatory synaptic transmission. GABA release is relatively less sensitive to adenosine (Yoon and Rothman, 1991; Lambert and Wilson, 1993).

Among other small molecules that act as neurotransmitters are the monoamines noradrenaline (norepinephrine), dopamine (DA), serotonin (5-HT), and histamine (Nicoll et al., 1990). Norepinephrine acts at metabotropic β-adrenergic receptors, serotonin activates both ionotropic depolarizing 5-HT<sub>3</sub> receptors and a large number of metabotropic receptors, and histamine acts at metabotropic H<sub>1-3</sub> receptors. The monoamines tend to be released from varicosities of extrinsic afferent fibers, mainly originating in hindbrain structures. Norepinephrine, acting via β receptors, increases the action potential frequency and reduces spike frequency adaptation during continued depolarizing current injection (Madison and Nicoll, 1982, 1984). This effect is mediated by a relatively selective inhibition of Ca<sup>2+</sup>-gated K<sup>+</sup> channels responsible for the slow after-hyperpolarization following an action potential (Haas and Konnerth, 1983) and requires a signaling cascade involving protein kinase A (Pedarzani and Storm, 1993). Serotonin and histamine have effects similar to those of norepinephrine but, in addition, exert other actions. Serotonin, in particular, activates GIRK channels (Andrade et al., 1986). The role of the ionotropic 5-HT<sub>3</sub> receptors is poorly understood. Histamine has been reported to enhance NMDA receptor-mediated currents (Bekkers, 1993).

The hippocampus receives dopaminergic projections from both the substantia nigra pars compacta and the ventral tegmental area. Dopamine acts at two groups of metabotropic receptors (Sealfon and Olanow, 2000). D1-like receptors (D1 and D5) are positively coupled to adenylate cyclase, which activates protein kinase A and leads to phosphorylation of the protein phosphatase inhibitor DARPP-32, whereas D2-like receptors (D2, D3, D4) are negatively coupled to this cascade. Transcripts for all of these receptors can be detected in the hippocampus. Relatively little is known about the synaptic function of this transmitter. Exogenous dopamine hyperpolarizes a proportion of pyramidal neurons, an action that is principally mediated by D1 receptors (Berretta et al., 1990).

However, whether this is relevant to the role of endogenous dopamine depends on how and where it is released, which remains to be determined. An alternative possibility is that the main role of dopamine is to modulate synaptic transmission. Such a possibility is prompted by analogy with the effects of dopamine in the striatum, which receives a much stronger projection from the substantia nigra. In this system, dopaminergic projections terminate on the necks of dendritic spines that receive glutamatergic terminals (Kotter, 1994). Activation of such dopamine receptors results in inhibition of EPSCs (Calabresi et al., 1997), an action that has also been reported at some hippocampal synapses (Otmakhova and Lisman, 1999).

Acetylcholine is also released from extrinsic afferents, although in this case their cell bodies lie in diencephalic structures, in particular the medial septal nuclei and the nucleus of the diagonal band (see Chapter 3). Acetylcholine acts on both ionotropic (nicotinic) and metabotropic (muscarinic) receptors.

Nicotinic receptors are pentameric, and two main types occur in the hippocampus: homomeric α<sub>7</sub> and heteromeric α<sub>4</sub>β<sub>2</sub>. These receptors can be distinguished by their affinity for acetylcholine, by the desensitization kinetics, and by selective agonists and antagonists. Homopentameric α<sub>7</sub> receptors have a lower affinity for the endogenous agonist than do α<sub>4</sub>β<sub>2</sub> receptors, desensitize fast, and are inhibited by methylacacetone (MLA) and α-bungarotoxin. Activation of these receptors by exogenous agonist application has been reported to enhance evoked glutamate and GABA release (McGehee et al., 1995; Albuquerque et al., 1997; Dani, 2001). This observation implies that they are located presynaptically (MacDermott et al., 1999), a conclusion that has recently been supported by immunohistochemical evidence for abundant α-bungarotoxin staining co-localized with both glutamatergic and GABAergic terminals in the hippocampus (Fabian-Fine et al., 2001). However, postsynaptic staining was also seen in this study. Heteromeric α<sub>4</sub>β<sub>2</sub> receptors have a relatively higher affinity for acetylcholine and nicotine, desensitize slowly, and are antagonized by dihydro-β-erythroidine and mecamylamine. Activation of these receptors has been reported to depolarize a subset of neocortical interneurons (Porter et al., 1999). A major limitation of these studies is that they have mainly relied on application of exogenous agonists. Thus, although they shed light on possible mechanisms of action of nicotine, it is not known under what conditions endogenously released acetylcholine is able to activate these receptors.

Four muscarinic receptors (M<sub>1-4</sub>) are found in the hippocampus. Activation of muscarinic receptors has several effects. The so-called M current is active at resting potentials (Brown and Adams, 1980) and is inhibited by muscarinic receptor agonists, thereby facilitating burst-firing of neurons. It is mediated at least in part by heteromultimeric K<sup>+</sup> channels containing KCNQ2 and KCNQ3 subunits (Wang et al., 1998; Selyanko et al., 1999; Shapiro et al., 2000). Muscarinic receptors have recently been reported to influence the M current by activation of phospholipase C, which leads to the breakdown

of phosphatidylinositol-4,5-bisphosphate (Suh and Hille, 2002). The depolarizing actions of muscarinic agonists are especially prominent in some interneurons (Pitler and Alger, 1992; Behrends and ten Bruggencate, 1993). This phenomenon may also play an important role in generating the hippocampal  $\theta$  rhythm (Fischer et al., 1999), although the precise synaptic and nonsynaptic mechanisms underlying this rhythm *in vivo* are far from clear (see Chapter 8). Other consequences of muscarinic receptor activation include prolongation of action potential duration (Figenschou et al., 1996) and activation of GIRK channels (Seeger and Alzheimer, 2001). The inhibition of  $\text{Ca}^{2+}$ -sensitive  $\text{K}^+$  channels by muscarinic receptors is reminiscent of the effect of  $\beta$  receptor activation by norepinephrine (see above). However, this action of muscarinic receptors is mediated not by protein kinase A but by  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase II (Pedarzani and Storm, 1996). Muscarinic receptors also exist presynaptically, where they depress transmitter release (Behrends and ten Bruggencate, 1993). This action is likely to be mediated by G protein-mediated inhibition of  $\text{Ca}^{2+}$  channels. Again, the physiological role of this effect is unknown.

In contrast to the amino acids glutamate and GABA, several of the transmitters considered in this section tend not to subserve conventional point-to-point (or “wiring”) transmission. Instead, they probably act principally by diffusing a relatively long distance from the axonal varicosities where they are released. Indeed, many such varicosities exist in the absence of identifiable postsynaptic structures. Although this principle would argue against an important role in the fast transmission of information through the hippocampal formation, these transmitters actually play crucial roles in regulating the excitability of the circuitry. The involvement of the cholinergic projection to the hippocampus in setting the theta rhythm is an important example of such a phenomenon (see Chapters 8 and 11).

A large number of peptides have also been shown to exist in axonal varicosities and to bind to specific receptors in the hippocampus (Hökfelt et al., 1980). They include the opioid peptides, somatostatin, neuropeptide Y, galanin, and cholecystokinin. Of these, the opioid peptides (enkephalins, endorphins, dynorphin, endomorphins) have been studied most extensively. They act at receptors that fall into three classes with distinct pharmacological profiles ( $\kappa$ ,  $\delta$ ,  $\mu$ ), although there is evidence that these receptors can heterodimerize (Jordan and Devi, 1999).

Peptides are thought to be contained in dense-core vesicles, which occur in GABAergic synapses and at mossy fiber synapses. Many peptides probably act principally via spillover to modulate either pre- or postsynaptic metabotropic receptors in the vicinity of the site where they are released (Weisskopf et al., 1993; Simmons and Chavkin, 1996).

Recently, brain-derived neurotrophic factor (BDNF) applied to hippocampal neurons was shown to evoke fast depolarizing currents mediated by an interaction between the TrkB receptor and  $\text{Na}_{\text{v}1.9}$   $\text{Na}^+$  channels (Blum et al., 2002). This finding is unexpected, not least because peptides gener-

ally exert only indirect control over membrane potentials via G proteins. Before BDNF is elevated to the rank of neurotransmitters, it is important to determine whether endogenous BDNF can evoke the same effect.

Some molecules have an uncertain status as neurotransmitters in the hippocampus. Glycine receptors occur in the hippocampus, where they open  $\text{Cl}^-$  conductance. However, glycinergic synaptic transmission has not been demonstrated (in contrast to the spinal cord). The amino acids taurine and  $\beta$ -alanine have recently been proposed to act as endogenous agonists at glycine receptors, although it is unclear whether they can be released in an activity-dependent manner (Mori et al., 2002).

The  $\text{Zn}^{2+}$  ion is associated with synaptic vesicles of glutamatergic synapses throughout the hippocampus but is especially prominent in mossy fibers.  $\text{Zn}^{2+}$  inhibits GABA<sub>A</sub> and NMDA receptors, as well as glutamate uptake, although it is unclear whether this occurs during synaptic transmission under physiological conditions (Draguhn et al., 1990; Smart et al., 1994; Spiridon et al., 1998; Frederickson et al., 2000; Vogt et al., 2000). The dipeptide *N*-acetylaspartate may also be released from presynaptic terminals and acts as an agonist at metabotropic glutamate receptors (Wroblewska et al., 1993).

Nitric oxide (NO) and carbon monoxide (CO) deserve mention, although they do not appear to function as synaptic neurotransmitters in the conventional sense. NO is synthesized in neurons expressing nitric oxide synthase (principally a subset of interneurons) in a  $\text{Ca}^{2+}$ -dependent manner and diffuses through membranes to its targets, which include soluble guanylyl cyclase (Baranano et al., 2001). This agent potentially acts as a retrograde messenger, but evidence to support this—let alone to indicate a physiological role for the phenomenon—is scanty.

Products of lipid metabolism may also play a role in intercellular communication. Notable among these products are arachidonic acid (AA) (Piomelli, 1994), and the endocannabinoids anandamide and 2-arachidonylglycerol (Davies et al., 2002). Both AA and endocannabinoids are synthesized in a  $\text{Ca}^{2+}$ -dependent manner and are potential retrograde messengers. The role of endocannabinoid signaling in modulation of inhibition is considered further below.

## 6.6 Special Features of Individual Hippocampal Synapses

In contrast to the neuromuscular junction, hippocampal synapses usually occur at axonal varicosities (the widely used term “terminal” is thus misleading). These varicosities occur at regular intervals along many axons. Their spacing is approximately 4  $\mu\text{m}$  for Schaffer collaterals and associational-commissural fibers and approximately 5  $\mu\text{m}$  for mossy fibers (Shepherd et al., 2002) (see Chapter 3). They often contain mitochondria, reflecting the energetic demands of transmitter

synthesis, vesicular packaging, release, and re-endocytosis (Shepherd and Harris, 1998).

Only one type of axo-axonic synapse is known in the hippocampus: the GABAergic synapse made by chandelier cells on axon initial segments (see Chapters 3 and 8). In contrast to the spinal cord, presynaptic specializations have not been reported in contact with distal axons or axonal varicosities. It can thus be inferred that heterosynaptic modulation of transmitter release by activation of metabotropic receptors occurs via spillover transmission (see below).

### 6.6.1 Small Excitatory Spine Synapses

The most abundant type of synapse in the hippocampus is the small glutamatergic synapse made on dendritic spines. This subserves transmission from the perforant path to dentate granule cells, as well as associational/commissural projections to CA3 pyramidal neurons and Schaffer collateral/commissural transmission to CA1 pyramidal neurons. The monosynaptic projection from the perforant path to the distal dendrites of CA1 and CA3 pyramidal neurons has received less attention but probably has broadly similar biophysical properties (Berzhanskaya et al., 1998; Otmakhova et al., 2002). Similar synapses relay excitatory signals from CA1 pyramidal neurons to subiculum pyramidal cells and from the latter to the entorhinal cortex. Just over half of the presynaptic varicosities in CA1 appear to contain mitochondria (Shepherd and Harris, 1998). The postsynaptic densities range widely in area: from less than  $0.07 \mu\text{m}^2$  at synapses on thin spines to at least  $0.42 \mu\text{m}^2$  (Harris and Sultan, 1995). Dendritic spines in the dentate gyrus measure up to  $0.8 \mu\text{m}$  in diameter and approximately  $1 \mu\text{m}$  in length (Trommald and Hulleberg, 1997), and generally receive only one presynaptic bouton. However, the presynaptic varicosity is sometimes in synaptic contact with more than one spine (Westrum and Blackstad, 1962; Sorra and Harris, 1993). Spines are thought to represent principally biochemical compartments rather than electrical barriers or amplifiers for the propagation of synaptic currents to the dendrite (Yuste et al., 2000).

The synaptic cleft is often closely apposed by an astrocytic process, although this is highly variable: In one study as few as 57% of glutamatergic synapses in CA1 were contacted, and of these only approximately 43% of the perimeter of the synaptic cleft was found to be bounded by an astrocytic process (Ventura and Harris, 1999). Because astrocytes express abundant glutamate transporters, this implies that there may be considerable variability in the spatiotemporal profile of glutamate in the vicinity of the synapse following exocytosis.

A combination of immunohistochemical and ultrastructural techniques has shown that both AMPA and NMDA receptors are localized to the postsynaptic density (Nusser et al., 1998; Takumi et al., 1998, 1999; Racca et al., 2000). Whether kainate receptors are also present is not known. However, glutamatergic EPSCs at Schaffer collateral–CA1 synapses are entirely blocked by antagonists of AMPA and NMDA receptors, leaving little room for the involvement of

postsynaptic kainate receptors (Castillo et al., 1997b; Vignes and Collingridge, 1997). The AMPA receptors at small spine synapses on principal neurons have a low permeability to  $\text{Ca}^{2+}$  and are nonrectifying, reflecting the presence of edited GluR2 subunits in almost all receptors (Jonas et al., 1994). Most AMPA receptors are thought to be GluR1/2 and GluR2/3 heteromers (Wenthold et al., 1996).  $\text{Ca}^{2+}$  influx, however, occurs as an indirect consequence of AMPA receptor activation because the consequent depolarization allows  $\text{Ca}^{2+}$ -permeable NMDA receptors to open (Yuste et al., 1999). In addition, the depolarization allows voltage-gated  $\text{Ca}^{2+}$  channels in the dendritic spine and nearby region of the dendrite to open. A final source of  $\text{Ca}^{2+}$  is from intracellular stores, triggered by second messengers including inositol trisphosphate and  $\text{Ca}^{2+}$  itself (Emptage et al., 1999). However, the latter is controversial as some studies have not found a substantial role for  $\text{Ca}^{2+}$  release from stores at these synapses (Kovalchuk et al., 2000). Some of the disagreement about the relative importance of the various sources of  $\text{Ca}^{2+}$  probably reflects differences in recording methods: Although whole-cell recordings allow voltage control of the dendrite, they may interfere with intracellular  $\text{Ca}^{2+}$  homeostasis. Intracellular microelectrode recordings, though minimizing this source of error, sacrifice voltage control.

Although AMPA and NMDA receptors both contribute to EPSCs evoked by simultaneous stimulation of numerous presynaptic fibers, EPSCs evoked by action potentials in single presynaptic axons sometimes lack an AMPA receptor-mediated component (Kullmann, 1994; Isaac et al., 1995; Liao et al., 1995). Such EPSCs are evoked only under conditions where the postsynaptic neuron is depolarized or  $\text{Mg}^{2+}$  ions are omitted from the extracellular solution to reveal the NMDA receptor-mediated component. This observation has led to the hypothesis that AMPA receptors are absent or nonfunctional at a proportion of synapses, which are consequently often referred to as “silent synapses.” Immunohistochemical studies provide some indirect support for this hypothesis: Some small and/or immature synapses appear not to stain for AMPA receptors (Nusser et al., 1998; Petralia et al., 1999; Takumi et al., 1999). However, given the finite sensitivity of the antibodies, inferring that the receptors are genuinely absent relies on extrapolation. In contrast, NMDA receptor density appears to be more uniform across synapses of different size (Racca et al., 2000). Taken together with the observation that the proportion of silent synapses diminishes with age, it is tempting to conclude that synaptic maturation develops by an initial expression of NMDA receptors, followed later by insertion of AMPA receptors (Durand et al., 1996). This phenomenon may share mechanisms in common with long-term potentiation.

Alternative explanations for silent synapses exist: Because NMDA receptors have a much higher steady-state affinity for glutamate than AMPA receptors (Patneau and Mayer, 1990), they might respond to a relatively low and prolonged pulse of glutamate that is insufficient to activate AMPA receptors. Such a glutamate profile could arise by diffusion from neighboring

synapses (“spillover”) (Asztely et al., 1997; Kullmann and Asztely, 1998). Thus, the NMDA receptors of the recorded cell might be acting as bystanders, eavesdropping on the excitatory traffic through many synapses formed on neighboring cells. In favor of this model is the observation that raising the recording temperature from room temperature (thereby enhancing glutamate uptake) reduces the discrepancy between the number of quanta detected by NMDA and AMPA receptors. Conversely, blocking glutamate uptake pharmacologically increases the ratio of NMDA to AMPA receptor-mediated signaling, consistent with an exacerbation of cross-talk among synapses. Further evidence in favor of glutamate spillover comes from examining the effects of manipulations of release probabilities and competitive glutamate antagonists on the time course of NMDA receptor-mediated EPSCs (Lozovaya et al., 1999; Diamond, 2001; Arnth-Jensen et al., 2002).

Another possible explanation for selective activation of NMDA receptors is that the glutamate released from the presynaptic terminal to activate AMPA receptors is insufficient. This could occur if release took place via a “fusion pore.” That is, glutamate could slowly escape from a vesicle via a small, possibly flickering, opening to the synaptic cleft. Evidence for this phenomenon comes in part from the observation that enhancing the affinity of AMPA receptors for glutamate with pharmacological tools can unsilence such a “whispering” synapse (Choi et al., 2000; Renger et al., 2001). Moreover, manipulation of the presynaptic release probability can differentially affect AMPA and NMDA receptor-mediated components of EPSCs (Gasparini et al., 2000).

The various explanations for silent synapses (absence of functional AMPA receptors, spillover, fusion pore release) are not mutually exclusive. Their relative importance is also unresolved. Indeed, a silent synapse could be “deaf” (that is, devoid of functional AMPA receptors) early in its development but be “mute” (presynaptically silent but potentially susceptible to spillover of glutamate from a neighbor) at a later stage.

Because these issues have profound implications for the interpretation of changes in quantal parameters following long-term potentiation or depression, they will no doubt continue to attract considerable attention (Kullmann, 2003) (see Chapter 10). One critical question that bears on the interpretation of silent synapses is the degree of occupancy of AMPA and NMDA receptors following presynaptic glutamate release. Despite much effort, there is still considerable uncertainty over the extent to which AMPA and NMDA receptors are bound by glutamate released from the presynaptic terminal. It is also unclear whether presynaptic terminals are able to release more than one vesicle of glutamate. Three approaches have been used to estimate the occupancy of receptors following a presynaptic action potential.

- First, by assuming that a single vesicle contains between 2000 and 5000 molecules of glutamate, and that all of them are released through a rapidly expanding pore, one can simulate diffusion of the glutamate molecules

and their interaction with receptors and transporters around the synapse (Wahl et al., 1996; Rusakov and Kullmann, 1998; Barbour, 2001). There are considerable uncertainties in several critical parameters, including the diffusion coefficient of glutamate in the extracellular space and the fraction of the local volume accounted for by the extracellular space. Nevertheless, some studies applying this approach have arrived at the conclusion that the glutamate concentration in the synaptic cleft reaches a peak of approximately 1 to 3 mM almost instantaneously and then drops rapidly with a multiexponential time course. Taking into account the kinetic properties of NMDA receptors, this glutamate profile implies that the NMDA receptors opposite a release site should be almost saturated by a single vesicle. The occupancy of AMPA receptors is generally found to be slightly lower than that of NMDA receptors, reflecting their lower affinity. Another result from numerical simulations is that glutamate spreads outside the synaptic cleft, although the extent of this extrasynaptic glutamate escape is sharply curtailed by transporters. Some studies have suggested that a significant proportion of NMDA receptors within a radius of approximately 500 nm are activated by such glutamate spillover (Rusakov and Kullmann, 1998). This roughly corresponds to the typical distance separating one synapse in the CA1 neuropil from its nearest neighbor, taking into account the fact that synapses are not arranged as a regular lattice (Rusakov et al., 1998; Kirov et al., 1999). One report arrived at lower estimates for the glutamate concentrations in both the synaptic cleft and the perisynaptic space (Barbour, 2001); however, the discrepancy is mainly explained by assuming a larger extracellular space fraction, which gives rise to a greater degree of dilution of neurotransmitter following release.

- The second approach to estimate receptor occupancy is to compare the effects of receptor antagonists with different properties on the amplitude of the postsynaptic response (Clements et al., 1992). Low-affinity antagonists should be more easily displaced from the receptors by a pulse of glutamate than high-affinity antagonists. By titrating the concentration of the antagonists and establishing the kinetic properties of the receptors in patches of membranes exposed to known concentrations of agonists and antagonists, this approach can yield information about the glutamate concentration profile in the synapse. This method relies on the assumption that receptors in somatic membrane patches are representative of synaptic receptors. Nevertheless, it leads to the conclusion that glutamate reaches a concentration in excess of 1 mM for 100  $\mu$ s, subsequently decaying with an exponential time constant of approximately 1 to 2 ms. These results have again argued for a relatively high occupancy of NMDA receptors (> 95% bound). Extending this method to AMPA receptors has been difficult because of the lack

of suitable antagonists; but driving kinetic models of AMPA receptors with a similar concentration profile leads to the prediction that they should be only approximately 60% bound at the peak of the response.

- The third approach has given a different picture of receptor occupancy. High-resolution optical methods have shown  $\text{Ca}^{2+}$  transients in single dendritic spines, which reflects NMDA receptor opening in response to presynaptic glutamate release and which can be distinguished from transmission failure (Mainen et al., 1999). When two presynaptic stimuli were given in rapid succession (with an interval too short to allow appreciable NMDA receptor unbinding), the  $\text{Ca}^{2+}$  transient was frequently larger than when only one stimulus was given. This implies that the receptors were not saturated by the first transient. This approach again depends on a number of assumptions, not least that voltage-sensitive  $\text{Ca}^{2+}$  channels and postsynaptic  $\text{Ca}^{2+}$  stores do not contribute to the signals and that the visualized synapses are representative of the overall population. Notwithstanding these caveats, it implies that NMDA receptors are less than 60% bound following a single release event. Again, it is difficult to extend this approach to AMPA receptors because normally they are not sufficiently permeable to  $\text{Ca}^{2+}$  for a postsynaptic signal to be detected directly. Nevertheless, the conclusion that NMDA receptor occupancy is less than 60% does not automatically imply that AMPA receptor occupancy should be less than this: The 100-fold difference in affinities of the two receptors applies to steady-state agonist application. With a very brief pulse of transmitter, the occupancy is determined principally by the binding rate, not by the balance of binding and unbinding rates (Kullmann, 1999). Because the binding rates of the two receptor types are similar, it is not impossible that both are equally and incompletely occupied by glutamate following a single release event.

Overall, the average release probability at Schaffer collateral-CA1 pyramidal neuron synapses is probably less than 50% (Raastad, 1995), although it is highly variable from synapse to synapse (Hessler et al., 1993; Rosenmund et al., 1993). In fact, it is difficult to estimate the mean probability because there may be a large number of release sites with a release probability close to 0. Moreover, the release probability at neocortical synapses has been reported to increase with the temperature of the preparation (Hardingham and Larkman, 1998), so estimates obtained at room temperature may be biased. Recent electrophysiological and optical approaches have suggested that more than one vesicle can be simultaneously released at small glutamatergic synapses (Bolshakov et al., 1997; Oertner et al., 2002). Spontaneous “miniature” EPSCs (mEPSCs), recorded in the presence of tetrodotoxin to block  $\text{Na}^+$ -dependent action potentials, have conventionally been taken to reflect the postsynaptic effect of individual quanta, corresponding to single vesicles released from presy-

naptic terminals. Equating mEPSCs with vesicles, however, relies on two assumptions: first, that exocytosis proceeds in the same way in the presence and absence of presynaptic action potentials; and second, that spontaneous presynaptic  $\text{Ca}^{2+}$  fluctuations do not trigger the simultaneous release of multiple vesicles. Nevertheless, mEPSCs recorded in individual pyramidal neurons show a broad, skewed distribution, ranging from detection threshold ( $< 5 \text{ pA}$ ) up to approximately 50 pA (Manabe et al., 1992). Part of this variability may be due to different degrees of cable filtering of EPSCs originating in different parts of the dendritic tree. Nevertheless, the median amplitude probably corresponds to about 100 AMPA receptor-gated channels opening.

It has been suggested that quantal parameters are positively correlated across different synapses (Schikorski and Stevens, 1997). Thus, synapses with large presynaptic elements tend to have many docked vesicles (as well as more vesicles in total), large active zones and PSDs, and large postsynaptic spines (Harris and Sultan, 1995). Thus, if multivesicular release occurs, it should do so preferentially at such synapses and give rise to large postsynaptic signals. Conversely, small synapses, some of which are possibly devoid of AMPA receptors, may not contribute appreciably to the excitatory traffic impinging on the postsynaptic neuron.

Even though a pyramidal neuron has 10,000 to 30,000 spine synapses (see Chapters 3 and 5), it has been estimated that only 16 to 26 need to fire synchronously to bring it to action potential threshold (Otmakhov et al., 1993). Clearly, fewer large quanta are required than small ones, and physiological patterns of discharges further complicate this equation. Because the dendrites of CA1 pyramidal neurons can extend up to 500  $\mu\text{m}$  from the soma, an important question is whether distal synapses are as effective as proximal ones (Andersen et al., 1980b). If the dendrites acted as passive cables, and the same synaptic current was injected irrespective of position, distal synapses would give rise to a somatic EPSP whose peak amplitude was considerably smaller than that generated by proximal synapses. However, if the total charge transfer is estimated, the difference between proximal and distal synapses decreases. It has recently been reported that EPSCs generated at different positions on the dendritic tree show a location-related scaling that further compensates for the effect of cable attenuation (Magee and Cook, 2000). This finding remains to be confirmed independently, and the biophysical mechanisms underlying such a scaling have yet to be resolved. Finally, voltage-dependent conductances may modulate the anterograde and retrograde propagation of electrical signals in the dendrites. These issues are considered further in Chapter 5.

Dentate granule cells are much smaller and have fewer total spines than pyramidal neurons, although they have the same spine density per unit length of dendrite (Trommald and Hulleberg, 1997). The two extrinsic excitatory projections to granule cells show a striking difference in their short-term plasticity when two presynaptic stimuli are delivered in rapid succession. Lateral perforant path synapses exhibit marked

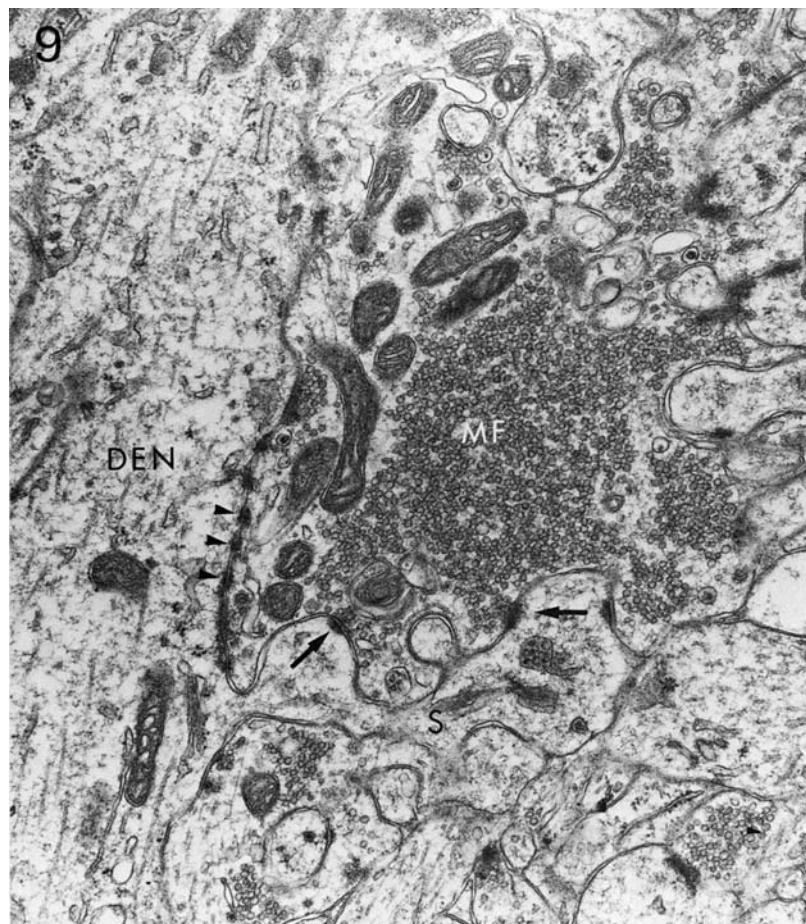

facilitation of the second EPSC compared to the first EPSC (“paired pulse facilitation”). This behavior is essentially the same as at Schaffer collateral synapses on CA1 pyramidal neurons. In contrast, medial perforant path synapses show less pronounced paired-pulse facilitation or even depression (McNaughton, 1980). This phenomenon is seen under conditions where inhibitory transmission is blocked, and it appears to reflect intrinsic differences between the glutamatergic synapses in the two pathways. Indeed, medial perforant path synapses appear to have a higher initial release probability than lateral perforant path synapses (Min et al., 1998).

Medial and lateral perforant path synapses also show several differences in sensitivity to neurotransmitters acting on presynaptic receptors. Notably, metabotropic glutamate receptor agonists depress transmission in the two pathways via distinct receptors (Macek et al., 1996), in approximate agreement with the distribution of subtypes resolved with immunohistochemical methods (Shigemoto et al., 1997). Muscarinic receptor agonists depress the medial perforant path input relatively selectively (Kahle and Cotman, 1989), and norepinephrine has also been reported to have pathway-specific actions (Dahl and Sarvey, 1989). It remains to be determined whether these differences have functional consequences.

Another difference between the two pathways is that LPP but not MPP synapses exhibit the silent synapse phenomenon seen at Schaffer collateral synapses (Min et al., 1998a). The pharmacological and/or morphological differences that underlie this difference are unknown.

### 6.6.2 Mossy Fiber Synapses

Mossy fibers are the thin, unmyelinated axons of dentate granule cells. They form several distinct types of synapse (Henze et al., 2000). Those formed on CA3 pyramidal neurons are in many ways unique (Fig. 6–8). First, they are much larger than any other synapses in the hippocampus, with a diameter up to 10  $\mu\text{m}$ . Second, the large presynaptic element (volume approximately 50  $\mu\text{m}^3$ ) contains numerous dense-core vesicles in addition to the small clear vesicles that predominate in other glutamatergic terminals. These dense-core vesicles are thought to contain dynorphin,  $\text{Zn}^{2+}$ , and other molecules, many of which are released in an activity-dependent manner. Although mossy fibers are excitatory, they contain abundant GABA (Sandler and Smith, 1991; Sloviter et al., 1996), raising the possibility that they may also package this neurotransmitter in some vesicles and release it following action potential invasion. Indeed, this possibility has been given indirect

**Figure 6–8.** Mossy fiber structure. The mossy fiber terminal (MF) contains numerous small (approximately 40 nm diameter) vesicles as well as mitochondria and larger vesicles, some of which are dense-cored. Some vesicles are found close to membrane specializations (arrows) that represent release sites in contact with a postsynaptic complex spine (S) belonging to a CA3 pyramidal neuron. DEN, dendrite. Arrowheads point to puncta adhaerentia, symmetrical membrane specializations often seen at synapses. (Source: Amaral and Dent, 1981, with permission.)

experimental support (Gutierrez, 2000; Walker et al., 2001). Third, the postsynaptic element is a highly branched structure (“thorny excrescence”) akin to a large, complex spine, occurring in the proximal part of the apical dendrite of the CA3 pyramidal neuron. These structures are also found in relatively small numbers in the proximal basal dendrites, although their incidence increases following intense excitatory traffic such as occurs during a prolonged seizure (see Chapter 15). The postsynaptic excrescence invaginates the presynaptic terminal. Mossy fiber synapses on CA3 pyramidal neurons can contain between 3 and 80 active zones, each of which is apposed to a PSD (Henze et al., 2000).

Mirroring their anatomical complexity, mossy fiber–CA3 synapses show many physiological and pharmacological peculiarities. EPSCs contain a kainate receptor-mediated component in addition to the AMPA receptor-mediated component (Castillo et al., 1997b; Vignes and Collingridge, 1997), whereas the NMDA component is relatively small (Jonas et al., 1993). These pharmacological features are in agreement with the relatively high kainate and low NMDA binding densities observed in the stratum lucidum (Monaghan et al., 1983; Benke et al., 1993). The kainate component is generally thought to be carried by GluR6-containing receptors (Mulle et al., 1998), although it remains unclear why this component of the EPSC is slow compared to the kinetics of recombinant GluR6-containing receptors. High-frequency stimuli also evoke a postsynaptic metabotropic glutamate receptor-mediated depolarizing current (Heuss et al., 1999; Yekel et al., 1999).

Mossy fiber EPSCs exhibit pronounced facilitation with very modest increases in discharge frequency, and part of this facilitation is mediated by presynaptic kainate autoreceptors (Schmitz et al., 2001c). Following a high-frequency burst of action potentials in the presynaptic axons, transmission at mossy fibers can remain elevated for hours (Henze et al., 2000). This form of long-term potentiation is distinct from that seen at other spine synapses in the hippocampus in that it is not dependent on NMDA receptors. Its underlying mechanisms are considered further in Chapter 10.

Transmission at mossy fiber synapses can be profoundly depressed by activation of several classes of presynaptic receptors, including group II (and in some species group III) metabotropic glutamate receptors (Yamamoto et al., 1983; Lanthorn et al., 1984; Kamiya et al., 1996), GABA<sub>B</sub> receptors (Min et al., 1998b; Vogt and Nicoll, 1999) and opioid receptors (Weisskopf et al., 1993). Presynaptic kainate receptors have a paradoxical function: With low concentrations of agonists, probably corresponding to that achieved with synaptic glutamate release, they facilitate transmission (Schmitz et al., 2001c), whereas with higher concentrations transmission is depressed (Chittajallu et al., 1996; Vignes et al., 1998; Kamiya and Ozawa, 2000; Kullmann, 2001; Schmitz et al., 2001c). The degree to which presynaptic receptors on mossy fibers are activated by neurotransmitters released from their own terminals, in contrast to neighboring axons (whether mossy fiber or

other afferent fibers) remains unclear. The functional role of presynaptic modulation of mossy fiber transmission is also unclear: It may act as a brake on further transmitter release or subserve a form of center-surround inhibition to sharpen the projection from the dentate gyrus. Such a role has been proposed for the release of dynorphin, which acts at κ receptors (Weisskopf et al., 1993; Simmons and Chavkin, 1996).

Although mossy fiber synapses on CA3 pyramidal neurons are large and complex, this projection is sparse: Each mossy fiber makes only about 14 synapses in CA3 (see Chapter 3). Moreover, at low frequencies unitary mossy fiber EPSCs evoked in individual CA3 pyramidal neurons have a peak amplitude corresponding to a synaptic conductance of approximately 1 nS and consist of approximately 5 quanta (Jonas et al., 1993). This conductance is only approximately fivefold larger than at the far more abundant glutamatergic input to CA3 pyramidal neurons, the associational-commissural fibers. However, because mossy fiber EPSCs can increase up to 10-fold with high-frequency activity (Regehr et al., 1994), the projection sometimes becomes powerful for depolarizing CA3 neurons. A brief train of action potentials in a single mossy fiber can bring a CA3 pyramidal neuron to firing threshold *in vivo* (Henze et al., 2002). The sparse connectivity of granule cells to CA3 pyramidal neurons has impeded detailed biophysical study of this pathway.

A second type of mossy fiber synapse is formed on glutamatergic mossy cells of the dentate hilus. The presynaptic varicosities are also large and contain pleiomorphic vesicles. Numerically far more important are small synapses on other hilar interneurons (Acsady et al., 1998). They have a very different shape in that the presynaptic element is a filopodial extension off the shaft of the mossy fiber itself, which makes a single contact with the target interneuron. These synapses are much smaller than the synapses on CA3 pyramidal neurons and probably contain only a single release site. Several physiological studies of mossy fiber–interneuron transmission have not systematically identified the postsynaptic neurons (Maccaferri et al., 1998; Toth et al., 2000; Lei and McBain, 2002). However, because small filopodial synapses far outnumber large synapses on mossy cells, they probably principally reflect the properties of the former. Although they are highly susceptible to presynaptic modulation via metabotropic glutamate receptors, many mossy fiber synapses on interneurons appear not to exhibit marked frequency-dependent facilitation or NMDA receptor-independent LTP (Maccaferri et al., 1998). However, this conclusion may not apply universally to the interneuronal targets of mossy fibers: Short- and long-term potentiation have recently been reported in identified basket cells in response to high-frequency trains of stimuli delivered to single presynaptic granule cells (Alle et al., 2001) (see Chapter 10).

Another peculiarity of mossy fiber transmission to some interneurons is that Ca<sup>2+</sup>-permeable AMPA receptors have been reported to mediate transmission (Toth et al., 2000). This property is shared with other excitatory synapses on

interneurons and probably depends on whether the interneuron expresses GluR2 receptors (see below). However, there may be a further level of refinement because it has been proposed that a given interneuron targets  $\text{Ca}^{2+}$ -permeable and  $\text{Ca}^{2+}$ -impermeable receptors to different synapses (Toth and McBain, 1998).

The fourth type of synapse formed by mossy fibers is on the proximal dendrites of other granule cells. Although this projection is normally sparse, it increases following intense seizure activity, in common with the infrapyramidal projection to CA3 ("mossy fiber sprouting") (see Chapter 16).

### 6.6.3 Other Glutamatergic Synapses on Interneurons

Excitatory synapses on interneurons made by pyramidal neurons are generally small and are made directly on the soma and dendrites (Box 6–3). From limited ultrastructural and electrophysiological data obtained in parallel, they contain a single release site (Gulyas et al., 1993). Two important pharmacological features distinguish them from small spine synapses on principal neurons. First, at a subset of synapses the AMPA receptors are permeable to  $\text{Ca}^{2+}$  (Jonas et al., 1994), which can be explained by the absence of the GluR2 subunit that confers  $\text{Ca}^{2+}$  impermeability at other receptors. Interestingly, many of the same interneurons express neuronal nitric oxide synthase (NOS) (Catania et al., 1995). It is tempting to speculate that  $\text{Ca}^{2+}$  influx via AMPA synaptic receptors may trigger the release of NO from these neurons, which could act as a diffuse messenger, affecting several target neurons within a small distance. This property is, however, not ubiquitous among interneurons; and many appear neither to express NOS nor to have  $\text{Ca}^{2+}$ -permeable AMPA receptors. Another highly variable property of glutamatergic synapses at interneurons is that some have a kainate receptor-mediated component (Cossart et al., 1998; Frerking et al., 1998), although it does not occur ubiquitously (Semyanov and Kullmann, 2001). In contrast to mossy fiber–CA3 synapses, interneurons are enriched in GluR5. It is not known whether the presence or absence of a kainate receptor-mediated component to EPSCs in interneurons correlates with the postsynaptic interneuron's morphological or immunocytochemical identity (see Chapter 7).

The kinetics of AMPA receptor-mediated EPSCs vary extensively among the various excitatory synapses in the hippocampus. In general, the rise times and decay time constants are slow in pyramidal neurons, intermediate in granule cells, and fast in interneurons (Geiger et al., 1997). Although this matches the passive membrane time constants of the various neurons, the difference persists once the cable properties of the neurons have been taken into account. That is, the different kinetics appear to be an intrinsic property of the neurons and/or synapses (Colquhoun et al., 1992) and, indeed, appear to reflect the subunit composition and splice variants of AMPA receptors expressed in each neuron (Lambolez et al., 1996).

#### Box 6–3

##### Methods Used to Study Transmission at Excitatory Hippocampal Synapses

The hippocampus has yielded many of the most important insights into synaptic transmission in the CNS. This is because of two principal factors. First, the hippocampal formation has a remarkable laminar organization: Many of the fibers making excitatory synapses run parallel to one another, and target neurons and their projections are tightly packed (see Chapter 3). Second, development of the slice preparation allowed neurons and their connections to be studied in vitro, where the chemical and physical environment of the synapses could be manipulated experimentally. An important consequence of the laminar structure of the hippocampus is that the currents evoked by synchronous activity in many synapses can be detected via extracellular electrodes. Because synapses represent a current sink (current moves from the extracellular medium into neurons), field EPSPs (fEPSPs) are detected as negative voltage deflections in the dendritic regions where most excitatory synapses occur (the stratum radiatum or stratum oriens of the hippocampus proper or the stratum moleculare of the dentate gyrus). In the cell body layer, there is a corresponding positive wave (representing current flowing out of the principal neurons) that completes the local circuit. With stimuli of sufficient amplitude, however, a sharp negative deflection is superimposed on the positive fEPSP in the cell body layer. This "population spike" reflects the synchronous discharge of principal cells that are brought to firing threshold by the EPSP propagating to the cell body (Andersen et al., 1971).

Intracellular records from hippocampal neurons in vivo have lent direct support for the identification of population spikes with somatic action potentials (Kandel and Spencer, 1961). With the development of the hippocampal slice, Schwartzkroin (1975) showed that the dendritic negative fEPSP was indeed due to activation of synaptic potentials generated at the dendritic level, recorded as an intracellular depolarizing EPSP in the soma. More recently, patch-clamp recordings have been widely used, either from somata or from dendrites close to the excitatory synapses. They have shown even more directly that EPSCs result from the local activation of afferent fibers (Hestrin et al., 1990).

Another difference between the synapses is the expression of presynaptic group III metabotropic glutamate receptors. As already mentioned, these receptors are present at mossy fiber synapses in some species (for instance in guinea pigs) but not at Schaffer collateral synapses in CA1 pyramidal neurons. However, excitatory transmission to interneurons is highly sensitive to agonists of group III metabotropic receptors (Scanziani et al., 1998). Small synapses on pyramidal neurons, in contrast, are insensitive. This differential sensitivity to group III agonists parallels the distribution of some subtypes of group III receptors imaged with high-resolution immunohistochemical methods. For instance, mGluR7 appears to be expressed in presynaptic active zones apposed to interneurons and not at active zones apposed to pyramidal neurons (Shigemoto et al., 1996, 1997). This target cell dependence in

the distribution of presynaptic receptors implies that a retrograde signal instructs the presynaptic membrane whether to anchor these receptors.

Many glutamatergic synapses on interneurons show similar patterns of short-term use-dependent plasticity as Schaffer collateral synapses on CA1 pyramidal neurons. That is, they show frequency-dependent facilitation with brief trains of action potentials. However, a subset of basket and bistratified cells receive glutamatergic synapses that depress prominently (Thomson, 2000). The molecular basis of this distinction has not been elucidated in the hippocampus but may again imply a retrograde signal from the target neuron that specifies some of the properties of the presynaptic terminal. Such a principle is supported by the finding that different synapses supplied by the same neocortical neurons can show either depression or facilitation with repeated stimulation, depending on the identity of the postsynaptic neurons (Reyes et al., 1998).

Finally, glutamatergic synapses to interneurons frequently appear not to express NMDA receptor-dependent LTP, although a form of LTD has been described (McMahon and Kauer, 1997). One report implicates a coincidence of  $\text{Ca}^{2+}$  influx via  $\text{Ca}^{2+}$ -permeable AMPA receptors and activation of presynaptic metabotropic receptors in the induction of this phenomenon (Laezza et al., 1999). This depression of inhibition potentially leads to a disynaptic disinhibition of principal cells (Lu et al., 2000).

#### 6.6.4 Inhibitory Synapses

GABAergic inhibition of principal neurons plays an essential role in regulating the transmission of information through the hippocampal formation (see Box 6–4). The wide range of interneuron morphologies is summarized in Chapter 3, and their connectivities are considered in Chapter 8. Not all interneurons are GABAergic: Mossy cells in the dentate hilus and giant spiny interneurons in the stratum radiatum are glutamatergic and more akin to pyramidal neurons. Because relatively little is known about synapses made by glutamatergic interneurons, this section restricts its attention to GABAergic signaling (Fig. 6–9). Complementing the variability of interneuron morphology, GABAergic synapses fall into various types depending on their location on the target neuron. Three main types are recognized: axo-axonic, axo-somatic, and axo-dendritic. This distinction appears to be valid whether the postsynaptic target is a pyramidal neuron or another interneuron.

Axo-axonic synapses are made by chandelier cells and occur 50 to 70  $\mu\text{m}$  from the soma of the target neuron. In pyramidal neurons, postsynaptic  $\alpha_2$  GABA<sub>A</sub> subunits are restricted principally to these synapses (Nusser et al., 1996). They are also distinguished from other GABAergic synapses by the presence of a postsynaptic  $\text{Ca}^{2+}$ -sequestering organelle (Benedeczky et al., 1994). Situated at the strategic point for impulse initiation, these synapses probably exert extremely powerful control over the discharge of target cells. From the small number of published paired recordings of pre- and

#### Box 6–4

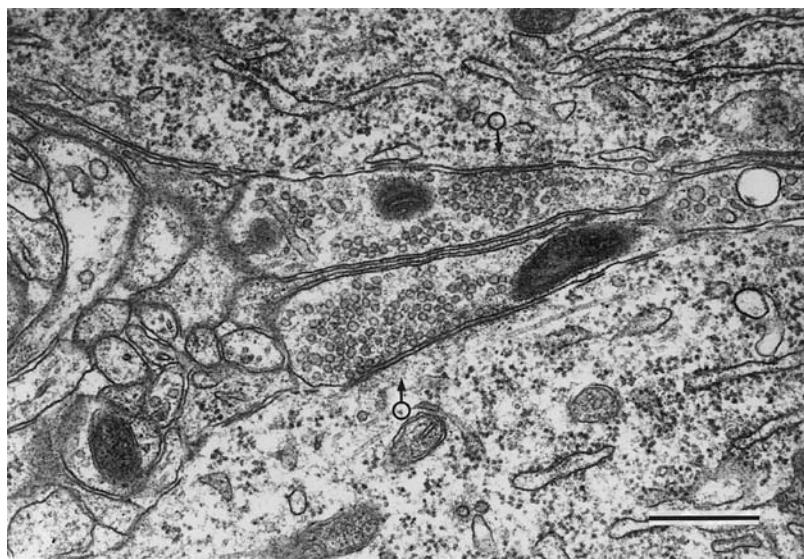

##### **Early Insights into Inhibitory Synaptic Signaling in the Hippocampus**

Early intracellular recordings from principal neurons in the hippocampus showed that following a strong afferent stimulus the initial discharge was often followed by a pause in spontaneous activity (Albe-Fessard and Buser, 1955). fEPSP recordings also showed that intense activation was followed by a temporarily reduced ability to excite CA1 pyramidal cells and dentate granule cells synaptically. These observations led to the hypothesis that inhibitory processes are entrained by the stimulus. The synaptic basis for this inhibition was not immediately established because intracellular recordings revealed long-lasting depolarizing waves. However, it was subsequently discovered that they were IPSPs whose polarity was artificially reversed by the leakage of  $\text{Cl}^-$  ions into the neurons from the recording microelectrodes (Spencer and Kandel, 1961). This inhibition was shown to be generated across the soma membrane (Andersen et al., 1964), as would be expected if it was mediated by the perisomatic terminals of basket cells. Extracellular stimuli not only recruited basket cells via axon collaterals of principal neurons (disynaptic “feedback inhibition”) but could also directly activate inhibitory interneurons, yielding a monosynaptic IPSP (“feedforward inhibition”). Both types of inhibition play an important role in regulating the excitability of the circuitry and in synchronizing the activity of populations of neurons (see Chapter 8). A potential role for feedforward inhibition in sharpening the temporal resolution of pattern discrimination has recently been proposed (Pouille and Scanziani, 2001).

postsynaptic neurons, these synapses appear to yield large-amplitude IPSCs with relatively fast kinetics and activity-dependent depression (Pawelzik et al., 1999; Maccaferri et al., 2000).

Axo-somatic synapses are made by basket cells, whose axon collaterals form clusters of boutons surrounding the soma of the target neurons (see Chapter 3). Basket cells mediate powerful inhibition of principal neurons by synchronous release of GABA from the multiple synapses. These synapses also tend to depress with repeated activation (Hefft et al., 2002). Interestingly, two subtypes of basket cells appear to signal via different postsynaptic GABA<sub>A</sub> receptors: Cholecystokinin-positive cells make synapses with a high  $\alpha_2$  content, and parvalbumin-containing basket cells signal preferentially via synapses containing  $\alpha_1$  subunits (Klausberger et al., 2002). How this complementary distribution of receptors fits with the physiological roles of these two subsets of interneurons is unknown.

Axo-dendritic synapses on pyramidal cells are made by a variety of interneurons whose cell bodies are found in the strata oriens, radiatum, and lacunosum-moleculare. Synapses formed on the distal dendrites are thought to control the excitability of the postsynaptic neuron relatively indirectly. They are unlikely to hyperpolarize the cell body effectively because they are electrically remote, but they may be highly

**Figure 6–9.** Inhibitory synapse structure. The arrows point to two symmetrical synapses on neighboring CA1 pyramidal cell bodies. Bar = 0.5 μm. (Source: Harris and Landis, 1986, with permission).

effective in shunting locally evoked EPSCs (Staley and Mody, 1992).

Possibly reflecting the different sites at which GABAergic synapses contact postsynaptic neurons, GABAergic IPSCs in pyramidal neurons have bimodal kinetics. So-called GABA<sub>A-Fast</sub> IPSCs have a faster rise-time (< 2 ms) and a correspondingly faster decay time constant (< 20 ms) than GABA<sub>A-Slow</sub> IPSCs (Pearce, 1993). This distinction is greater than can be explained entirely by cable filtering by the dendritic tree and suggests, instead, that different GABA<sub>A</sub> receptor subunits with differing kinetics are segregated to different synapses. Indeed, GABA<sub>A-Fast</sub> IPSCs are sensitive to furosemide (Pearce, 1993), which is consistent with presence of the α<sub>4</sub> subunit (Wafford et al., 1996). Circumstantial evidence suggests that they originate from basket cells and may be primarily responsible for generating relatively high-frequency (gamma range, approximately 40 Hz) oscillations in the hippocampus (Banks et al., 2000). In contrast, GABA<sub>A-Slow</sub> IPSCs are insensitive to furosemide, are more likely to arise from dendritic synapses equipped with α<sub>1</sub>-containing receptors, and may play a more important role in generating theta-rhythm (approximately 8 Hz) oscillations.

Although GABA is the principal transmitter released at all of the synapses considered above, some are also thought to release peptides from dense-core vesicles. Basket cells contain either cholecystokinin (CCK) or parvalbumin but not both. Although little is known about differences in the physiology of the synapses supplied by these two cell types, only cholecystokinin-positive neurons appear to express CB1 cannabinoid receptors (Marsicano and Lutz, 1999; Tsou et al., 1999). The evidence for a synaptic role for cholecystokinin and other neuro-active peptides such as somatostatin, CCK, and substance P is scanty.

In contrast to most glutamatergic synapses, most GABAergic synapses show marked depression with repetitive activity at moderate frequencies (Thomson, 2000). This may reflect a high baseline release probability, but the presence of Ca<sup>2+</sup>-buffering proteins also attenuates the accumulation of

free Ca<sup>2+</sup> with repeated action potential invasion (Caillard et al., 2000). Another phenomenon that may underlie differences in use-dependent plasticity is that some GABAergic synapses rely exclusively on either N- or P/Q-type Ca<sup>2+</sup> channels to trigger transmitter release (Poncer et al., 1997; Wilson et al., 2001) in contrast to glutamatergic synapses, which tend to use a mixture of both types. Because N-type channels tend to inactivate more rapidly and are a more sensitive to G protein-mediated inhibition (Zhang et al., 1996), it is tempting to speculate that synapses relying on this Ca<sup>2+</sup> channel subtype depress more readily.

Although GABAergic IPSCs evoked by a single basket cell are generally multiquantal (Edwards et al., 1990), this probably reflects the numerous synapses made by a single neuron (Kraushaar and Jonas, 2000). The number of vesicles released at a single synapse is not known with certainty. Evidence exists for multivesicular release at some cerebellar GABAergic synapses (Auger et al., 1998), but whether this also holds for hippocampal synapses is not known. Because the occupancy of postsynaptic GABA<sub>A</sub> receptors following release of a single vesicle may be greater than 50% (Perrais and Ropert, 1999), it cannot be inferred that release of two vesicles gives rise to a response twice as large.

GABAergic synapses in the hippocampus show a different profile of modulation by presynaptic receptors than most glutamatergic synapses. Thus, μ opioid receptors depress GABA release relatively selectively (Simmons and Chavkin, 1996). Cannabinoid receptors have a similar effect at some basket cell synapses (Katona et al., 1999; Hoffman and Lupica, 2000) and mediate an unusual form of short-term depression triggered by Ca<sup>2+</sup> transients in postsynaptic pyramidal neurons (Ohno-Shosaku et al., 2001; Wilson and Nicoll, 2001). Because the CB1 cannabinoid receptors mediating this phenomenon are apparently restricted to CCK-positive basket cells, this form of retrograde signaling could exert a powerful disinhibitory effect. Moreover, it could relatively selectively interfere with rhythmogenesis, possibly contributing to the cognitive and hallucinatory effects of exogenous cannabinoid agonists.

In contrast to glutamatergic synapses, GABA release is relatively resistant to adenosine (Yoon and Rothman, 1991; Lambert and Wilson, 1993). Surprisingly, GABAergic synapses on interneurons are as sensitive to group III metabotropic glutamate agonists as glutamatergic synapses (Semyanov and Kullmann, 2000) even though only the latter actually release the endogenous agonist. GABAergic transmission to pyramidal neurons, however, is relatively insensitive to group III agonists, mirroring the lack of sensitivity of Schaffer collateral synapses on pyramidal neurons. Thus, the expression of presynaptic group III receptors appears to be determined in large part by the target cell identity. The presence of these receptors on GABA-releasing synapses is difficult to explain unless they have evolved to detect glutamate released from neighboring synapses. Evidence that glutamate spillover modulates inhibition via these receptors has been reported (Semyanov and Kullmann, 2000).

There is relatively little evidence for long-term use-dependent plasticity at GABAergic synapses akin to long-term potentiation (see Chapter 10). However, some manipulations in neuronal cultures can enhance the surface expression of GABA<sub>A</sub> receptors (Wan et al., 1997), underlining the importance of this phenomenon for the development of synapses, if not their regulation in adults.

GABA<sub>A</sub> receptors in cerebellar granule cells can mediate a continuous current, a phenomenon known as “tonic” inhibition (to distinguish it from “phasic” inhibition represented by the occurrence of IPSCs) (Brickley et al., 1996; Wall and Usowicz, 1997). Tonic GABA<sub>A</sub> receptor-mediated inhibition also occurs in hippocampal granule cells (Overstreet and Westbrook, 2001; Stell and Mody, 2002). In the hippocampus proper, interneurons appear to express tonic inhibition relatively selectively, possibly reflecting a homeostatic role in regulating circuit excitability (Semyanov et al., 2003).

Inhibitory synapses are also made among interneurons. These synapses appear to show use-dependent depression similar to that seen at most GABAergic synapses on principal cells, although the kinetics of the IPSCs are generally faster (Bartos et al., 2001). Some parvalbumin-positive basket cells are also coupled by gap junctions (Fukuda and Kosaka, 2000). Genetic deletion of connexin 36 perturbs  $\gamma$  frequency oscillations, possibly because of impaired electrical coupling among these interneurons (Hormuzdi et al., 2001).

## 6.7 Unresolved Issues

There are numerous unresolved issues surrounding synaptic function that cannot be listed completely here. Many are fundamental questions concerning transmitter release, such as the mechanisms by which synaptotagmin transduces the  $\text{Ca}^{2+}$  surge to trigger exocytosis, how the degree of filling of a vesicle affects its readiness for release, and whether and under what conditions exocytosis can take place via a fusion pore. Other important questions concern postsynaptic mechanisms. Some of these questions, such as the targeting and clus-

tering of glutamate receptors at synapses, have attracted intense interest because of their potential role in the development and plasticity of excitatory transmission. They are taken up in greater detail in Chapter 7. Other areas, such as the detailed postsynaptic signaling cascades, leading to effects as remote as nuclear transcription, are discussed, in the context of LTP, in Chapter 10.

As in so many areas of neuroscience, insights at a molecular level are outpacing progress at a more macroscopic level. It is some of these areas that ultimately may require major breakthroughs to relate the mechanisms of synaptic function to the function of the network as a whole. For instance, although the involvement of cholinergic mechanisms in theta rhythms is on a relatively secure footing, this understanding remains at a qualitative level. Many critical parameters remain far from established: What is the temporal profile of acetylcholine release? Where are the target receptors in relation to the sites of release? How many individual terminals cooperate to activate muscarinic and nicotinic receptors? Which of the numerous actions of these receptors actually take place *in vivo*?

Similar questions occur for each of the other neurotransmitters described here. Most of this chapter has concentrated on the fast ionotropic signaling by glutamate and GABA; this is because, to a great extent, electrophysiological methods are so powerful in detecting and quantifying EPSP/Cs and IPSP/Cs. More diffuse types of signaling mediated by metabotropic receptors or even by extrasynaptic actions at ionotropic receptors may be of similar or even greater importance for understanding the roles of these transmitters in intercellular signaling. As for the monoamines and peptides, they are considered less important only on the grounds that the releasing axons are relatively sparse. However, not until their actions have been put on a sound quantitative footing similar to that of the amino acid neurotransmitters will it be possible to know if this ranking is correct.

## ACKNOWLEDGMENTS

My thanks to the editors, in particular Per Andersen, for helpful input to this chapter.

# Molecular Mechanisms of Synaptic Function in the Hippocampus: Neurotransmitter Exocytosis and Glutamatergic, GABAergic, and Cholinergic Transmission

## 7.1 Overview

In the hippocampus, excitatory (also termed principal or pyramidal) neurons, the basic working units of the mammalian central nervous system (CNS), form a highly organized three-layer circuit. Excitatory input from the entorhinal cortex enters the hippocampus largely via dentate gyrus granular cells, which in turn connect through the mossy fiber synapses to the CA3 pyramidal neurons. CA3 pyramids process the input via a dense network of recurrent connections and send their output through the Schaffer collaterals synapsing onto the CA1 pyramidal cells. Finally, CA1 pyramids send the hippocampus-processed information via the subiculum back to the cortex. Within this circuit, fast excitatory synaptic transmission is mediated by inward excitatory postsynaptic currents (EPSCs) flowing through the ionotropic  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and, to a lesser extent, kainate types of glutamate receptors. Slower hippocampal EPSCs are the result of activation of N-methyl-D-aspartate (NMDA) receptors and certain subtypes of metabotropic glutamate receptors.

The activity of hippocampal principal neurons is tightly controlled and synchronized by an inhibitory system comprised of  $\gamma$ -aminobutyric acid (GABA)<sub>A</sub>ergic interneurons interspersed throughout the hippocampus. Fast inhibitory postsynaptic currents (IPSCs) are the result of ionotropic GABA<sub>A</sub> receptor activation, and slow IPSCs are due to the activation of metabotropic GABA<sub>B</sub> receptors. In addition, activation of some metabotropic glutamate receptors may also have inhibitory rather than excitatory effects. Cholinergic projections in the hippocampus comprise a prominent modulatory system, where acetylcholine binds to muscarinic and nicotinic receptors and produces either excitatory or inhibitory effects depending on the receptor type, the cell type that expresses the receptor, and the synaptic location of the receptors in a given cell. Finally, a set of neuropeptide receptors [e.g., receptors for somatostatin, neuropeptide Y (NPY)] and receptors that bind

modulators such as serotonin, steroids, and endocannabinoids play important roles in the hippocampus, as does electrical transmission through gap junctions.

In this chapter, we primarily restrict ourselves to a description of the molecular biology of excitatory and inhibitory transmission. We start by describing the basis of all signal transmission processes, the release of the signaling transmitter from the presynaptic terminal. Next we give details of the key glutamate and GABA receptors responsible for the “nuts and bolts” of hippocampal chemical transmission. We end by discussing—as an example of modulatory transmission—how acetylcholine muscarinic and nicotinic receptors influence information flow in the hippocampal cell types. To fully integrate our chapter into the overall theme of the book, we focus in detail on hippocampal-specific features of synaptic transmission, such as the hippocampal distribution of the individual receptor types. In addition, we discuss the growing number of mouse models aimed at genetic analysis of presynaptic or postsynaptic functions, which are typically assayed for behavioral phenotype in a battery of hippocampus-dependent tasks. As these mouse models are becoming increasingly more refined, particularly with improved spatiotemporal control over the onset of the genetic manipulation, this line of work is beginning to uncover previously unsuspected differences in the molecular and cellular mechanisms of various hippocampus-based functions, such as the differences in synaptic transmission and plasticity underlying hippocampal working and spatial memory.

## 7.2 Neurotransmitter Exocytosis

### 7.2.1 Introduction: Proteins Involved in Synaptic Release

Neurotransmitter release occurs at specialized sites of the presynaptic axon terminals, termed the active zones, and is

tightly linked to intraterminal influx of extracellular  $\text{Ca}^{2+}$ . The event itself is a culmination of numerous trafficking steps of the synaptic vesicle cycle that was introduced in general terms in Chapter 6. The temporal and spatial complexity of these processes is accomplished by the highly synchronized “collaboration” of a large number of presynaptic proteins. On the basis of their function during the synaptic vesicle cycle, they can be grouped as proteins regulating (1) the reserve pool of vesicles, (2) mobilization of vesicles toward the active zone, (3) docking and priming of vesicles at the active zone, (4)  $\text{Ca}^{2+}$ -triggered neurotransmitter release, and (5) vesicle endocytosis, recycling, and refilling.

### 7.2.2 Reserve Pool of Synaptic Vesicles

Synaptic vesicles are kept in two spatially and functionally distinct pools: the reserve pool and the readily releasable pool. The reserve pool, approximately 200 to 500 nm away from the active zone plasma membrane, provides a supply of vesicles after depletion of the readily releasable pool. The equilibrium between the reserve and the releasable pool is maintained largely by abundant synaptic vesicle proteins termed synapsins, which tether the vesicles to the presynaptic cytoskeletal network made up of filamentous actin (F-actin), microtubules and brain spectrin (for review see Hilfiker et al., 1999; Doussau and Augustine, 2000). Synapsins comprise a family of three phosphoproteins, termed synapsin I, II, and III, each of which undergoes alternative splicing in the variable C-terminal part of the molecule, generating isoforms termed “a” and “b.” Whereas the distribution of synapsin I and II is highly overlapping throughout the CNS (Südhof et al., 1989), differences in function between the two isoforms in the hippocampus were recently revealed in synapsin I and II knockout mice (see below). In contrast, synapsin III is largely restricted to mossy fiber terminals of the granule cells in the adult hippocampus (Pieribone et al., 2002).

The function of synapsins is tightly regulated by protein kinases: During repetitive synaptic release, activated protein kinases phosphorylate synapsins on several residues, inducing their unbinding from synaptic vesicles and subsequent mobilization of the vesicles toward the active zone. Two kinases implicated in the phosphorylation of synapsin I are  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase (CaM kinase) and mitogen-activated protein kinase (MAPK). Interestingly, the two kinases regulate synapsin I function in response to different rates of activity: A lower rate of presynaptic stimulation activates phosphorylation of synapsin I by CaM kinase, whereas a higher rate is more selective for MAPK phosphorylation (Chi et al., 2003). Even though the functional significance of the two kinase pathways is presently not clear, these observations suggest that synapsins may be fine-tuned to different firing frequencies *in vivo* and may participate in regulating the mobilization of synaptic vesicles during different patterns of activity.

Direct experimental support for the above proposed role of synapsins comes from mice lacking synapsin I and/or II,

which indeed have a decreased number of reserve vesicles at hippocampal synapses (Rosahl et al., 1993, 1995; Li et al., 1995; Takei et al., 1995). In addition, the mice show interesting phenotypes with respect to synapsin I and II functions in the hippocampus. First, synapsin I, II, or I/II knockout mice all have normal long-term synaptic plasticity as assessed by measurements of long-term potentiation (LTP) at either mossy fiber to CA3 or CA3 to CA1 synapses. Thus maintaining a reserve pool of synaptic vesicles is not necessary for LTP in the hippocampus. However, the mice show changes in short-term plasticity. Synapsin I knockout mice show an increase in paired pulse facilitation (PPF) but no change in posttetanic potentiation (PTP) at CA3 to CA1 synapses, whereas mice lacking synapsin II and I/II show a loss of PTP but no change of PPF. Even more interestingly, synapsin II and I/II but not synapsin I knockout mice show impaired hippocampus-dependent contextual learning (Silva et al., 1996). This suggests that a deficit in short-term plasticity (i.e., in PTP) in the presence of normal LTP can cause an impairment of hippocampus-dependent learning; this finding, although perhaps surprising, is supported by a similar result from animals lacking the presynaptic protein RIM1 $\alpha$  (see Section 7.2.5).

### 7.2.3 Synaptic Vesicle Docking and Priming at the Active Zone: Role of the SNARE Complex, Munc18, and Munc13

Synaptic vesicles, after their mobilization toward the active zone, undergo a number of trafficking steps before achieving a state at which they are ready to fuse with the presynaptic plasma membrane, the so called readily releasable state. Although the functions of numerous proteins involved in these processes are now understood in some detail, a complete “unified” model that would explain how synaptic vesicles dock and become primed at the active zone is yet to be established. Perhaps the least-understood step during the vesicle mobilization concerns the initial docking (tethering) of synaptic vesicles at the active zone membrane. It seems likely, based on data from membrane fusion in many secretory pathways, that vesicle tethering is mediated by small guanosine triphosphate (GTP)-binding proteins of the Rab family: A vesicle-associated, GTP-bound Rab links the vesicle to a Rab effector protein (tether) that is present selectively at the target membrane. Several Rab proteins are associated with synaptic vesicles, the most abundant of which is Rab3A (other Rab3 isoforms are Rab3B, -C, and -D). Analysis of knockout mice, however, revealed that Rab3A functions during neurotransmitter release, after docking and priming (Geppert et al., 1994a, 1997). (See Section 7.2.5 on the role of Rab3A in the later stages of the synaptic vesicle cycle.) Furthermore, quadruple Rab3A/B/C/D knockout mice have normal gross brain and synaptic morphology (the mice die at birth owing to respiratory failure), and cultured hippocampal neurons prepared from these mice have normal spontaneous and only partially reduced evoked release (Schlüter et al., 2004). Thus,

other proteins, perhaps yet another Rab isoform or a protein with a different function altogether, are sufficient for docking of synaptic vesicles at hippocampal synapses in the absence of Rab3.

Past the initial docking step, proteins principally involved in the regulation of priming of synaptic vesicles at the active zone include the SNARE (SNAP REceptor) complex, Sec1/Munc18 homologues (SM proteins), Munc13-1, and complexins (reviewed in Rizo and Südhof, 2002). The role of synaptotagmin 1 is discussed in the section relating directly to  $\text{Ca}^{2+}$ -triggered release (see Section 7.2.4). The SNARE complex is a critical component of most if not all intracellular membrane fusion events. Assembly of the SNARE complex from proteins of the vesicular and target membranes (v- and t-SNAREs) is believed to bring the two membranes into close contact; this primed state is a prerequisite for initiation of membrane fusion (Fig. 7–1) (see Chapter 6). At the presynaptic terminals, the SNAREs involved in neurotransmitter release are a v-SNARE termed synaptobrevin (also VAMP) and two t-SNAREs present at the active zone termed SNAP25 and syntaxin1; synaptobrevin and syntaxin are single transmembrane proteins, and SNAP25 is a membrane-attached protein. The critical importance of the SNAREs for synaptic functions was first demonstrated in experiments with clostridial neurotoxins, which cause site-specific cleavage of the individual SNARE proteins: A loss of SNARE function abolished neurotransmitter release (reviewed in Rizo and Südhof, 2002). These experiments also showed that in the absence of the SNARE assembly synaptic vesicles can accumulate at the active zone in a similar way as at wild-type synapses, indicating that SNAREs are not involved in synaptic vesicle docking.

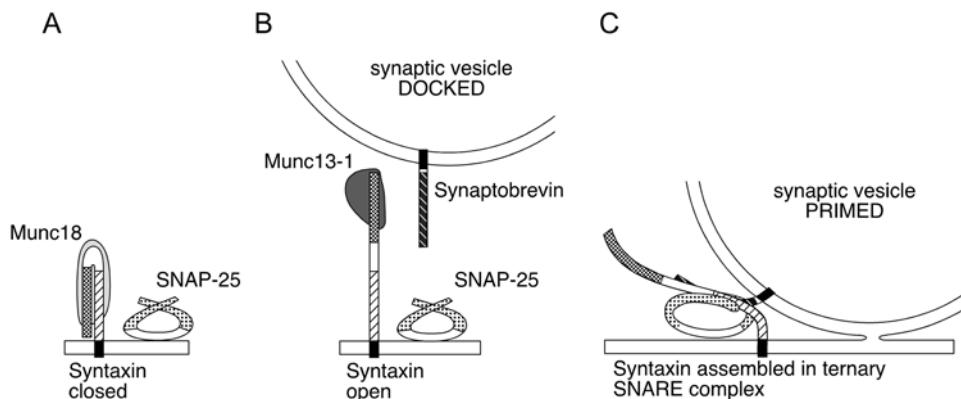

The molecule key to understanding the function of the SNARE complex during synaptic release is the t-SNARE syntaxin1, a neuronal isoform of the syntaxin protein family.

Syntaxin1 comprises a large cytoplasmic domain, one transmembrane domain, and a short extracellular C-terminus. Functionally, Syntaxin1 exists in three conformational states (Fig. 7–1) (reviewed in Brose et al., 2000; Rizo and Südhof, 2002). In the “closed” state, syntaxin1 binds to Munc18-1 (also known as nSec1, a neuronal isoform of the sec1/Munc18 protein family). Because the binding of syntaxin1 to Munc18-1 and to SNAP25 is mutually exclusive, it is postulated that Munc18-1 controls the pool of free syntaxin1 and inhibits formation of the SNARE complex. However, surprisingly, genetic deletion of Munc18-1 in mice caused complete loss of neurotransmitter release despite an apparently normal number of docked vesicles at the presynaptic membrane (Verhage et al., 2000). This indicates that in addition to its restrictive function in binding to syntaxin1 Munc18-1 plays a more positive and yet to be identified role during late steps of the synaptic vesicle cycle prior to synaptic release. Strikingly, these mice are born with essentially normal gross brain anatomy and morphologically defined synapses, demonstrating that SNARE-dependent neurotransmitter release is not required for brain assembly or formation of synaptic contacts; the mice, however, die immediately after birth owing to complete paralysis and exhibit widespread apoptosis in the brain.

In the next step, before formation of the SNARE complex, syntaxin1 undergoes conformational transition, from a “closed” to an “open” state, which disinhibits the binding of Munc18-1. Based on the following evidence, the main candidate for initiating this transition is Munc13 (reviewed in Brose et al., 2000; Rizo and Südhof, 2002). First, the carboxy-terminal region of Munc13-1 binds to syntaxin1 and displaces the binding of Munc18-1 in vitro. Second, double knockout mice lacking two Munc13 isoforms (Munc13-1 and Munc13-2) exhibit complete loss of neurotransmitter release at hippocampal synapses but no change in the total or docked number of vesicles at synapses; this demonstrates that

**Figure 7–1.** Three conformations of syntaxin during assembly of the ternary SNARE complex. *A*. Syntaxin in a “close” conformation is bound with Munc18 via its N-terminal  $H_{abc}$  (also termed  $H_A H_B H_C$ ) domain (checkered region of the syntaxin molecule) and a part of its juxtamembrane H3 domain (dashed region). *B*. During a switch from a “closed” to an “open” state, Munc18 is displaced

from syntaxin by Munc13. In the “open” state, syntaxin can interact with SNAP25 and synaptobrevin from a docked vesicle. *C*. The resulting “assembled” state corresponds to syntaxin binding within the ternary SNARE complex. The vesicle is now primed for synaptic release triggered by  $\text{Ca}^{2+}$  entry into the terminal (see Fig. 7–2). (Source: Brose et al., 2000, with permission.)

Munc13-1 and 13-2 function after synaptic vesicle docking, during priming, and prior to synaptic release (Varoqueaux et al., 2002). Importantly, a constitutively “open” mutant of syntaxin1, which does not bind Munc18-1, rescues the loss of Unc-13 (homologue of Munc13) in *Caenorhabditis elegans* (Richmond et al., 2001); these data provide further evidence that the Munc-13/Unc-13 proteins function during a conformational switch of syntaxin1 into the “open” state (see Section 7.2.5 for another role of Munc13-1 in binding with RIM1 and Rab3A). Other potential mechanisms that may modulate syntaxin1 transition to the open state include syntaxin1 binding to tomosyn, which also displaces Munc18-1, and/or a direct modulation of Munc18-1 by phosphorylation or by an interaction with other presynaptic proteins (reviewed in Rizo and Südhof, 2002).

The third conformational state of syntaxin corresponds to its binding in the SNARE complex, initially forming a binary complex with SNAP25, which is followed by assembly of the ternary SNARE complex with SNAP25 and synaptobrevin (Fig. 7–1). The complete “zipped” SNARE complex is formed by a tight four-helix bundle formed among coil-coil domains of all three SNAREs (one coil domain of syntaxin and synaptobrevin, and two of SNAP25). The orientation of the coil-coil domains in the complex is in parallel, which brings the docked vesicle in close contact with the active zone membrane, resulting in a primed readily releasable state. The unstable nature of the primed vesicles is reflected by occasional spontaneous miniature release events, electrophysiologically measured as miniature excitatory and inhibitory postsynaptic currents: mEPSCs and mIPSCs, respectively; these events can thus be seen as failures of the mechanism(s) that normally prevent  $\text{Ca}^{2+}$ -independent release at the synaptic terminals (see Section 7.1.5 for the role of synaptotagmin in the initiation of  $\text{Ca}^{2+}$ -triggered synaptic exocytosis).

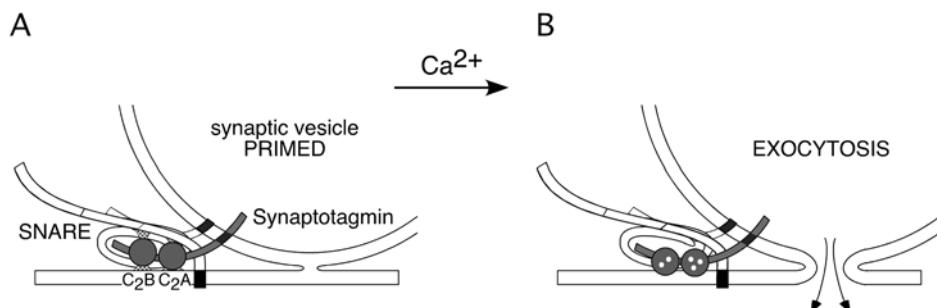

Mice engineered to lack either synaptobrevin or SNAP-25 were generated to explore the SNARE complex function *in vivo* (Schoch et al., 2001; Washbourne et al., 2002). Both genotypes were born with normal brain anatomy but died immediately after birth, likely owing to respiratory failure. Strikingly, although they showed drastically reduced (in the case of synaptobrevin knockout mice) or completely abolished (SNAP-25 knockout) action potential-evoked neurotransmitter release in hippocampal cultured neurons, spontaneous synaptic release was either only 10-fold decreased (synaptobrevin knockout) or occurred at wild-type frequency and amplitude (SNAP-25 knockout). These mice thus confirm that the SNARE complex is not required for synaptic vesicle docking, as previously indicated by the experiments with clostridial neurotoxins (see above). In addition, the persistence of spontaneous release indicates that the SNARE complex is not essential for fusion of docked vesicles at the active zone membrane. It remains to be determined if the release in the absence of synaptobrevin or SNAP-25 is due to compensation by other cellular SNAREs or is mediated via a truly SNARE-independent mechanism.

During or closely following formation of the SNARE complex, low-molecular-weight proteins termed complexins bind to the core complex at 1:1 stoichiometry in a groove between the synaptobrevin and syntaxin coil-coil domains. It has been proposed that complexins stabilize the SNARE complex prior to evoked neurotransmitter release. Mice lacking both complexin 1 and 2 isoforms show normal brain anatomy but die a few hours after birth (Reim et al., 2001). Analysis of synaptic functions in hippocampal cultured neurons revealed normal spontaneous release but dramatically reduced probability of evoked synaptic release. Complexins thus appear to fine-tune the competence of the docked vesicles to respond to a cytoplasmic influx of  $\text{Ca}^{2+}$ .

#### **7.2.4 $\text{Ca}^{2+}$ -triggered Synaptic Release: Role of Synaptotagmin**

The first step in the sequence of events underlying  $\text{Ca}^{2+}$ -triggered exocytosis is the activation of voltage-gated  $\text{Ca}^{2+}$  channels of the N and P/Q types by action potential-driven depolarization of the nerve terminal membrane (for review see Meir et al., 1999). For transmitter release to occur, the intracellular  $\text{Ca}^{2+}$  concentration must reach a threshold, which is set by the sensitivity of a  $\text{Ca}^{2+}$  sensor responsible for triggering the release. The bulk  $\text{Ca}^{2+}$  concentration in the presynaptic terminal reaches about 500 nM following an action potential. However, the  $\text{Ca}^{2+}$  concentration required for synaptic release is estimated to be as high as 10  $\mu\text{M}$  (from measurements made at the large calyx of the Held synapse) (Bollmann et al., 2000; Schneggenburger and Neher, 2000). Because such a high  $\text{Ca}^{2+}$  concentration is likely to be reached only in close proximity to the openings of the  $\text{Ca}^{2+}$  channels, it is important to maintain a close link between the channels and proteins of the presynaptic release machinery. This is mediated, at least in part, by direct protein–protein coupling of  $\text{Ca}^{2+}$  channels to the SNARE complex as well as to synaptotagmin 1 and 2, vesicular proteins proposed to function as presynaptic  $\text{Ca}^{2+}$  sensors (for a review on  $\text{Ca}^{2+}$  channel interactions with the active zone proteins, see Seagar et al., 1999). In addition, because neurotransmitter release at the CNS synapses is comprised of two kinetically distinct components—a major fast component followed by a smaller slower component—it is likely that at least two distinct  $\text{Ca}^{2+}$  sensors are employed to regulate the event.

Synaptotagmins constitute an 11-gene family of  $\text{Ca}^{2+}$ -binding proteins, the most abundant of which in the brain is synaptotagmin 1. The molecular structure of synaptotagmin consists of a small intravesicular domain, a single transmembrane domain, and a large cytoplasmic C-terminal domain, which contains two  $\text{Ca}^{2+}$ -binding  $\text{C}_2$ -domains ( $\text{C}_2\text{A}$  and  $\text{C}_2\text{B}$ ). The  $\text{Ca}^{2+}$  affinity of the  $\text{C}_2$  domains of synaptotagmin is highly increased by binding to phospholipid membranes. In the primed state, synaptotagmin  $\text{C}_2$  domains bind to the SNARE complex and to phospholipids of the active zone plasma membrane; upon  $\text{Ca}^{2+}$  entry, the  $\text{C}_2$  domains insert

**Figure 7–2.** Synaptotagmin role as a  $\text{Ca}^{2+}$  sensor for synaptic release. *A*. In the primed state, synaptotagmin  $\text{C}_2$  domains ( $\text{C}_2\text{A}$  and  $\text{C}_2\text{B}$ ) bind with phospholipids of the active zone plasma membrane and the SNARE complex (the SNARE components are shown as in Fig. 7–1). *B*. Upon  $\text{Ca}^{2+}$  entry, synaptotagmin binds  $\text{Ca}^{2+}$  ions

themselves farther into the plasma membrane, a step that may act as a final trigger for fusion between the synaptic vesicle and active zone membranes during synaptic exocytosis (reviewed in Südhof, 2004) (Fig. 7–2).

Perhaps the best evidence for the role of synaptotagmin in  $\text{Ca}^{2+}$ -induced synaptic release comes from synaptotagmin 1 knockout mice, which exhibit a severely depressed fast phase and a normal slow (asynchronous) phase of  $\text{Ca}^{2+}$ -dependent synaptic release in cultured hippocampal neurons. Note that the mice die after birth, indicating that the fast  $\text{Ca}^{2+}$ -dependent release is essential for life (Geppert et al., 1994b). As expected, presynaptic vesicle docking appears normal in these mice, with the readily releasable pool of synaptic vesicles, frequency of mEPSCs, and  $\text{Ca}^{2+}$ -independent neurotransmitter release all comparable to that in wild-type terminals. In addition, Fernandez-Chacon et al. (2001) used a sophisticated knock-in approach to introduce a single point mutation in the synaptotagmin 1  $\text{C}_2\text{A}$  domain, which decreased its  $\text{Ca}^{2+}$  affinity by 50%. This genetic manipulation resulted in a proportional decrease of  $\text{Ca}^{2+}$  sensitivity of neurotransmitter release in cultured hippocampal neurons prepared from the mutant mice (Fernandez-Chacon et al., 2001). (See Section 7.2.5 for a discussion of behavioral phenotype of synaptotagmin mutant mice.) Taken together, these findings strongly indicate that synaptotagmin 1 functions after docking and priming, during the fast phase of  $\text{Ca}^{2+}$ -triggered release.

### 7.2.5 $\text{Ca}^{2+}$ -triggered Synaptic Release: Role of Rab3A and RIM1

The abundant synaptic vesicle-associated protein Rab3A, a member of the Rab family of low-molecular-weight GTP-binding proteins, cycles between two functional states: a synaptic vesicle-associated GTP-bound form and a cytoplasmic GDP-bound form. Rab3A GTP hydrolysis, which occurs during or after neurotransmitter exocytosis, releases Rab3A from its association with the vesicular membrane. Cytoplasmic Rab3A-GDP is then recognized by the Rab3-

(marked as white dots; three per  $\text{C}_2\text{A}$  and two per  $\text{C}_2\text{B}$ ), which may further insert the  $\text{C}_2$  domains into the plasma membrane phospholipids. Such conformational change was proposed to act as the final trigger for synaptic exocytosis (Source: Südhof, 2004, with permission.)

GDP/GTP exchange factor, and Rab3A-GTP rebinds with synaptic vesicles.

Rab3A interacts, in a GTP-dependent manner, with two proteins proposed to function as its effectors, rabphilin and RIM1 (reviewed in Südhof, 2004). Both proteins have an N-terminal zinc finger domain (which mediates the binding with Rab3A) and two C-terminal  $\text{Ca}^{2+}$ -binding  $\text{C}_2$  domains. Rabphilin, a cytoplasmic protein, is recruited to synaptic vesicles by its interaction with Rab3A-GTP. RIM1, which is stably associated with the active zone membrane, binds via its zinc finger to Rab3A and Munc13-1, via its  $\text{C}_2\text{B}$  domain to synaptotagmin 1 and 2, and to liprins.

Rab3A does not play an essential role in docking or priming of synaptic vesicles as initially believed, as Rab3A knockout mice have a normal gross brain as well as synaptic morphology and normal spontaneous transmitter release (Geppert et al., 1994a). Rather, the function of Rab3A seems to be to modulate synaptic release, with distinct roles at various hippocampal synapses. At the CA3 to CA1 synapses, loss of Rab3A results in altered short-term plasticity with enhanced paired-pulse facilitation (Geppert et al., 1994a, 1997). In contrast, the mossy fiber to CA3 synapse shows normal short-term plasticity, but mossy fiber LTP (mfLTP) is abolished (Castillo et al., 1997a). Somewhat surprisingly, knockout of rabphilin showed no phenotype, indicating that rabphilin is not an essential Rab3A effector in the synaptic vesicle cycle (Schlüter et al., 1999). However, knockout of the major brain RIM isoform, RIM1 $\alpha$ , showed a broader phenotype than that of Rab3A, indicating additional roles for RIM1 $\alpha$  in synaptic release. First, mfLTP is abolished, as in the Rab3A knockout mice, suggesting that RIM1 $\alpha$  is the main effector of Rab3A at the mossy fiber to CA3 synapse (Castillo et al., 2002). Second, both the probability of evoked synaptic release and short-term plasticity are altered, but LTP can still be induced at CA3 to CA1 synapses (Schoch et al., 2002; Calakos et al., 2004).

Although the exact molecular mechanisms underlying the RIM1 $\alpha$ -based deficits remain to be explained, recent behav-

ioral experiments showed that the synaptic functions that are disturbed in the RIM1 $\alpha$  knockout mice are crucial for hippocampus-based behavior. The mice showed normal coordination and anxiety-like behavior but were deficient in two forms of hippocampus-dependent associative learning and memory: context-dependent fear conditioning and spatial learning in the Morris watermaze (Powell et al., 2004). In parallel experiments, the same authors found that mice lacking Rab3A, which are selectively deficient in mFLTP (see above), showed normal behavior. Thus, mFLTP is not essential for these hippocampus-dependent forms of learning. In addition, mice with a synaptotagmin C<sub>2</sub>A point mutation, which exhibit a decrease in the probability of release at hippocampal excitatory synapses similar to that seen in RIM1 $\alpha$  knockout mice (see Section 7.2.4), also showed normal behavior. The RIM1 $\alpha$  knockout behavioral phenotype thus cannot be simply correlated with the decreased release probability at excitatory synapses. The observed behavioral deficits in the RIM1 $\alpha$  knockout may result from the combined alterations in mossy fiber to CA3 transmission and CA3 to CA1 transmission. Alternatively, short-term plasticity, even in the presence of normal LTP, may play an important role in learning, as was already suggested with experiments using the synapsin II and I/II knockout mice (Silva et al., 1996) (see Section 7.2.2).

## 7.2.6 NSF-mediated Disassembly of the SNARE Complex

The SNARE complex, assembled by the  $\alpha$ -helical domains of t- and v-SNAREs during the steps of docking and priming, is thermodynamically stable. To initiate recycling of SNARE proteins for the next round of synaptic vesicle cycle after synaptic exocytosis, the SNARE complex must be first disassembled by a chaperon protein, the hexameric ATPase N-ethylmaleimide-sensitive fusion protein (NSF) (for review see May et al., 2001). The NSF molecule consists of three domains: an N-terminal domain responsible for binding with the  $\alpha$ -SNAP–SNARE complex (below) and two C-terminal ATP-binding domains, termed D1 and D2. The D1 domain is essential for NSF ATPase activity, and the D2 domain is required for NSF hexameric assembly. The association between NSF and the SNARE complex is not direct but mediated by an adaptor protein termed  $\alpha$ -SNAP (soluble NSF attachment protein). NSF binds to the  $\alpha$ -SNAP–SNARE complex only in the presence of ATP, forming the so-called 20 S particle. The quick-freeze/deep-etch electron microscopic image of the 20 S particle shows  $\alpha$ -SNAP and NSF wrapping as a “sleeve” along the rod-like  $\alpha$ -helical domains of the SNARE complex (Hanson et al., 1997). Binding of NSF to the  $\alpha$ -SNAP–SNARE complex stimulates NSF ATPase activity, resulting in subsequent disassembly of the SNARE complex driven by NSF-mediated ATP hydrolysis. The monomeric SNARE proteins syntaxin1, synaptobrevinm and SNAP25 are then sorted for the next round of vesicular cycling during endocytotic uptake of the components of the vesicular membrane (see below).

## 7.2.7 Synaptic Vesicle Endocytosis, Recycling, and Refilling

Currently, the model of recycling of the synaptic vesicular membrane and its integral proteins at the CNS synapses includes two pathways: “kiss-and-run” and clathrin-mediated endocytosis.

The kiss-and-run hypothesis proposes that the lumen of the synaptic vesicle briefly opens and closes again, without the vesicle membrane collapsing to the active zone plasma membrane; in the next step, the vesicle is recaptured mostly intact. Compelling evidence for kiss-and-run recycling comes from fluorescence imaging of single-vesicle release in hippocampal primary cultures, documenting partial loss of the vesicular content and recovery of the same vesicle afterward (Aravanis et al., 2003; Gandhi and Stevens, 2003). However, many questions about the molecular mechanisms that may regulate this form of release remain unanswered; for example, it is not known what prevents full collapse of the vesicle into the presynaptic membrane or how the vesicle is pinched off before it can “run” again.

The mechanisms of clathrin-mediated endocytosis of synaptic vesicles, in contrast, are understood in much more detail (reviewed in Slepnev and De Camilli, 2000). The general outline of the distinct molecular steps include formation of clathrin-coated invaginations (pits) followed by fission of the coated pits to generate free clathrin-coated vesicles, rapid loss of the clathrin coat, and reentry into the synaptic vesicle cycle. The formation of the clathrin-coated pits is initiated by binding of adaptor proteins AP-2 and AP-180 to synaptic vesicle proteins, such as synaptotagmin, that are undergoing sorting at the plasma membrane after neurotransmitter release and to phospholipids. The adapters then recruit the three-legged clathrin triskelia and synergistically induce clathrin polymerization, resulting in membrane invagination.

In addition to adaptor proteins, a number of accessory proteins are involved in the mechanisms of invagination of the clathrin-coated pit and formation of a uniform-size vesicle. Amphiphysin 1 and 2 are multifunctional adapters that bind to clathrin, AP-2, and synaptosomal and dynamin, which are involved in uncoating and fission of the vesicles (see below). In addition to their adaptor role, amphiphysins may also participate in the formation of membrane curvature during endocytosis via its N-terminal Bin/Amphiphysin/Rvs (BAR) domain; amphiphysins directly bind the membrane lipid bilayer and force membrane curving via BAR domains dimerized into a banana-like shape. As with many other synaptic proteins, the role of amphiphysins in the CNS has been examined by mouse genetics. Amphiphysin 1 knockout mice showed drastically diminished levels of amphiphysin 2, indicating that the proteins exist as functional heterodimers; and in vitro assays using lysates and cultured hippocampal cells from the knockout animals revealed defects in the assembly of the synaptic endocytic protein machinery as well as decreased rates of activity-dependent endocytosis and recycling of the vesicles (Di Paolo et al., 2002). Interestingly, the

mice have morphologically normal presynaptic terminals and unaffected evoked glutamate release, but they are prone to seizures and show cognitive deficits in hippocampus-based spatial learning (Di Paolo et al., 2002). Thus the exact role of amphiphysins in clathrin-mediated endocytosis remains to be established.

Another gene family of clathrin accessory proteins comprises the endophilins (endophilin 1, 2, and 3, of which endophilin 1 is the major isoform in the brain). Endophilins share the BAR and SH3-domain structure with amphiphysins and, in addition, exhibit enzymatic lysophosphatidic acid acyl transferase (LPAAT) activity. Endophilin 1 is proposed to promote negative membrane curvature directly during endocytosis by LPAAT activity-induced change in the composition of the plasma membrane and to act as an adaptor in recruiting synaptojanin and dynamin.

The key molecule during the fission of clathrin-coated vesicles is the GTPase dynamin (for review see Schmid et al., 1998). GTP-bound dynamin, which is recruited to the clathrin-coated membrane by its interaction with SH3 domains of amphiphysin, endophilin, and other accessory proteins, forms rings around the stalk of the clathrin pit. It has been proposed that dynamin-driven GTP hydrolysis induces conformational change in the dynamin ring and pinches off the coated vesicle by either restricting or elongating the stalk membrane.

It has been proposed that clathrin uncoating, a final step in clathrin-dependent endocytosis, is mediated by synaptojanins (synaptojanin 1 and 2—synaptojanin 1 is the main isoform in the brain). Synaptojanins have polyphosphoinositide phosphatase activity and degrade phosphatidylinositol-4,5-biphosphate, PI(4,5)P<sub>2</sub>, to phosphatidylinositol (for review see Slepnev and De Camilli, 2000). Because PI(4,5)P<sub>2</sub> is a positive regulator of clathrin assembly, its degradation is believed to be the mechanism for vesicle uncoating after dynamin-mediated fission. Mice lacking synaptojanin 1 die shortly after birth (indicating a crucial role of the gene for life) and show increased levels of PI(4,5)P<sub>2</sub> in cortical neurons, accumulation of clathrin-coated vesicles in nerve terminals, and depression of hippocampal Schaffer collateral CA1 transmission, rather than LTP, after high-frequency stimulation (Cremona et al., 1999).

Finally, before the vesicles are re-sorted back to the active zone membrane or to the reserve pool, they must be refilled with a corresponding neurotransmitter. The energy necessary for uptake of a specific neurotransmitter is provided by an electrochemical gradient with positively charged, acidic vesicle lumen; this gradient is generated by an ATP-driven proton pump termed “vacuolar H<sup>+</sup>-ATPase” (V-ATPase) (reviewed in Nishi and Forgac, 2002). The uptake is mediated by vesicular neurotransmitter transporters (VNTs), which pump neurotransmitter in exchange for protons. There are three types of VNT in the brain: vesicular amine transporters, vesicular inhibitory amino acid transporters, and vesicular excitatory amino acid transporters (reviewed in Eiden, 2000; Torres et al., 2003; Fremeau et al., 2004). The type of VNT expressed in

a specific cell type determines the neurotransmitter that is loaded into vesicles and subsequently released at axon terminals.

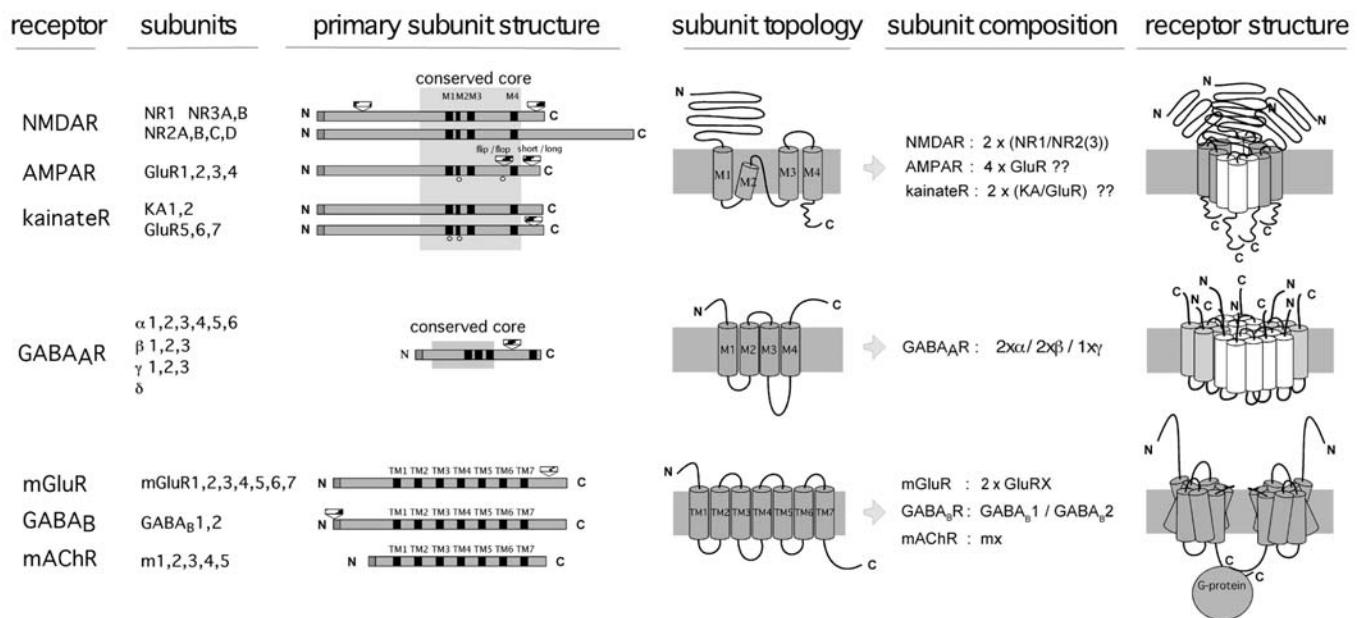

The vesicular monoamine transporter 2 (VMAT2) is responsible for synaptic vesicle uptake of catecholamines, serotonin, and histamine; and the vesicular acetylcholine transporter (VACHT) mediates uptake of acetylcholine. The two transporters are closely related, with the same protein topology consisting of 12 transmembrane domains and cytoplasmic N- and C-terminal domains. The vesicular GABA transporter (VGAT), also termed the vesicular inhibitory amino acid transporter (VIAAT), is responsible for loading of neurotransmitters GABA and glycine. VGAT has a topology of 10 predicted transmembrane domains. Finally, vesicular uptake of glutamate is mediated by a protein family of the vesicular glutamate transporters (VGLUT1-3). Interestingly, the first identified vesicular transporter for glutamate (termed “VGLUT1”) was originally cloned as a gene upregulated in cerebellar granule cells after treatment with NMDA; the gene was termed “Brain, Na<sup>+</sup>-dependent P<sub>i</sub> transporter1” (BNP1) because of its 32% amino acid identity with the Na<sup>+</sup>-dependent P<sub>i</sub> transporter from the kidney. However, 5 years later, BNP1 was localized selectively to glutamatergic synaptic vesicles and was shown to mediate vesicular glutamate uptake. The fact that VGLUT1 expression can be regulated by activation of NMDA-type glutamate receptors suggests that the levels of VGLUT1 may have a functional relevance for regulation of synaptic transmission. At the molecular level, VGLUT1 is a protein with predicted six to eight transmembrane domains. VGLUT1 and VGLUT2 show largely complementary expression in the CNS, with hippocampal glutamatergic neurons expressing mainly the VGLUT1 transporter (Fremeau et al., 2004).

### **7.3 Glutamate Receptors: Structure, Function, and Hippocampal Distribution**

#### **7.3.1 Introduction: Ionotropic and Metabotropic Receptors**

Glutamatergic synaptic transmission and, in particular, synaptic plasticity play a central role in hippocampus-dependent learning and memory. Activation of the ionotropic glutamate receptors provides an essential mechanism required for the induction of at least some forms of Hebbian synaptic plasticity; the metabotropic receptors play more modulatory roles in these processes. After a brief introduction to the nomenclature of the receptors (see Fig. 7–3 for an overview of ligand-gated receptor types), we discuss the molecular principles that enable the receptors to mediate their functions, the distribution of receptors in hippocampal neurons, and the mechanisms of the transport of receptors to excitatory synapses, with a particular focus on how glutamate receptor trafficking may regulate synaptic plasticity. Finally, we con-

**Figure 7-3.** Molecular organization of neurotransmitter receptors. From top to down: Receptors are grouped into NMDA, AMPA, and kainate receptor ion channels (iGluRs), GABA<sub>A</sub> receptor ion channels (GABA<sub>A</sub>Rs), and GABA<sub>B</sub>, mGlu, and mACh receptors (GABA<sub>B</sub>Rs, mGluRs, mAChRs). From left to right: (1) Receptor nomenclature. (2) Individual subunit nomenclature. (3) Primary structure of the subunits with indicated amino-termini (N) and carboxy-termini (C). The N-terminal signal peptides and the positions of membrane domains are indicated in dark gray and black boxes, respectively; the positions of alternative spliced exons are indicated in striped boxes and RNA-edited sites in open circles; con-

served regions between subunits of a receptor family have a gray background. (4) Membrane topology of the receptor subunits. Membrane spanning alpha helices are numbered and depicted as barrels; the cell membrane areas are in gray. (5) The subunit composition of the receptors is given as a formula. For example, NMDAR = 2 × [NR1/NR2(3)] – NMDA receptors are trimers consisting of two NR1 and two NR2 or NR3 subunits. (6) The oligomeric receptor structure shows the formation of the receptors from the individual subunits; in the cell membrane they are given as gray background.

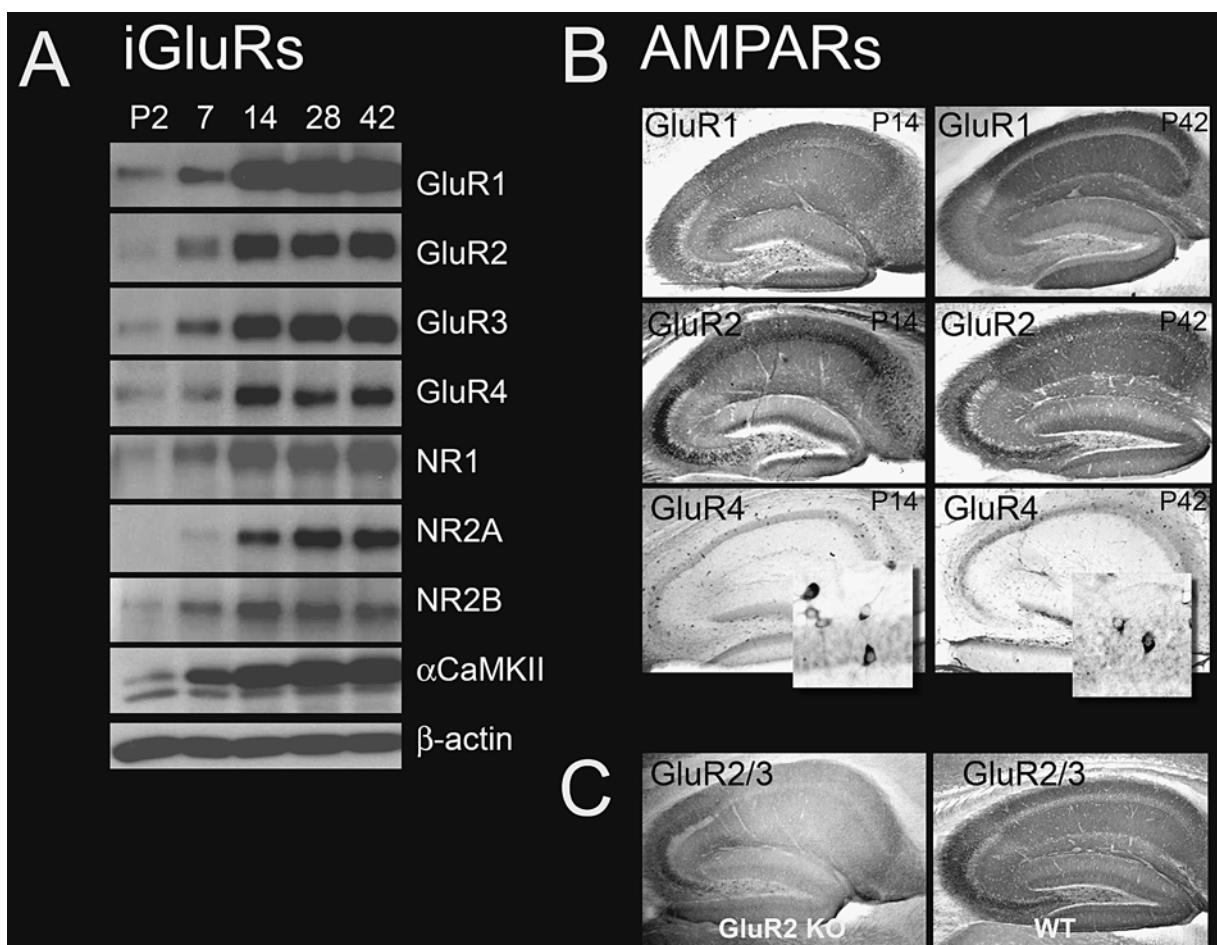

sider how genetically modified mice can be models of glutamate receptor function *in vivo*.

Ionotropic glutamate receptors (iGluRs) are ligand-gated ion channels that mediate most of the excitatory neurotransmission in the hippocampus (and elsewhere in the brain). Traditionally, iGluRs are classified into NMDA and non-NMDA (AMPA and kainate) receptors. The receptors are heteromeric assemblies of four subunits, with each distinct subunit encoded by its own gene. The molecular structure-function complexity is further extended by alternative splicing of the primary transcripts and by recoding through posttranscriptional RNA editing. The receptor subunits are glycosylated membrane-spanning polypeptides with an average length of 900 amino acids. According to our current understanding, the subunit segments M1, M3, and M4 are membrane-spanning; the M2 segment, which does not traverse the membrane bilayer, forms a pore-loop region, which determines the ion selectivity of the channel. The complete channel pore is built by amino acid residues of M1 and M3 together with the M2 loop; it is permeable to monovalent and, in some instances, divalent cations. The extracellular ligand-binding site is formed by the S1 region of the N-terminal domain and the S2 region of the extracellular loop between M3 and M4. The carboxy-terminal domain of each subunit is

intracellular and carries binding sites for several proteins regulating trafficking and signaling of the receptors at synapses.

The expression of most iGluR subunits in the hippocampus increases with development and reaches peak levels approximately 2 weeks after birth (Fig. 7-4). This developmental profile closely resembles that of the  $\alpha$  subunit of CaMKII, a kinase that critically contributes to the conversion of glutamatergic synaptic transmission into intracellular signaling during synaptic plasticity and learning. The iGluRs and  $\alpha$ -CaMKII can be viewed as the molecular core of hippocampal synaptic plasticity and learning.

In addition to the direct feedforward excitatory role mediated by activation of the iGluRs, glutamate plays modulatory roles in regulating its own release as well as GABA release and neuronal excitability in the hippocampus. This is achieved by activation of the kainate and metabotropic glutamate receptors (mGluRs). mGluRs are G protein-coupled receptors, which exhibit excitatory or inhibitory effects depending on the receptor subtype and the cell context: EPSPs are often reduced by presynaptic mGluR activation and enhanced by activation of postsynaptic mGluRs. Localization of mGluRs is often outside of pre- and postsynaptic sites, which suggests that optimal activation of mGluRs takes place during intense synaptic activity resulting in neurotransmitter spillover.

**Figure 7-4.** AMPA receptor subunit expression in mouse hippocampus. *A*, Immunoblots of mouse hippocampal extracts at postnatal day 2 (P2), P7, P14, P28, and P42 probed with antibodies against ionotropic glutamate receptor subunits and the  $\alpha$ -subunit of CaMKII (indicated on the right side of the panel). Anti- $\beta$ -actin staining was used for normalization of the amount of protein loaded (bottom lane). *B*, Expression of the GluR1, 2, and 4 subunits in the mouse hippocampus at P14 and P42 visualized by immunohistochemistry with subunit-specific antibodies. For GluR4 expres-

sion, higher magnification inserts demonstrate strong expression in interneurons in the pyramidal cell layer. (*Source:* Modified from Jensen et al., 2003b, with permission). *C*, GluR3 expression was visualized by an anti-GluR2/3 antibody in the hippocampus of adult GluR2 knockout mice (GluR2 KO, left panel); the right panel shows staining with the same antibody in wt hippocampus; the GluR2/3 signal represents mainly the GluR2 subunit (compare to GluR2-specific staining in the GluR2 panel, second from the top).

### 7.3.2 AMPA Receptors

The non-NMDA ionotropic receptors consist of two subgroups: AMPA and kainate receptors. In the hippocampus, AMPA receptors are responsible for “general purpose” transmission at all excitatory synapses. The properties of AMPA receptors allow high temporal precision and short latency of action potential initiation.

#### Posttranscriptional Modifications of AMPA Receptor Subunits

AMPA receptors are heterotetramers of GluR1 to GluR4 (or GluR-A to -D) subunits, all of which are expressed in the hippocampus. Of the four subunits, GluR2 plays the most critical role in determining ion channel properties: GluR2-containing

channels have low  $\text{Ca}^{2+}$  permeability and a linear I/V function relating evoked current to membrane potential. This electrophysiological profile is determined by a single amino acid residue of the GluR2 M2 pore-loop segment. Whereas GluR1, 3, and 4 subunits contain glutamine (Q) in this position, the GluR2 primary transcript undergoes selective RNA editing that changes the glutamine into an arginine (R)—so-called Q/R site editing (for review see Seuberg et al., 1998). In the hippocampus, the mature GluR2 transcript is 100% edited, and the Q-to-R coding change is essential for normal brain function (see Section 7.4.3 for consequences of disrupted Q/R editing in mice). In addition, GluR2, 3, and 4 transcripts are edited at an R/G site (the glycine codon replacing genetically encoded arginine), which is located just before the flip/flop exons (see below). R/G editing is somewhat less efficient, resulting in the editing of approximately 80% to 90% of

GluR2, 3, and 4, except for GluR4 flip, which is only 50% edited. Editing at the R/G site was shown to reduce the amplitude of and accelerate recovery from desensitization for recombinant GluR3 and GluR4; the physiological role for this AMPA receptor modification, however, is still unclear.

In addition to RNA editing, a second type of posttranscriptional modification—alternative splicing—modulates the properties of AMPA receptor channels in the hippocampus at distinct synapses (for review, see Dingledine et al., 1999) (see below for hippocampal distribution of different subunit splice forms). All AMPA receptor primary transcripts undergo alternative splicing of two exons encoding a 38-amino-acid segment of the extracellular loop between M3 and M4, just before the start of the M4 domain. Each subunit thus exists as either a “flip” or a “flop” variant, depending on which exon is retained. The flip/flop domain influences receptor desensitization: Flip forms desensitize with slower kinetics compared to flop forms. The GluR2 and GluR4 primary transcripts undergo, in addition to flip/flop splicing, alternative splicing of their C-terminal domain-coding sequences. The AMPA receptor subunit C-terminal domains are grouped into “long” (~70 to 80 amino acids; e.g., 81 aa in the rat GluR1 sequence) and “short” (~50 amino acids; e.g., 50 aa in rat

GluR3). The prevalent splice of the GluR2 transcript codes for a short C-terminal tail (50 amino acids); the 68 amino acid long splice form, termed GluR2<sub>long</sub>, is expressed at significantly lower levels but may be functionally important in the young postnatal hippocampus, where it mediates a juvenile GluR1-independent form of LTP (see Section 7.3.1). The GluR4 subunit is expressed in the hippocampus only in its long form, with a 68-amino-acid residue C-terminal domain. The role of the AMPA receptor subunit C-terminal peptides in mediating subunit-specific interactions with proteins regulating intracellular trafficking of the receptors is discussed further in Section 7.4.

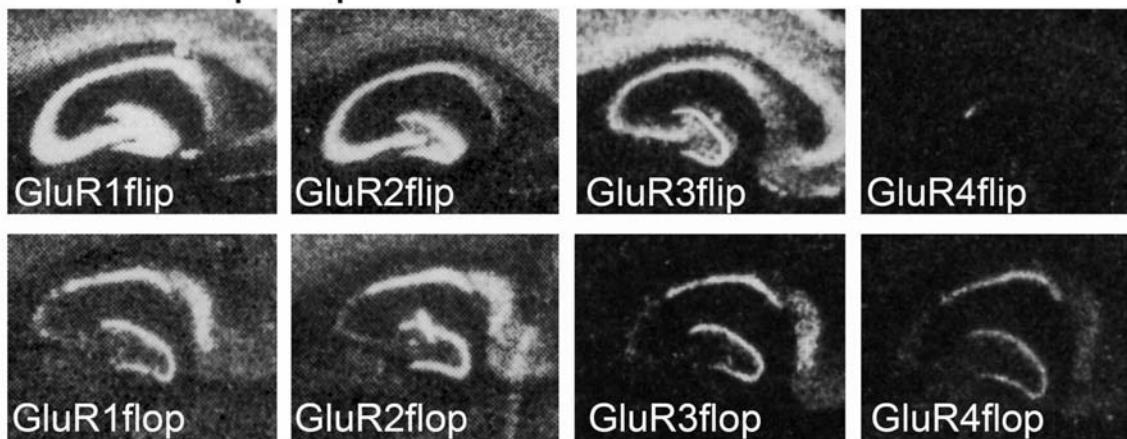

#### Hippocampal Distribution of AMPA Receptor Subunits

AMPA receptor subunit distribution varies significantly among hippocampal cell types (Fig. 7–4), resulting in different receptor properties between, for example, excitatory and inhibitory neurons. Hippocampal principal cells express mainly GluR1 and GluR2, whereas GluR3 is present at lower levels and GluR4 only in embryonic and early postnatal principal cells (see mRNA *in situ* detection in Keinanen et al.,

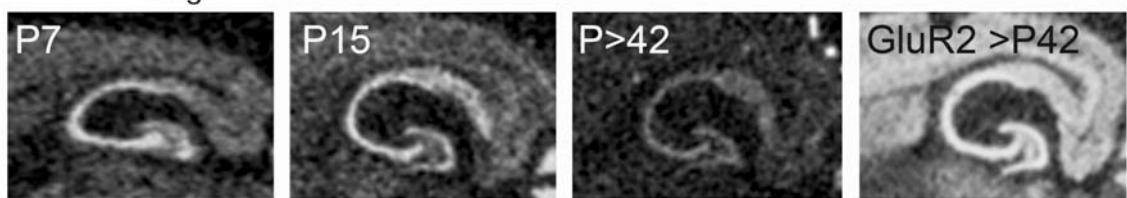

**Figure 7–5.** Expression of AMPA receptor-subunit splice variants in rodent hippocampus. A. *In situ* hybridization with specific oligonucleotides detects the mRNAs of the “flip” and “flop” versions of each AMPA receptor subunit in rat hippocampus at P15. (Source: Modified from Monyer et al., 1991, with permission). B. Developmentally regulated expression of the GluR2<sub>long</sub> subunit

in the mouse hippocampus, visualized by *in situ* hybridization with GluR2<sub>long</sub>-specific oligonucleotides at P7, P15, and mice older than P42 (P>42). For an approximate comparison of mRNA expression of both GluR2 isoforms, GluR2<sub>short</sub> (marked as GluR2) *in situ* is shown on the right.

#### A AMPAR flip/flop isoforms

#### B GluR2<sub>long</sub>

1990; protein detection in Petralia and Wenthold, 1992). The receptor assemblies are predominantly GluR1/2 channels, with some GluR2/3 and GluR1 homomeric channels. The fact that most AMPA receptor assemblies in the principal cells contain the edited GluR2 subunit guarantees that they conduct AMPA currents with low  $\text{Ca}^{2+}$  permeability. (Note that GluR1 does not appear to form channel assemblies with GluR3 in the principal cells, even though the GluR1/GluR3 channels are efficiently formed from recombinant subunits in heterologous expression systems; the mechanism of this selective AMPA receptor assembly is not understood.)

Both flip and flop splice versions of GluR1, 2, and 3 are expressed in CA1 pyramidal cells (Fig. 7–5). In contrast, CA3 pyramidal neurons synthesize only the flip versions of GluR1, 2, and 3. Dentate granule cells express GluR1, 2, and 3 flip and flop forms, with flop > flip forms (Sommer et al., 1990; Monyer et al., 1991) (Fig. 7–5). In addition, the flip and flop splice variants are also differently regulated during the development. The flop versions are expressed at low levels prior to postnatal day 8 (P8), and their characteristic high expression in CA1 pyramidal cells becomes apparent only during the second postnatal week, in parallel with synaptic maturation. In contrast, flip mRNA levels are already substantial in pyramidal cells at birth (Monyer et al., 1991). Hippocampal pyramidal cells also express both C-terminal splice forms GluR2 and GluR2<sub>long</sub>. GluR2<sub>long</sub> is expressed as early as the embryonic stage and reaches peak expression between P7 and P15. However, GluR2<sub>long</sub> is considerably less abundant than GluR2 (at the protein level, the GluR2<sub>long</sub>/GluR2 ratio is 1:5 in young hippocampus and 1:20 in adult hippocampus) (Kolleker et al., 2003).

Hippocampal interneurons express mainly GluR1 and GluR4 subunits. The fact that interneurons lack significant levels of GluR2 means that their synaptic AMPA currents show voltage dependence with high permeability to  $\text{Ca}^{2+}$  ions (Geiger et al., 1995). Both GluR1 and GluR4 are expressed mainly as the flop splice form in hippocampal interneurons (Monyer et al., 1991).

In addition to the cell type-specific expression patterns, there is now evidence that receptors with different subunit compositions are selectively targeted to distinct subcellular locations in individual neurons; this could potentially allow selective tuning of postsynaptic responses to glutamate release at different anatomical inputs projecting onto a particular cell. In the hippocampus, stratum lucidum interneurons express both  $\text{Ca}^{2+}$ -permeable (GluR2-lacking) and  $\text{Ca}^{2+}$ -impermeable (GluR2-containing) AMPA receptors at synapses receiving mossy fiber input, whereas synapses receiving input from CA3 pyramidal neurons express selectively  $\text{Ca}^{2+}$ -impermeable AMPA receptors (Toth and McBain, 1998). Functionally, whereas induction of synaptic plasticity (LTD) requires an elevation of postsynaptic  $\text{Ca}^{2+}$  at both synapse types, the requirement for NMDA receptor activation is restricted to the  $\text{Ca}^{2+}$ -impermeable synapses (Laezza et al., 1999; Lei and McBain, 2002).

In addition to synapse-specific targeting, AMPA receptors

are selectively distributed in the proximal versus the distal dendritic segments of hippocampal CA1 pyramidal neurons, with an increasing density toward more distal localization (Magee and Cook, 2000). This distance-dependent scaling of AMPA receptor distribution provides a mechanism that may help normalize the amplitudes of distal versus proximal synaptic inputs onto the same cell.

### 7.3.3 NMDA Receptors

NMDA receptors differ from AMPA receptors in several important properties, including voltage-dependent  $\text{Mg}^{2+}$  block of the channel pore, high permeability to  $\text{Ca}^{2+}$  ions, slower activation kinetics, longer open time, and higher affinity for glutamate (reviewed in Dingledine et al., 1999). At resting and slightly depolarized membrane potentials, the ion channel is blocked by the binding of extracellular  $\text{Mg}^{2+}$  in the ion pore. However, this  $\text{Mg}^{2+}$  block is released when the postsynaptic membrane is sufficiently depolarized (for example, due to strong activation of AMPA receptors). This unique feature gives NMDA receptors the ability to act as coincidence detectors for presynaptic activity (glutamate release) and postsynaptic activity (sufficient depolarization of the postsynaptic membrane). The subsequent postsynaptic influx of  $\text{Ca}^{2+}$  transduces the activation of NMDA receptors into  $\text{Ca}^{2+}$ -dependent intracellular signaling. These integrative and ion channel properties of NMDA receptor function underlie the induction of NMDA receptor-dependent synaptic plasticity, a process involved in many types of learning and memory formation (see Section 7.5.2 for genetic dissection of NMDA receptor-dependent plasticity in hippocampal learning in mice and Chapter 10 for a full account of synaptic plasticity in the hippocampus).

Seven genes encode the family of NMDA receptor subunits termed NR1; NR2A, 2B, 2C, 2D; and NR3A and 3B. The NR1 and NR3 subunits contain a binding site for glycine; and NR2 subunits bind glutamate. As demonstrated in mice with genetic deletion of the NR1 gene, NR1 is the essential subunit of all NMDA receptor channels; and in its absence, no functional NMDA receptors are formed in the brain (Forrest et al., 1994). Native tetrameric NMDA receptor assemblies are probably built of two NR1 and two NR2 or NR3 subunits. Depending on the presence of the NR2 and NR3 subunits, the NMDA receptors can be subdivided into the NR2A subtype (tetramer of two NR1 plus two NR2A), NR2B subtype (two NR1 plus two NR2B), and so on. The NR2 subunits determine the electrophysiological and pharmacological profile of the channels, affecting its open time, conductance, and  $\text{Mg}^{2+}$  sensitivity. The NR2B receptors stay open longer, providing a larger time window for coincidence detection than the NR2A receptor type. Compared to the NR2A or NR2B subtypes, the NR2D-type receptors show slow activation and deactivation kinetics (in the range of seconds rather than hundreds of milliseconds) as well as lower sensitivity to voltage-dependent  $\text{Mg}^{2+}$  block. Similarly, NR3 subunits determine that NR1/NR3 assemblies function as glycine-gated ion channels (Chatterton

et al., 2002). With the exception of the NR3B subtype, all NMDA receptor subtypes are expressed in the hippocampus; the NR2A and NR2B subtypes are the major hippocampal forms.

### Hippocampal Distribution of NR1 and NR1 Splice Variants

The NR1 subunit is expressed in dentate granule cells, in all pyramidal neurons, and in many interneurons (Laurie and Seburg, 1994; Monyer et al., 1994). Alternative splicing generates eight splice forms of the NR1 subunit. First, there are NR1 splice forms that either lack (NR1a) or contain (NR1b) exon 5 of the NR1 gene, which encodes the so-called N1 cassette; this cassette influences gating kinetics and is a part of the extracellular N-terminal domain of the receptor. A second group of NR1 forms is generated by alternative splicing of the last two carboxyl-terminal exons, 21 and 22. Exon 21 encodes the C-terminal domain C1 and exon 22 the C-terminal domains C2 and C2'. In the first set of splice forms, exon 21 is excluded and C2 or C2' are used for coding the NR1 C-terminal domain (NR1-2 and NR1-4). In the second set, exon 21 is present, which leads to C1-C2 and C1-C2' carboxy-termini (NR1-1 and NR1-3). The eight NR1 isoforms are then termed NR1a-1, NR1a-2, NR1a-3, NR1a-4, NR1b-1, NR1b-2, NR1b-3, and NR1b-4.

The NR1 splice forms are differentially expressed in the hippocampus (Laurie and Seburg, 1994) (Fig. 7–6). The NR1a, NR1-1, and NR1-2 splice forms are prominently expressed in all pyramidal cell layers of the hippocampus throughout development. In general, NR1-4 and NR1b are less expressed but show more prominent levels in CA3 pyramidal cells. NR1-3 expression is not detectable in the embryonic hippocampus and remains low in adult rats. The proposed roles of the various NR1 C-terminal splice forms in NMDA receptor trafficking and function, through mediating splice form-specific protein–protein interactions, are discussed in Section 7.4.2.

### Hippocampal Distribution of NR2 Subunits

Functionally, NR2A and NR2B receptor subtypes differ in their channel kinetics. As already discussed, NR2B receptors stay open longer, providing a larger time window for coincidence detection compared to the NR2A receptor type. Both NR2A and NR2B are prominently expressed in all cell layers of the hippocampus (Fig. 7–6). The NR2A/NR2B expression ratio increases strongly during postnatal development, indicating that the NR2B-type NMDA receptors are more important at the early postnatal stage, whereas the NR2A receptors play a major role at mature hippocampal synapses (Monyer et al., 1994). In addition to the developmental differences, NR2A and NR2B receptors are also selectively targeted to different synapses in the CA1 and CA3 principal cells. In CA3 cells, the NR2A receptors are preferentially located at commissural/associational synapses and the NR2B receptors

at the fimbrial–CA3 synapses (Ito et al., 1997). The NR2B-type receptors are also reported to be selectively targeted to the apical versus the basal dendrites of CA1 neurons of the mouse hippocampus at synapses receiving either ipsilateral or contralateral CA3 inputs (Kawakami et al., 2003). Finally, the NR2A- and NR2B-type receptors are distinctly localized in the same synapse, with the NR2B type placed more extrasynaptically and the NR2A type restricted to the center of glutamatergic synapses in hippocampal principal neurons (Tovar and Westbrook, 1999). The distinct expression profiles of the two subunits thus provide a mechanism for expression of different types of NMDA receptor-dependent synaptic plasticity at different synapses and developmental stages in the hippocampus (see Section 7.5.2 for NR2 mutant mice).

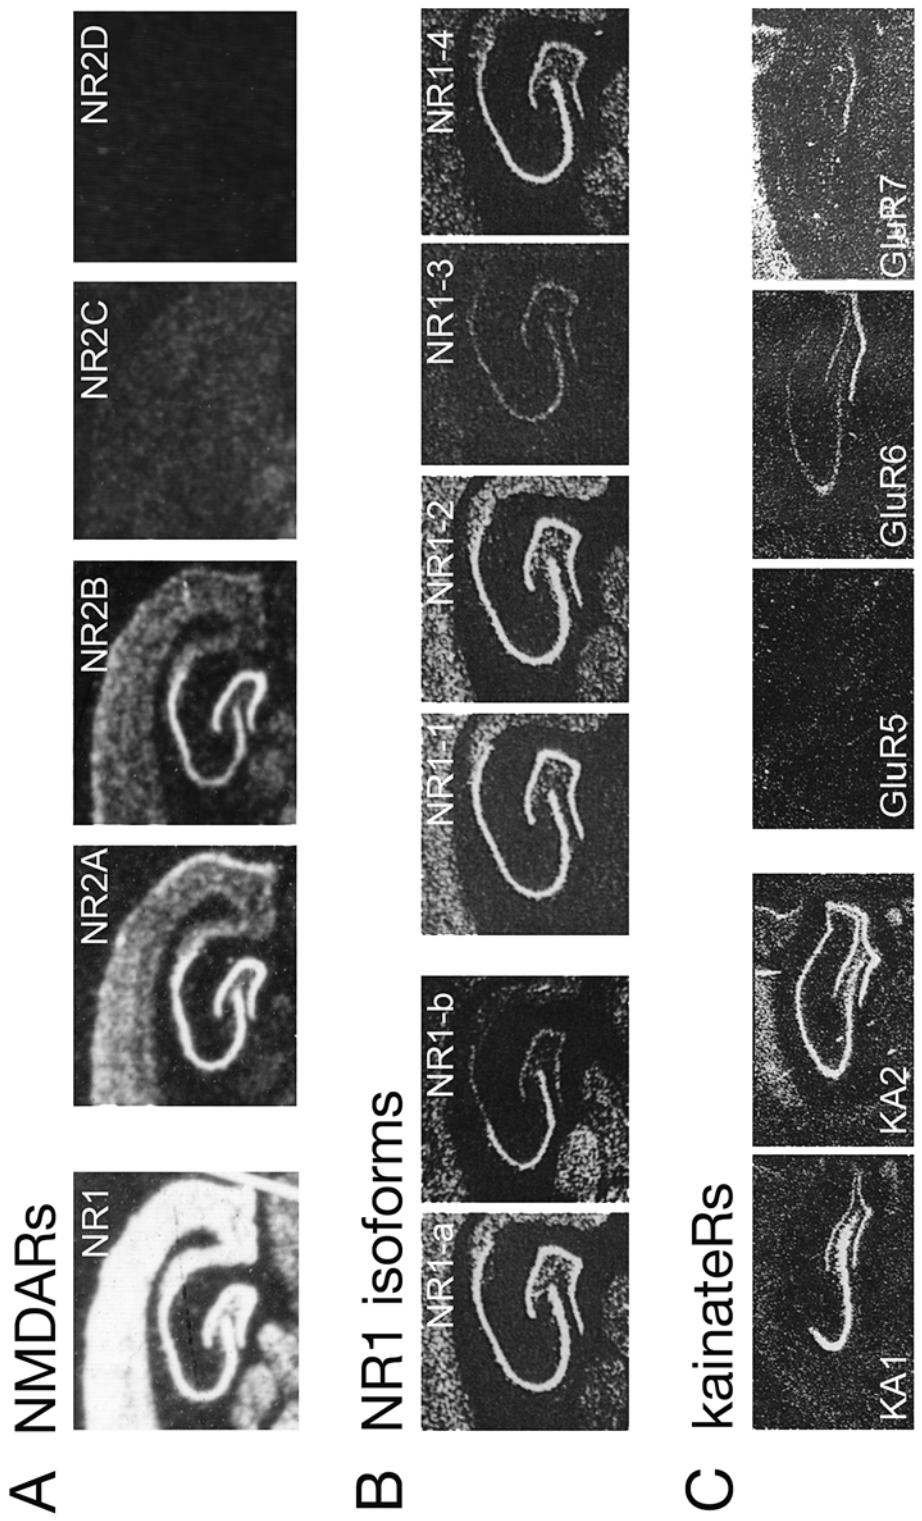

The NR2C receptor type is not significantly expressed in the hippocampus. NR2D expression is restricted to hippocampal GAD67-, parvalbumin-, and somatostatin-positive interneurons in the stratum radiatum of the CA1 and CA3 regions (Standaert et al., 1996). Functionally, as noted above, the NR1/NR2D receptors show slower activation and deactivation kinetics (in the range of seconds rather than hundreds of milliseconds) and lower sensitivity to voltage-dependent Mg<sup>2+</sup> block than do the NR1/NR2A or NR1/NR2B receptors (Monyer et al., 1994). Cells expressing the NR1/NR2D receptors would thus be expected to conduct NMDA currents without the need for strong coincident depolarization. However, hippocampal interneurons do not show the expected NR2D-type channel characteristics, possibly because NR2B has dominance over channel properties in NR1/NR2B/NR2D assemblies (cf. the NMDA receptor responses of NR1-, NR2B-, and NR2D-expressing cholinergic interneurons in the caudate-putamen) (Götz et al., 1997).

As with NR2D, the NR3A subunit is expressed in the hippocampus during embryogenesis and early postnatally, mainly in area CA1 and the subiculum (Ciabarri et al., 1995; Sucher et al., 1995). In the adult hippocampus, NR3A mRNA remains expressed in CA1 pyramidal cells, possibly forming NR1/NR3A glycine-gated excitatory cation channels. NR3B subtype receptors are not expressed in the hippocampus.

### 7.3.4 Kainate Receptors

Kainate receptors are tetrameric assemblies composed of GluR5, -6, -7 and KA1 and KA2 subunits, depending on which genes are expressed in a given cell type (Wisden et al., 2000). Recombinant GluR5, -6, and -7 subunits form functional homomeric as well as heteromeric channels; but most native receptors probably coassemble from both GluR and KA subunits.

Characterization of native kainate currents in the hippocampus has been made possible by using an antagonist (GYKI 53655), which selectively inhibits AMPA but not kainate receptors. With this pharmacological approach, kainate receptor-mediated currents were identified in the hippocampus at the mossy fiber synapses onto CA3 principal cells and the Schaffer collateral projections onto CA1

**Figure 7–6.** Expression of NMDA receptor subunits in rat hippocampus. A. In situ hybridization with specific oligonucleotides detects the mRNAs of NR1 and NR2A-D subunits. B. Expression of NR1 splice variant mRNAs visualized by in situ hybridization with splice form-specific oligonucleotides. C. Expression of kainate receptor subunit mRNAs in the adult rat hippocampus. (Sources: A: Modified from Monyer et al., 1994; B: modified from Laurie and Seuberg, 1994; C: modified from Wisden and Seuberg, 1993, all with permission.)

interneurons (Castillo et al., 1997b; Vignes and Collingridge, 1997; Cossart et al., 1998; Frerking et al., 1998). Further characterization of kainate receptor function was made possible by the development of knockout mice for the receptor subunit genes. At the mossy fiber–CA3 pyramidal cell synapse, kainate receptors participate in multiple aspects of transmission both pre- and postsynaptically. GluR6/KA2 receptors provide the postsynaptic response; GluR6/KA2/KA1 receptors contribute to presynaptic modulation (Contractor et al., 2003) (see more below). For the presynaptic component, applying low concentrations of kainate facilitates glutamate release; high concentrations depress release because of a depolarizing block of axonal conduction.

Kainate receptor currents constitute only about 10% of the total peak current generated by AMPA receptors on hippocampal pyramidal cells. However, the slow deactivation kinetics of kainate receptor currents means that during a mossy fiber composite EPSC a significant proportion of the total charge transfers through kainate receptors. Kainate receptors thus contribute to glutamate transmission by enhancing as well as extending the postsynaptic membrane depolarization. In addition, repetitive stimulation of the mossy fibers markedly increases kainate receptor currents; there is evidence that kainate receptors on mossy fiber terminals positively modulate synaptic release at higher firing frequencies of dentate granule cells (reviewed in Lerma, 2003).

### **Posttranscriptional Modifications of Kainate Receptor Subunits**

As with AMPA receptors, the structural/functional complexity of kainate receptors is increased by posttranscriptional modifications (reviewed in Dingledine et al., 1999). The subunits GluR6 and GluR7 each come in two splice forms, with different C-terminal sequences (GluR6-1, 2; GluR7a, b). The GluR5 subunit displays four alternatively splice C-tails; additionally, an exon encoding 15 amino acids in the N-terminal domain occurs in some transcripts. Functionally, recombinant homomeric GluR7a channels have 5- to 10-fold larger currents in HEK 293 cells compared to GluR7b, suggesting that the C-tail splicing may regulate kainate receptor function. In addition, the various C-terminal domains are likely to play distinct roles in receptor trafficking by binding with splice form-specific regulatory proteins.

The GluR5 and GluR6 subunits are also regulated by site-selective RNA editing. Like the AMPA receptor GluR2 subunit (see Section 7.2.2), RNA editing at the Q/R site (a glutamine to arginine coding change) in the M2 domain of the GluR5 and GluR6 subunits reduces the single-channel conductance and  $\text{Ca}^{2+}$  permeability and changes the I–V relation. In contrast to GluR2, however, the glutamine residue is edited only in some GluR5 and GluR6 transcripts, with a gradual increase in the expression of the edited forms of both subunits during postnatal development. In the adult, approximately 50% of

GluR5 and 80% of GluR6 are edited at the Q/R site. In addition, GluR6 undergoes editing at the I/V and Y/C sites in the M1 segment. Editing efficiency at these site is variable, giving a rise to a high number of functional variants (reviewed in Seuberg et al., 1998).

### **Hippocampal Distribution of Kainate Receptor Subunits**

In hippocampal principal cells, the KA1 gene is mainly expressed in CA3 cells and dentate granule cells, with markedly weaker expression in CA1 pyramidal cells (Werner et al., 1991; Wisden and Seuberg, 1993) (Fig. 7–6). At the electron microscopic level, KA1 immunoreactivity was found on presynaptic mossy fiber boutons and, to a lesser degree, in postsynaptic spines (Darstein et al., 2003). KA2 mRNA is abundant in both CA1 and CA3 pyramidal cells and in the dentate granule cells (Bahn et al., 1994). The GluR6 subunit is moderately expressed in all CA pyramidal cells and in the dentate granule cells, with expression in CA3 higher than in CA1 (Egebjerg et al., 1991; Wisden and Seuberg, 1993). Using a GluR7 knockout mouse and a GluR6/7-selective antibody, GluR6 immunoreactivity was strong in the stratum lucidum (suggesting mossy fibers) and the CA3 pyramidal cell layer (Darstein et al., 2003). GluR7 mRNA is present in dentate granule cells but absent from CA pyramidal cells (Bettler et al., 1992). Using a GluR6 knockout mouse and the GluR6/7-selective antibody showed that GluR7 immunoreactivity was confined to the somatodendritic regions of dentate gyrus granule cells (Darstein et al., 2003); thus, GluR7 may not contribute to the KA1/KA2/GluR6 receptors on the mossy fiber terminals (alternatively, GluR7 axonal transport may require subunit coassembly with GluR6). Taken together, based on the subunit distributions, immunoprecipitation assays, and electrophysiological analyses from knockout mice, kainate receptors in hippocampal principal cells are assemblies of KA2/GluR6 in CA1 pyramidal cells; KA2/GluR6 and KA1/GluR6 or KA1/KA2/GluR6 in CA3 pyramidal cells; and KA1-, KA2-, GluR6-, and GluR7-derived receptors in dentate granule cells. A significant expression of KA1/KA2/GluR6 receptors is presynaptically assembled on mossy fiber terminals. Note that KA1 and KA2 subunits selectively assemble with GluR6 but not GluR7 subunits in the mouse hippocampus (Darstein et al., 2003).

In hippocampal interneurons, the most prominent kainate receptor subunit is GluR5 (Bettler et al., 1990; Wisden and Seuberg, 1993; Bahn et al., 1994); approximately half of the interneurons in the stratum oriens of adult CA1 express GluR5 (Paternain et al., 2000). Some of these GluR5-positive cells are probably oriens/alveus/lacunosum-moleculare (OLM) interneurons. In addition, there are a few GluR5-positive cells in the stratum radiatum (approximately 14% of all GABAergic cells), and in the pyramidal cell layer itself (approximately 30% of all GABAergic cells located in the pyramidal cell layer). However, disruption of the GluR5 gene

does not cause a loss or reduction of functional kainate receptors in CA1 stratum radiatum interneurons, indicating that other kainate receptor subunits are also expressed in hippocampal interneurons (Mulle et al., 2000). Indeed, most of the GABAergic cells in the pyramidal cell layer also express GluR6 (Paternain et al., 2000), and combined deletion of GluR5 and GluR6 abolishes their kainate receptor-mediated currents. In addition, presynaptic GluR6- but not GluR5-containing receptors modulate synaptic transmission between inhibitory interneurons, indicating synapse-specific distribution of kainate receptor subunits in interneurons (Mulle et al., 2000).

Considering the GluR-6 expressing interneurons in more detail, there are a few GluR6-positive cells in the CA1 stratum oriens (6% of total GABAergic cells) and the stratum radiatum (approximately 3%); however, there are many GluR6-positive cells in the CA3 stratum lucidum; 85% of these GluR6-expressing stratum lucidum cells are also GAD65-positive. There are a few GluR6 mRNA-positive cells in the mouse stratum oriens and radiatum layers of both CA1 and CA3 (Bureau et al., 1999). Kainate receptor-mediated modulation of synaptic transmission between inhibitory interneurons in the stratum radiatum is impaired in GluR6 knockout mice (Mulle et al., 1998). However, excitation of the interneurons by activation of kainate receptors was still possible, suggesting the existence of two populations of kainate receptors in hippocampal interneurons (Mulle et al., 2000). GluR7 is expressed in occasional cells in the pyramidal cell layer; it is unknown if they are pyramidal cells or interneurons. There are a few GluR7 mRNA-positive cells in the mouse stratum oriens and stratum radiatum (Bureau et al., 1999).

### 7.3.5 Metabotropic Glutamate Receptors

Metabotropic glutamate receptors (mGluRs) are G protein-coupled and modulate glutamate release, GABA release, and neuronal excitability (for a review, see De Blasi et al., 2001). Metabotropic glutamate receptor activation inhibits or excites, depending on the receptor subtype and cell context. EPSPs are often reduced by presynaptic mGluR activation and enhanced by activation of postsynaptic mGluRs. An interesting aspect of the function of mGluRs in synaptic transmission comes from their subcellular localization: The mGluRs are typically outside of the pre- and postsynaptic membranes, indicating that they are selectively activated during intense synaptic activity, such as repetitive high-frequency firing, leading to a spillover of neurotransmitter into the perisynaptic space (Baude et al., 1993; Lujan et al., 1996; Shigemoto et al., 1997).

The eight mGluR receptor subtypes, each consisting of a large extracellular N-terminal domain with a binding site for glutamate, seven transmembrane domains, and an intracellular C-terminal peptide, are closely related to the family of GABA<sub>B</sub> receptors but have low sequence identity with “classic” G protein-coupled receptors such as the muscarinic receptors

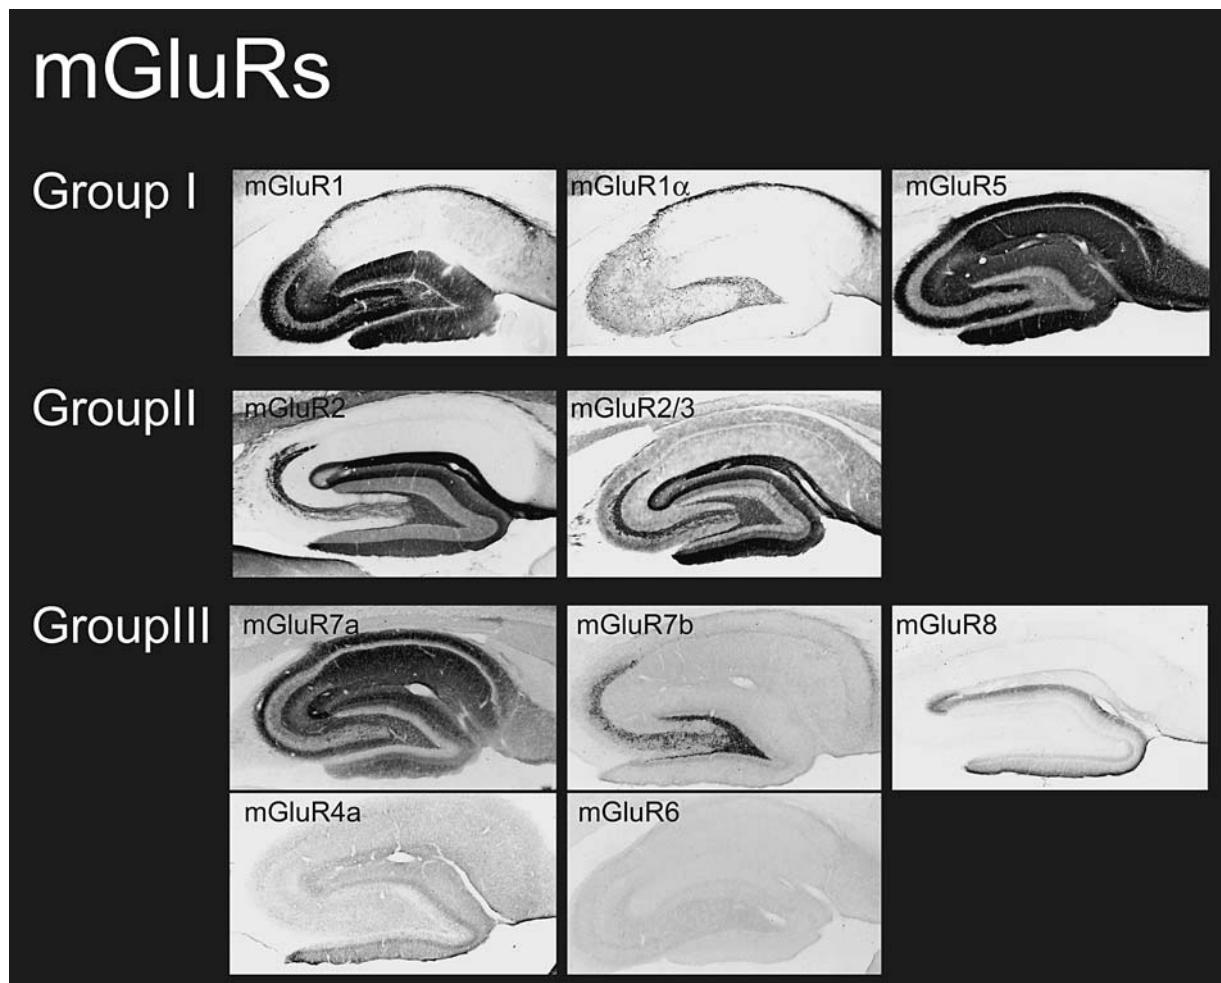

(considered later in the chapter). Unlike the heteromeric GABA<sub>B</sub> receptors (see Section 7.5.3), all mGluR receptors are homodimers. The mGluR family subdivides into three groups based on their pharmacological and functional properties: group I (mGluR1, mGluR5), II (mGluR2, mGluR3), and III (mGluR4, mGluR6, mGluR7, mGluR8) (Shigemoto et al., 1997). Group I mGluRs are selectively activated by 3,5-dihydroxyphenylglycine (DHPG) and positively couple via Gq to phospholipase C, thus stimulating protein kinase C activation and inositol triphosphate (IP3) production. Group I mGluRs have a somatodendritic distribution (see below); and their activation leads to enhanced excitability of hippocampal neurons via modulation of Ca<sup>2+</sup>, K<sup>+</sup>, and nonselective cation channels and to an increase in postsynaptic intracellular Ca<sup>2+</sup> via IP3-mediated release from internal Ca<sup>2+</sup> stores. Group II and III mGluRs are selectively activated by 2-(2,3-dicarboxy-cyclopropyl)glycine (DCG-IV) and 2-amino-4-phosphonobutyrate (L-AP4), respectively, and negatively couple via Gi to adenylate cyclase, thus inhibiting cAMP production. The mGluRs 2, 3, 4, 7, and 8 are located in axons near and within presynaptic terminals (see below). They suppress neurotransmitter release by inhibiting voltage-dependent Ca<sup>2+</sup> channels and/or by interfering directly with the release machinery. In the hippocampus, group III mGluRs mediate inhibition of excitatory transmission in the Schaffer collateral(CA1 cell synapses, whereas both group II and group III mGluRs contribute to presynaptic inhibition in the perforant path–granule cell synapses.

### mGluR Distribution in the Hippocampus

All mGluR genes, except mGluR6, are expressed in the hippocampus and show a diverse cellular distribution (Fig. 7–7). Their expression has been studied in detail by *in situ* hybridization and with subtype-specific antibodies.

From group I mGluRs, mGluR1 mRNA is in all principal cells, with the order of expression level DG > CA3 > CA1 (Shigemoto et al., 1992). Many interneurons in the CA1 stratum oriens and the stratum oriens and radiatum in CA3 are strong mGluR1 expressors (Shigemoto et al., 1992). Within the detection limits of the method, double-labeling *in situ* hybridization shows that mGluR1 mRNA is in somatostatin-positive but not parvalbumin-positive interneurons (Kerner et al., 1997). mGluR-5 mRNA is abundant in the hippocampus, expressed strongly in CA pyramidal cells, dentate granule cells, and many types of GABAergic interneurons (Fotuhi et al., 1994). mGluR-5 mRNA was also detected by double-labeling *in situ* hybridization in somatostatin-positive and parvalbumin-positive interneurons (Kerner et al., 1997). Group I mGluRs have a selective somatodendritic perisynaptic distribution in principal neurons and are typically located at the outer edge of postsynaptic densities of dendritic spines (Lujan et al., 1996; Shigemoto et al., 1997).

From group II and III mGluRs, mGluR3 mRNA is abundant in dentate granule cells but absent from pyramidal cells;

**Figure 7-7.** Expression of mGluRs in the rat hippocampus. Immunohistochemistry with sub-unit-specific antibodies was used to visualize expression patterns of individual mGluRs in adult hippocampus. (Source: Modified from Shigemoto et al., 1997, with permission.)

mGluR3 is also expressed in hippocampal white matter tracts, the fimbria, and the fornix (Ohishi et al., 1993). In contrast to the largely presynaptic localization of most group II and III mGluRs, mGluR3 protein is expressed perisynaptically in dendrites of the dentate granule cells in a pattern reminiscent of mGluR1 and mGluR5 expression (Tamaru et al., 2001). mGluR4 and mGluR7 mRNAs are both expressed in CA1 and CA3 pyramidal cells, dentate granule cells, and scattered interneurons (Ohishi et al., 1995). mGluR4 is more marked in CA2 pyramidal cells. The mGluR2 and mGluR7a proteins are on axons and terminals of the medial perforant path, whereas the lateral perforant path is prominently immunoreactive for mGluR8 in the dentate gyrus and the CA3 area. Mossy fibers contain mGluR2, mGluR7a, and mGluR7b, whereas Schaffer collateral axons display only mGluR7a. Group II (mGluR2) and group III (mGluR4, 7, and 8) mGluRs are in different parts of the presynaptic elements: Group III receptors predominate in presynaptic active zones of both asymmetrical (glutamatergic) and symmetrical (GABAergic) synapses,

whereas group II receptors are found in the preterminal portions of axons (Shigemoto et al., 1997).

#### 7.4 Trafficking of Glutamate Receptors and Hippocampal Synaptic Plasticity

In mammalian neurons, subcellular compartments, often located in near proximity to each other, comprise distinct protein complexes. For example, in principal neurons, excitatory synapses are positioned on dendritic spines, which contain glutamatergic receptors and cytoskeletal and signaling proteins relevant to their functions—all components of the so-called postsynaptic density (PSD). GABA receptors and their specialized cytoskeletal proteins, on the other hand, are positioned at GABAergic synapses scattered between the dendritic spines; whereas dendritic voltage-gated ion channels, regulating integration of the excitatory and inhibitory inputs along

the dendritic branches, are mostly excluded from the synaptic sites and show either uniform or gradient-like distributions in the dendrites. To maintain such function-specific subcellular distribution of proteins, neurons have a variety of trafficking proteins that mediate intracellular targeting, retention, and removal of particular receptors, channels, kinases, phosphatases, and other molecules at their corresponding destination sites.

The most prevalent type of protein–protein interaction underlying intracellular trafficking is between a short amino acid motif typically present at the C-terminal end of the trafficked protein and a PDZ domain of its cytoskeletal interactor. The PDZ abbreviation is derived from three proteins originally identified to contain this approximately 90-amino-acid structural motif: PSD-95 (postsynaptic density protein of 95 kD molecular weight), DlgA (*Drosophila* discs-large protein; present in septate junctions) and ZO-1 (protein of epithelial tight junctions). There are three PDZ domains that bind different amino acid sequences. The class 1 PDZ domain recognizes the X-S/T-X-V/L motif (where X is any amino acid), class 2 the X-f-X-f motif (f = hydrophobic aa), and class 3 the X-D-X-V motif (reviewed in Sheng and Sala, 2001). Next to the carboxyl sequence, PDZ domains can also bind to an internal motif that forms a β-hairpin structure, although this form of PDZ interaction is much less frequent.

#### **7.4.1 Synaptic Transport of AMPA Receptors in LTP and LTD**

Intracellular trafficking of ionotropic glutamate receptors includes selective somatodendritic transport to the postsynaptic membrane of glutamatergic synapses and anchoring of the receptors by cytoskeletal proteins. In addition, AMPA receptors undergo activity-dependent cycling between two pools: the functional pool of AMPA receptors inserted at the synaptic surface and the reserve pool of AMPA receptors present either intracellularly (in which case the movement is regulated by local endo- and exocytosis) or at the extrasynaptic surface membrane (in which case the receptors are transported by lateral diffusion). Such activity-dependent local synaptic recycling of AMPA receptors is believed to be one mechanism by which hippocampal pyramidal neurons—particularly in the CA1 region—can regulate the strength of their synaptic transmission.

#### **GluR1-dependent Trafficking and GluR1-binding Proteins: Relevance to Hippocampal LTP**

Trafficking mechanisms mediated by the GluR1 C-terminal domain were proposed to regulate synaptic insertion of GluR1-containing AMPA receptors at the Schaffer collateral to CA1 synapses. The initial evidence for this came from a series of electrophysiological experiments studying synaptic delivery of recombinant receptors in organotypic slice cultures (reviewed in Malinow and Malenka, 2002). In this work, synaptic insertion of recombinant GFP-tagged GluR1 recep-

tors, either homomeric GluR1 or heteromeric GluR1/2 channels, was shown to be triggered during the induction of LTP and to depend on the activation of NMDA receptors as well as α-CaMKII. Direct evidence of the role of GluR1 in LTP and in specific forms of learning came from mice that either lack the GluR1 gene altogether or contain the gene with knock-in mutations in its C-terminal phosphorylation sites (Zamanillo et al., 1999; Reisel et al., 2002; Lee et al., 2003) (these mouse models are discussed in detail in Section 7.5.3).

The search for trafficking proteins binding specifically to the GluR1 C-terminal domain has yet to yield a clear candidate for mediating synaptic delivery of GluR1-containing AMPA receptors. To date, the list of GluR1 C-tail interactors includes 4.1N protein, which binds at juxtamembrane C-tail region; PDZ domain-containing protein SAP-97, which binds at the class I PDZ binding motif at the C-tail carboxyl end; and PDZ and LIM domain-containing protein RIL (reverse-induced LIM domain protein), which binds at the last 10 amino residues of GluR1 C-tail via its LIM domain (reviewed in Malinow and Malenka, 2002; Song and Huganir, 2002). Note that the PDZ domain-binding motif of the GluR1 C-tail is not required for synaptic delivery/accumulation of the receptors or for synaptic plasticity in the CA1 hippocampus (Lee et al., 2003). Functionally, 4.1N protein was proposed to anchor GluR1-containing AMPA receptors at the synaptic surface by a linkage to spectrin/actin cytoskeleton; SAP-97 may regulate the transport of newly synthesized receptors through Golgi and ER compartments; and RIL was proposed to link the intracellular transport of the receptors in the dendritic spine compartment to the actin/α-actinin cytoskeleton (Song and Huganir, 2002; Schulz et al., 2004).

#### **GluR2-dependent Trafficking and GluR2-binding Proteins: Relevance to Hippocampal LTD**

It has been proposed that the prevalent C-terminal splice form of GluR2, with its 50-amino-acid residue “short” C-terminal tail, regulates activity-independent (constitutive) synaptic delivery of GluR2/3 receptors in the CA1 pyramidal neurons (this model of transport is again primarily based on electrophysiology experiments with recombinant channels) (reviewed in Malinow and Malenka, 2002). Interestingly, the GluR2/3 receptor insertion does not change the overall strength of synaptic transmission but, rather, replaces the GluR1/2-containing receptors. The GluR2-containing receptors, however, undergo activity-dependent endocytosis from the synaptic surface during protocols resulting in the induction of LTD. Based on these experiments, it was suggested that the synaptic transport of AMPA receptors is regulated by subunit-specific interactions where the GluR1 subunit plays a critical role in upregulating the strength of AMPA receptor-mediated transmission during LTP, and the GluR2 subunit mediates downregulation of the glutamatergic transmission seen in LTD.

Trafficking proteins that bind to the GluR2 C-terminal domain include N-ethylmaleimide-sensitive fusion protein

(NSF), glutamate receptor interacting protein (GRIP) and a closely related AMPA receptor-binding protein (ABP, also termed GRIP2), protein interacting with C-kinase (PICK1), and clathrin adaptor protein complex AP2 (reviewed in Song and Huganir, 2002). In general, the function of individual GluR2 interactors is not clearly resolved; the overall conclusions, however, tend to agree with the proposed role of GluR2-interacting proteins in endocytosis and recycling of the receptors and support the electrophysiology findings that GluR2-dependent transport plays a role in LTD. NSF is an ATPase that is essential for SNARE-dependent intracellular membrane fusion (see Section 7.2.6 for the role of NSF in neurotransmitter release). It was proposed that NSF binding to the GluR2 C-tail regulates the recycling of GluR2-containing AMPA receptors after their endocytosis from synaptic sites toward new synaptic insertion. One model of NSF function suggests that the ATPase regulates disassembly of the internalized receptors from their binding with PICK1 (Hanley et al., 2002). The binding by GRIP/ABP (proteins containing 6/7 PDZ domains) and PICK1 (single PDZ domain protein) at the same class II PDZ-binding motif of the GluR2 C-tail is regulated by phosphorylation: PICK1, but not GRIP/ABP, binds to the phosphorylated TEV motif. Functionally, GRIP/ABP binding was proposed to mediate anchoring of the GluR2-containing receptors at the hippocampal CA1 synapses (Osten et al., 2000), and PICK1 binding may regulate internalization of GluR2-containing receptors during LTD (Kim et al., 2001). Interestingly, PICK1-based GluR2 trafficking may also enhance the proportion of synaptic  $\text{Ca}^{2+}$ -permeable (GluR2-lacking) AMPA receptors, suggesting a further, more complex role for PICK1 in hippocampal synaptic functions (Terashima et al., 2004). The role of the AP2 adaptor, in agreement with its well established role in clathrin-dependent endocytosis (see also Section 7.1.7), appears to be necessary for activity-dependent internalization of the GluR2-containing receptors during LTD (Lee et al., 2002).

#### **Glutamatergic “Silent Synapses”: GluR2<sub>long</sub>-dependent and GluR4-dependent Trafficking**

Mature glutamatergic synapses contain both AMPA- and NMDA-type receptors. In contrast, electrophysiological recordings of synaptic currents in hippocampal slices prepared from rats less than 2-weeks old demonstrated that a large portion of young synapses contain only NMDA receptors and lack functional AMPA receptors. Because NMDA receptors are inhibited by their voltage-dependent  $\text{Mg}^{2+}$  block at a resting membrane potential (see Section 7.3.3), glutamate release at these sites fails to evoke postsynaptic currents; and hence such synapses were named “silent synapses” (reviewed in Malinow and Malenka, 2002). In addition to the electrophysiological demonstration of silent synapses, anatomical support for their existence was provided by an electron microscopy-based analysis of AMPA and NMDA receptor distribution, which confirmed the predicted large portion of

AMPA receptor-lacking synapses in the young hippocampus (Nusser et al., 1998b; Petralia et al., 1999).

The initial delivery of AMPA receptors to silent synapses—the conversion of silent to functional AMPA receptor-expressing synapses—has been proposed to be mediated primarily by two subunits, GluR4 and GluR2<sub>long</sub>, with closely related C-terminal domains (Zhu et al., 2000; Kolleker et al., 2003); GluR2<sub>long</sub> is a C-terminal splice form of GluR2 (see section 7.2.2). Both subunits are synaptically inserted during the induction of LTP as well as by synchronized spontaneous synaptic activity resembling the giant depolarizing potentials (GDPs) that frequently occur in the juvenile hippocampus. Interacting proteins specific for the GluR4 and/or GluR2<sub>long</sub> subunits, which could potentially regulate the trafficking of AMPA receptors to the silent synapses, are yet to be identified.

#### **AMPA Receptor Pan-subunit-interacting Proteins: Narp and Stargazin**

Two proteins, neuronal activity-regulated pentraxin (Narp) and stargazin (also termed  $\gamma 2$ ), were shown to bind to AMPA receptors without selectivity for individual subunits (reviewed in Bredt and Nicoll, 2003). Narp is a secreted immediate early gene product that binds to the extracellular portions of the GluR1/2/3 subunits. Narp was shown to induce AMPA receptor clustering and may function during glutamatergic synaptogenesis (O’Brien et al., 1999).

The stargazin gene was originally identified because of its spontaneous loss-of-function mutation in a mouse line with head-tossing movements (hence the name stargazer for the mouse and stargazin for the gene), ataxic gait, impaired eye-blink conditioning, and spike-wave seizures characteristic of absence epilepsy (reviewed in Letts, 2005). Stargazin is a four-transmembrane protein, with three closely related brain-specific isoforms:  $\gamma 3$ ,  $\gamma 4$ , and  $\gamma 8$ . The trafficking function of stargazin with respect to AMPA receptors was revealed first in stargazer cerebellar granule cells, which show a striking failure of AMPA receptor synaptic delivery (Chen et al., 2000). Note that these cells appear to express only stargazin, whereas most other CNS neurons express multiple stargazin isoforms (Tomita et al., 2003). Thus, the cerebellar granule cells can be considered a cellular model of a complete  $\gamma 2$ ,  $\gamma 3$ ,  $\gamma 4$ , and  $\gamma 8$  knockout. In the hippocampus,  $\gamma 8$  is the most prominent isoform but  $\gamma 2$ ,  $\gamma 3$ , and  $\gamma 4$  are also expressed; cellularly, stargazin and its isoforms are expressed in pyramidal neurons and interneurons (Tomita et al., 2003). In agreement with the overlapping expression in the hippocampus, genetic deletion of  $\gamma 8$  did not cause complete breakdown of AMPA receptor trafficking: Synaptic AMPA receptor-mediated currents in the CA1 pyramidal neurons were only modestly decreased in the  $\gamma 8$  knockout; however, the total protein levels of GluR1 and GluR2/3 receptors were strongly reduced, a portion of the remaining receptors appeared retained somatically, and extrasynaptic receptor pools were depleted; furthermore, LTP in the CA1 neurons was also impaired (Rouach et al., 2005).

How does this phenotype, which strikingly resembles genetic deletion of GluR1 in the hippocampus (see Section 7.4.3), compare to what is known about stargazin functions? Stargazin appears to be stably associated (as an auxiliary subunit) with a large portion of native AMPA receptors (Nakagawa et al., 2005; Vandenberghe et al., 2005) and was proposed to chaperone the transport of the receptors through early endoplasmatic reticulum and Golgi compartments (Vandenberghe et al., 2005). In the hippocampal CA1 pyramidal neurons, most mature AMPA receptor complexes thus appear to require the presence of GluR1 (see Section 7.4.3) and  $\gamma$ 8. In addition, stargazin and its  $\gamma$  isoforms are also likely to play direct roles in synaptic functions of AMPA receptors in the hippocampus: first, by anchoring the receptors to the postsynaptic cytoskeletal protein PSD-95 (Chen et al., 2000) (see Section 7.3.2 for PSD-95 role in synaptic function of NMDA receptors) and, second, by reducing the receptor desensitization in response to synaptic glutamate (Priel et al., 2005; Tomita et al., 2005; Turetsky et al., 2005). These functions may be sufficiently compensated by  $\gamma$ 2,  $\gamma$ 3, and/or  $\gamma$ 4 in the  $\gamma$ 8-knockout hippocampus.

#### 7.4.2 NMDA Receptor-associated Cytoskeletal and Signaling Proteins

Until recently, NMDA receptors were believed to be less synaptically “mobile” than AMPA receptors, and the trafficking of NMDA receptors was originally proposed to be largely limited to their synaptic delivery and subsequently transport for degradation. However, it is becoming evident that NMDA receptors undergo activity-dependent trafficking, which may be quite similar (for example, with regard to the subunit-specific transport mechanisms) to that of AMPA receptors, though perhaps happening on a slower time scale. At the same time, synaptic functions of NMDA receptors appear to depend critically on interactions with cytoskeletal and signaling proteins of the postsynaptic density, which directly or indirectly bind to the C-terminal domains of the receptor subunits. As described in Section 7.2.3, the major NMDA receptor types in the hippocampus are the NR1/NR2A, NR1/NR2B, and to a lesser extent NR1/NR2A/NR2B subunit assemblies. The NMDA receptor C-terminal domains are quite large, varying from approximately 100 amino acid residues for the longer NR1 splice forms to more than 600 amino acid residues for the NR2A/2B subunits. These receptor domains are thus well suited to accommodate a large number of interacting proteins and their associated protein complexes.

##### Regulation of NMDA Receptor Function via PSD-95 and Its Interacting Proteins

The identification of PSD-95 as an NMDA receptor-binding protein (which incidentally was also the first identification of a protein–protein interaction at a C-terminal tail of a glutamate receptor subunit) came from a yeast two-hybrid screen

with the entire 627-amino-acid residue NR2A C-terminal domain (Kornau et al., 1995). The yeast two-hybrid method is used to identify protein interactions by screening a cDNA library, such as a brain or hippocampal library, with a transcription-reporter system in yeast; it has been used for isolation of most of the glutamate receptor-interacting proteins described to date. NR2A, as well as the other NR2 subunits, binds to the second and third PDZ domains of PSD-95 via a conserved class I PDZ-binding motif; in addition, NR1 splice forms containing the C2' segment, NR1-3, and NR-4, may also bind to PSD-95 via a different PDZ-binding sequence (reviewed in Sheng and Sala, 2001).

PSD-95 is an abundant postsynaptic protein that contains three PDZ domains, an SH3 domain, and a nonfunctional guanylate kinase (GK) domain. The PSD-95 protein family consists of three additional closely related proteins: SAP102, SAP97, and PSD-93 (note that SAP97 binds to GluR1) (see Section 7.3.1). Functionally, PSD-95 acts as a scaffold linking a number of other postsynaptic proteins to the NMDA receptor complex (reviewed in Sheng and Pak, 2000). For example, PSD-95 binds, via its GK domain, to a protein termed GKAP. GKAP binds to Shank, and Shank in turn binds to Homers and cortactin. Dimers of Homer may link the NMDA receptors to internal  $\text{Ca}^{2+}$  stores or to the metabotropic receptors, as Homer also binds to the IP<sub>3</sub> and/or ryanodine receptors of the  $\text{Ca}^{2+}$  stores and to the C-terminal domains of mGluR1a/mGluR5 (see more on Homer in Section 7.3.3). Cortactin, on the other hand, links the NMDA receptors to the actin cytoskeleton. Other proteins are associated with PSD-95 via binding to one of its three PDZ domains; these proteins include the neuronal nitric oxide synthase (nNOS); neuronal cell adhesion proteins neuroligins, microtubule-binding protein CRIP; synaptic GTPase-activating protein for Ras termed SynGAP; Rho effector citron; nonreceptor tyrosine kinase Fyn; and possibly Src. Taken together, the scaffold function of PSD-95 is twofold: First, PSD-95 anchors the receptors to postsynaptic cytoskeletal proteins; and second, it links signaling molecules to the near proximity of the receptors. In addition, PSD-95 directly clusters NMDA receptors at the postsynaptic membrane, a function that depends on its ability to multimerize and to associate with membrane lipids via palmitoylation of cysteine residues in the N-terminal portion of the PSD-95 molecule (reviewed in el-Husseini Ael and Bredt, 2002).

The importance of PSD-95 for NMDA receptor function was directly tested in mice engineered to lack the PSD-95 gene (Migaud et al., 1998). Somewhat surprisingly, the subcellular distribution of the receptors in hippocampal CA1 neurons was normal, indicating that PSD-95 is not essential for NMDA receptor targeting to and accumulation at excitatory synapses. In contrast, synaptic plasticity at the Schaffer collateral to CA1 synapses was altered: The frequency threshold for the induction of NMDA receptor-dependent LTD and LTP was shifted in favor of LTP, resulting in strikingly enhanced LTP at stimulation frequencies ranging from 1 to 100 Hz. In agreement

with the belief that LTP and LTD are both required for normal learning and memory, the PSD-95 knockout mice showed a profound deficit in hippocampus-based spatial learning in the Morris watermaze (Migaud et al., 1998). One possible explanation of the PSD-95 null phenotype is that other members of the PSD-95 family are able to compensate for the trafficking and clustering functions but are not sufficient to bind one or more of the signaling molecules that are normally linked by PSD-95 in the proximity of NMDA receptors (see above). Presently, it is not clear which PSD-95-dependent signaling molecules/cascades may be impaired in the knockout mice. The cellular and behavioral phenotypes do, however, provide evidence regarding the importance of the NMDA receptor subunit C-terminal domains for normal NMDA receptor function. This conclusion was even more dramatically established in mice engineered to lack the complete C-terminal peptides of the NRA, NR2B, or NR2C (Sprengel et al., 1998) (see Section 7.5.2).

### NMDA Receptor-interacting Proteins (Other than PSD-95)

In addition to PSD-95, a number of other postsynaptic proteins bind directly to the NMDA receptor complex—primarily to the NR1 C-terminal domain (see above for NR1 C-terminal splice forms). The juxtamembrane region of the NR1 C-terminal peptide, termed C0, serves as a binding site for  $\alpha$ -actinin, an actin-binding protein. This interaction may contribute to anchoring of the receptors at the postsynapse, as actin is the major cytoskeleton of dendritic spines. (Note that there are at least three other possible ways for linking NMDA receptors to actin cytoskeleton: via NR2B binding to  $\alpha$ -actinin, via NR1/2A/2B binding to spectrin, and via the PSD-95-GKAP-Shank-spectrin complex—as reviewed by Sheng and Pak, 2000.) Other interactions give rise to functional changes. Calmodulin binds to the C0 and C1 segment of NR1; this interaction is  $\text{Ca}^{2+}$ -dependent and causes an approximately fourfold reduction of open NMDA channel probability. It has been proposed that competitive binding between  $\alpha$ -actinin and  $\text{Ca}^{2+}$ /calmodulin at the C0 segment mediates activity/ $\text{Ca}^{2+}$ -dependent inactivation of NMDA receptors (Zhang et al., 1998; Krupp et al., 1999). In addition to calmodulin, two other proteins bind to the NR1 C1 segment: yotiao and neurofilament L. Yotiao may serve to link the type I protein phosphatase (PP1) and the adenosine 3',5'-monophosphate (cAMP)-dependent protein kinase (PKA) to the proximity of the receptor (Sheng and Pak, 2000). This close physical association of kinases and phosphatases with the NMDA receptors is an elegant mechanism that enhances the coupling of the  $\text{Ca}^{2+}$  influx to downstream signaling molecules. Perhaps the best example of such “symbiosis” is the binding of the most abundant postsynaptic kinase, CaMKII, to the NR2A/NR2B subunits.

CaMKII plays a critical role in plasticity at Schaffer collateral to CA1 synapses, where it has been shown to be both necessary and sufficient for the induction of LTP (see Section

7.5.1 on deficits in LTP and learning in mice lacking the  $\alpha$ -isoform of the kinase). The current model of CaMKII in LTP suggests that the kinase, after its activation by postsynaptic  $\text{Ca}^{2+}$  influx through the NMDA receptors, undergoes a molecular switch by autophosphorylation of a single residue in the regulatory domain (Thr286 in  $\alpha$ -CaMKII), which allows the dodecameric holoenzyme to become persistently active even in the absence of  $\text{Ca}^{2+}$ /calmodulin; as a next step, the kinase translocates to the NMDA receptor complex and binds to the C-tails of NR2A/B and/or NR1 (reviewed in Lisman et al., 2002). The switch back to a normal state requires dephosphorylation of the kinase; similar dephosphorylation by PP1 may occur during LTD (note that PP1 is also localized to the NMDA receptor complex by its interactions with yotiao, see above). In addition, binding of activated CaMKII selectively to the NR2B C-tail locks the kinase in an autoactive state that does not require autophosphorylation (Bayer et al., 2001). Once at the PSD site, CaMKII can phosphorylate the GluR1 C-terminal Ser831, which directly increases the channel conductance of GluR1-containing AMPA receptors; furthermore, CaMKII-mediated phosphorylation of a yet to be identified protein(s) was proposed to regulate the synaptic insertion of AMPA receptors during the induction of LTP (see Section 7.4.1) (reviewed in Malinow and Malenka, 2002).

### Synaptic Trafficking of NMDA Receptors: Relevance to Homeostatic Plasticity and LTP

Intracellular transport of NMDA receptors appears to be tightly regulated at several levels, from the assembly and trafficking in the endoplasmatic reticulum to agonist induced internalization at synapses. As discussed in Section 7.3.3, the NR2B receptors are more prevalent at young and NR2A at mature hippocampal synapses; in the adult, NR2B receptors are expressed at lower levels and perhaps mainly extrasynaptically. Some of the first evidence for regulated synaptic trafficking of NMDA receptors came from studies showing that long-term changes in overall synaptic activity regulate the synaptic expression of both AMPA and NMDA receptors, a phenomenon termed “homeostatic plasticity.” Chronic (several hours or even days) suppression of excitatory network activity upregulates AMPA and NMDA receptor-mediated responses, whereas chronic elevation of excitatory network activity has the opposite effect (reviewed in Turrigiano and Nelson, 2004). This form of plasticity was proposed to protect excitatory circuits from both runaway excitation and too little excitation (in other words, to maintain an overall balance between synaptic input and spiking output in excitatory networks).

Synaptic delivery of the NR2A and NR2B receptors at hippocampal synapses is also differently regulated by activity: NR2B insertion at synapses occurs constitutively, whereas the exchange of NR2B for NR2A receptors is driven by synaptic activity (Barria and Malinow, 2002). This transport mechanism may guarantee that NR2B receptors are freely inserted during development and prior to and/or during the formation

of synaptic contacts, whereas the NR2A receptors are delivered only to preexisting synapses. Recently, synaptic recruitment of NMDA receptors was also observed during LTP, analogous to the delivery of AMPA receptors but with a delay of approximately 2 hours (Watt et al., 2004); this finding provides a mechanism for maintaining a constant ratio of AMPA to NMDA receptors at synapses, as observed on a longer time scale during the homeostatic form of plasticity.

#### 7.4.3 Proteins Regulating Transport and Function of mGluRs

As with ionotropic glutamate receptors, the subcellular trafficking and function of mGluRs are also regulated via proteins binding at their intracellular C-terminal domains. However, fewer mGluR-binding partners have been identified so far (see below). In view of the numerous mGluR C-terminal splice variants, further mGluR trafficking proteins may be expected to be found in the coming years (mGluR C-terminal variations due to alternative RNA splicing include four versions of mGluR1, termed mGluR1a to d; and two versions each of mGluR4, 7, and 8, termed mGluR4a and b, mGluR5a and b, mGluR7a and b, and mGluR8a and b).

Both members of the mGluR I group (mGluR1 and mGluR5) bind to proteins of the Homer gene family, which, in turn, interact with the NMDA receptor-PSD-95 complex (see above). Homers exist in two forms: constitutively expressed Homers (Homer 1b and c, 2, and 3), which contain an N-terminal EVH domain and a C-terminal dimerizing coil-coil domain; and an immediate early gene (IEG) homer (Homer 1a), which lacks the coil-coil domain (reviewed in Xiao et al., 2000; Fagni et al., 2002). Due to the lack of the coil-coil domain, Homer1a cannot dimerize; it can, however, act as a competitive decoy and disrupt the interactions between full-length Homer dimers and their associated proteins. Homers bind via their EVH domain to the Pro-Pro-X-X-Phe motif present in the distal part of the mGluR1a/5 C-terminal domains. The mGluR-Homer interaction may serve several functions. First, Homer proteins may direct the targeting of mGluR1a/5 to dendrites rather than axons, and anchor mGluR1a/5 within intracellular membrane compartments. In this scenario, the induction of the IEG Homer1a would act to release the intracellular anchor and lead to the delivery of the receptors at the perisynaptic membrane. Second, as with NMDA receptors, the Homer dimer complex may link group I mGluRs to the cytoskeleton of dendritic spines via a mGluR1a/5-Homer-Homer-Shank complex. However, because NMDARs and mGluR1a/5 are differentially localized in spines (the former in the postsynaptic density, the latter perisynaptically), it seems likely that protein(s) other than Homers mediate the precise localization of mGluR1a/5 at the cellular membrane. Third, Homers may couple mGluR1a/5 directly to intracellular  $\text{Ca}^{2+}$  stores via the mGluR1a/5-Homer-IP3/ryanodine receptor complex. Fourth, and finally, Homers may directly regulate the function of mGluR1a/5, as full-length Homer forms have been shown to

inhibit the constitutive activity of this mGluR species. Under this last scenario, the induction of Homer1a would not only increase the surface expression of mGluR1a/5, as described above, but also enhance mGluR activation even in the absence of glutamate.

Axonal transport of the presynaptic mGluR7 in hippocampal neurons is directed by a sequence in the mid-region of its C-terminal peptide (Stowell and Craig, 1999). The distal region of the mGluR7 C-terminal tail interacts with the PDZ domain-containing protein PICK1 (Boudin et al., 2000), a protein that also binds to the C-terminal domains of the AMPA receptor subunits GluR2 and GluR3. The mGluR7-PICK1 interaction may mediate the clustering of metabotropic receptors at the presynaptic terminal membrane.

### 7.5 Glutamate Receptor Mutant Mice: Genetic Analysis of Hippocampal Function

#### 7.5.1 Introduction: Building of Hippocampus-specific Genetic Models

As discussed in detail in Chapter 10, modulation of excitatory synaptic transmission between principal neurons, typically via Hebbian synaptic plasticity, is believed to constitute the principal neural mechanism of hippocampus-dependent learning and memory. Mouse models engineered to lack a specific gene related to functions underlying synaptic plasticity or to express a modified version of such a gene with an altered function, are becoming increasingly powerful in addressing molecular and cellular mechanisms underlying the various types of hippocampal learning and memory that are studied in rodents (see Chapter 10 for hippocampus-based learning in rats and mice). A pioneering work in this direction was the generation of mice lacking the  $\alpha$  subunit of the  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase (CaMKII), an enzyme postulated to be a critically important player in the process of memory formation in the hippocampus (see Section 7.4.2 and Chapter 10 for activation of CaMKII in LTP). The  $\alpha$ -CaMKII knockout mice showed impairment of LTP at CA3 to CA1 synapses, as well as deficits in hippocampus-dependent learning (Silva et al., 1992a,b). This was a critical piece of evidence highlighting the importance of  $\alpha$ -CaMKII in LTP; even more importantly, together with the contemporaneous study of the fyn mutant (Grant et al., 1992), it provided the first genetic evidence that LTP is involved in hippocampal memory formation.

In many other genetic studies, however, the correlation between the introduced manipulation and hippocampus-based memory formation is not as easily interpretable. Typically, this is due to lack of a spatiotemporal regulation over the onset of the manipulation, resulting in alteration of a specific gene function that is present in many different brain regions and throughout development. The straightforward

explanation of the results of Silva et al. was possible because of the prominent expression of  $\alpha$ -CaMKII in the hippocampus as well as the fact that the onset of  $\alpha$ -CaMKII expression is limited to a later stage of postnatal development. For other genes one wishes to study with respect to their hippocampal functions, this problem has been overcome, at least to some extent, by the development of genetic techniques that are spatially restricted to the frontal cortex including the hippocampus or to hippocampal pyramidal cell types (e.g., CA1 neurons or dentate gyrus granule cells) (see Box 7-1). So far, such hippocampus-specific mutations have been mainly used to examine the functions of AMPA and NMDA receptors. As described below, these studies not only support the conclusions of Silva et al. and Grant et al. and those of the earlier pharmacological studies (Morris et al., 1986) regarding the role of LTP in learning, they also threw light on the importance of glutamate receptors for both the induction and expression of synaptic plasticity. The experiments showed that different mechanisms are used to establish and maintain different forms of LTP used in different forms of learning (for example, spatial working versus reference memory).

### 7.5.2 NMDA Receptor Mutant Mice

The first mouse model aimed at studying NMDA receptor function was a knockout of the NR1 subunit (Forrest et al., 1994); these mice showed that NR1 is essential for formation of functional NMDA receptor channels (the mice died 8–15

hours after birth). Mice with reduced expression of the NR1 gene were generated by insertion of the “neo gene cassette” in an intronic region of the NR1 gene, which resulted in silencing NR1 gene expression and subsequent reduction of NR1 protein expression down to 5% of the wild-type level (Mohn et al., 1999). Note that the neo gene cassette serves as a selection marker during preparation of knockout targeting constructs (see Box 7-1); the presence of the cassette sometimes interferes with normal mRNA processing of the transcribed gene product, causing indirect silencing of gene expression. The NR1 “neo” mice survived to adulthood, showed normal AMPA and kainate receptor functions, but displayed deficits in social and sexual interactions, increased motor activity, and stereotypical behavior that was similar to the behavior observed in pharmacologically induced animal models of schizophrenia.

### Hippocampal Region-specific NR1 Knockout Mice

Hippocampal CA1-specific NR1 knockout mice were generated using the Cre/lox-recombination system, with the Cre recombinase expressed under the control of the  $\alpha$ -CaMKII promoter (see Box 7-1) (Tsien et al., 1996a,b). Although this promoter is typically active in most postnatal excitatory forebrain neurons, a transgenic line with Cre expression restricted almost exclusively to the CA1 region (due to a chromosomal integration effect) was selected. The CA1 cell-specific NR1 gene deletion had no apparent effect on mRNA levels of

(text continued on page 265)

#### Box 7-1 Tools to Generate Conditional Mouse Mutants

Conditional mouse mutants are used for temporally and spatially regulated transgene expression, gene deletion, or gene activation. The two most commonly used systems are the tTA system and the *Cre* system. In both systems, two genetic modules are introduced separately into the mouse genome: the *activator gene*, which regulates expression of the second module, and the *responsive target gene*, the function of which one wishes to study. After first obtaining independent, “activator” and “responder” mouse lines, the two are bred together to create the “conditional mouse” line (see Box Table 7-1).

Activator mice function in two ways (see Box Fig. 7-1). First, the expression of the activator gene is controlled spatially and, to some extent, temporally by the selection of a specific promoter. The promoters that have been used to drive activator genes include the following: the  *$\alpha$ -CaMKII promoter*, which restricts expression of the activator to pyramidal neurons in postnatal brain (spatially ranging from most pyramidal cells of the forebrain to only selective hippocampal CA1 expression, depending on the integration of the transgenic construct), and the *kainate receptor subunit KA-I promoter*, which restricts the expression to CA1 and CA3 pyramidal neurons. Second, the activator itself can be controlled pharmacologically, typically by systemic drug application (for example, in drinking water). The transactivators tTA and rtTA are regulated by tetracycline (or its analogue doxycycline); tTA is inactivated, which means that it does not bind to the *tet operators* in the promoter of the target gene in the presence of doxycycline (often referred to as a “let off” protocol); rtTA is regulated in the opposite way (“tet on”). Fusion protein of Cre recombinase and the hormone-binding portion of the estrogen receptor, named CreERT2, was developed for temporal activation of the Cre recombinase: In the cell, CreERT2 is present in the cytoplasm, thus restricting the nuclear localization of Cre; but it translocates into the nucleus in the presence of drugs such as tamoxifen. Finally, expression of Cre recombinase alone from various cell-specific promoters, such as the  $\alpha$ -CaMKII promoter, has been used for conditional knockout of target genes in selected neuronal populations.

**Box Table 7–1.**  
**Activator, Responder, and Conditional Mice**

Activator Mice	Responder Mice
<i>Activator genes</i>	<i>Responder Genes</i>
tTA or rtTA	Any transgene (wt or mutant) under the control of a promoter with tet operon regulation
Cre or CreERt2	Floxed genes for conditional gene knockout, floxed hypomorphic alleles for gene activation
Activator genes determine <i>where</i> and <i>when</i> genetic manipulation occurs	Responder genes determine the type of the genetic manipulation in the responder gene
No phenotype	No phenotype

**Conditional Mice (obtained by breeding activator and responder mice)**

Type of Genetic Manipulation	Responder Involved	Activator Involved
Knockout rescue	wt “flagged” transgene	tTA or rtTA in knockout mice
Expression of mutant genes	Mutant “flagged” transgenes	tTA or rtTA
Conditional gene knockout	Floxed gene	Cre or CreERt2
Conditional gene activation	Floxed hypomorphic alleles	Cre or CreERt2

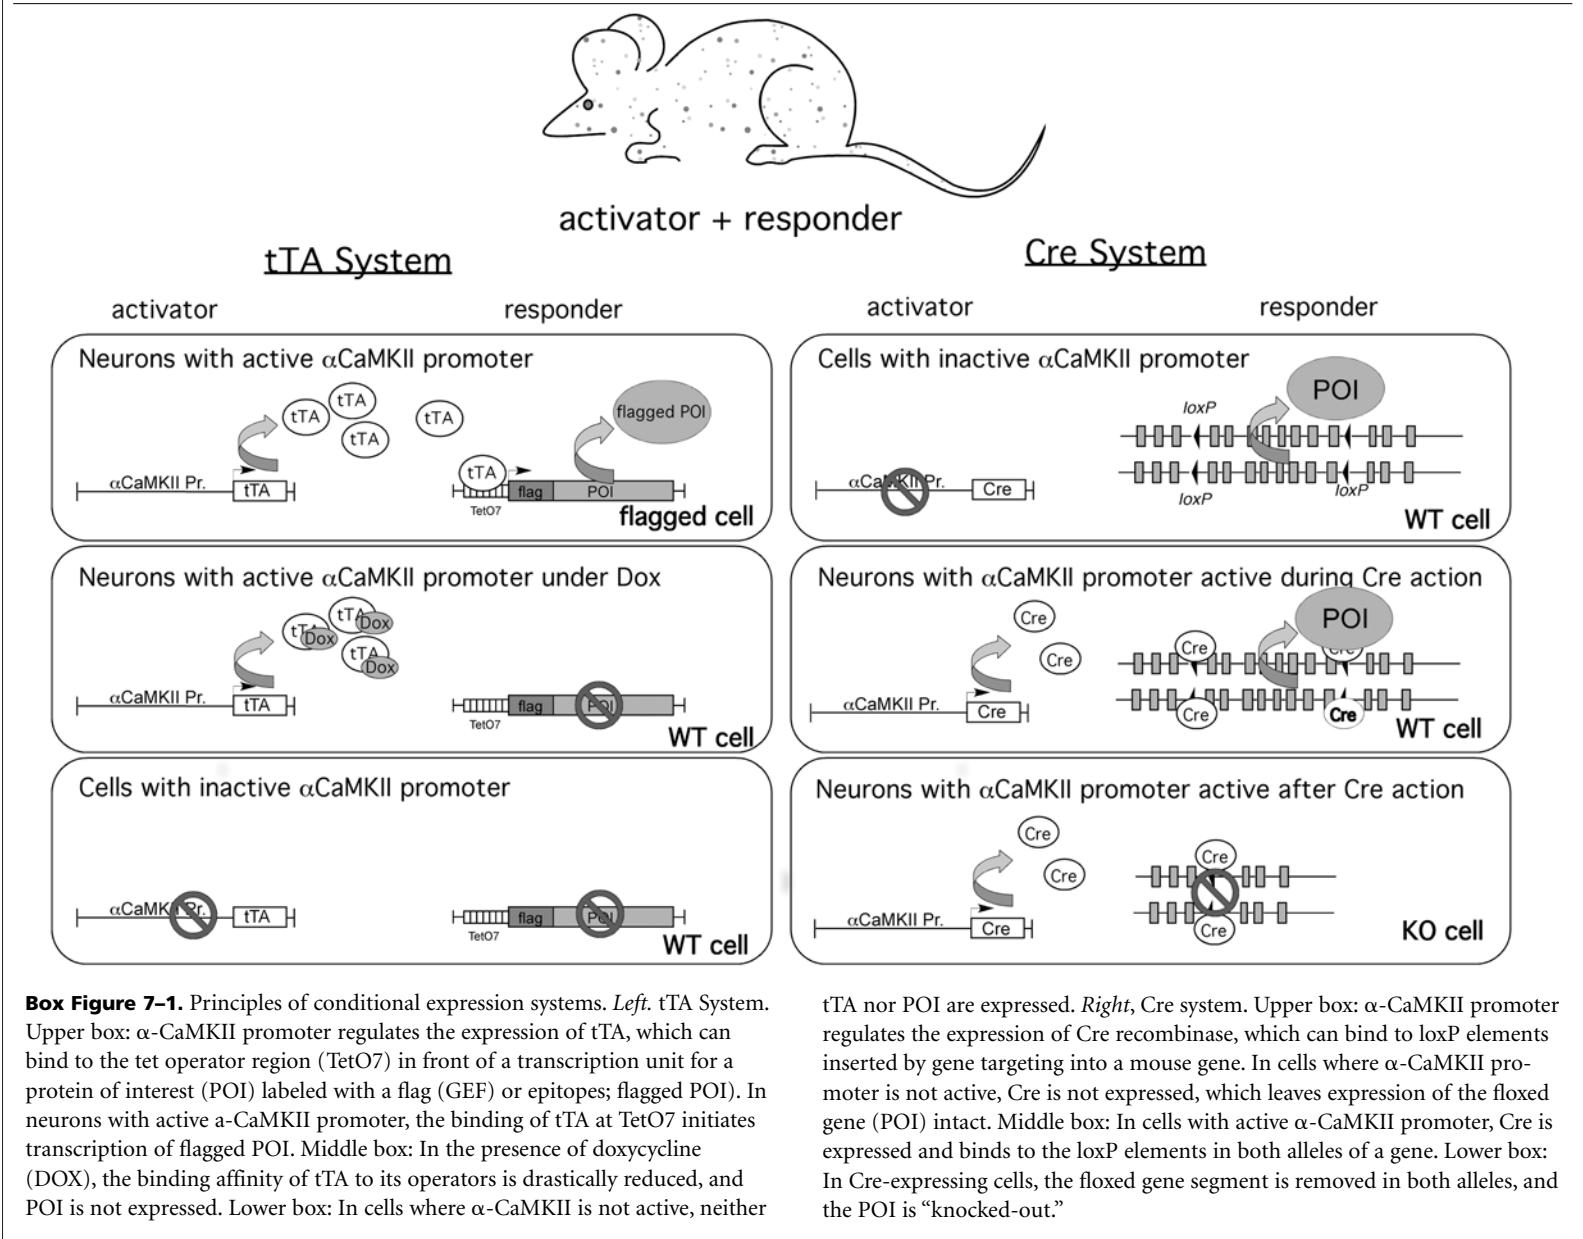

Conditional phenotype is mediated by activation of the genetic manipulation of the responder gene in brain regions where activator gene is expressed.

There are two types of responder mice (see Box Fig. 7–1), depending on the activator used. Mice regulated by tTA or rtTA expression are typically generated by transgenic insertion of the responder gene under control of a pol II transcription initiation site containing several upstream tet operators. After binding of tTA/rtTA at the tet operators, transcription of the target gene is initiated by the tTA/rtTa VP16 activation domain. In contrast, the target genes in mice regulated by the expression of Cre recombinase are endogenous genes with genetically introduced Cre-recognition (lox P) sites in two intronic regions flanking one or several functionally important exons. The Cre recombinase binds to the loxP elements and eliminates the in-between genomic sequence by DNA recombination, creating a knockout form of the target gene. As an alternative use of the Cre-based approach, a loxP-flanked neo gene is sometimes inserted into a small intron of a target gene, which in most cases inhibits the target gene expression by disturbing its transcription or RNA processing (such target genes are called hypomorphic). Expression of the hypomorphic target allele can be activated by Cre-mediated removal of the floxed neo gene. Because this activation can be performed in mice heterozygous or homozygous for the hypomorphic alleles, it can be also used for studying gene-dose effects.

tTA = tetracycline-regulated transactivator; rtTA-reverse tetracycline-regulated transactivator; Floxed = exon(s) of a gene flanked by loxP site; flagged = proteins tagged by GFP or a short epitope recognized by selective antibody, such as Myc or Flag -epitopes.

(Continued)

**Box 7-1****Tools to Generate Conditional Mouse Mutants (Continued)**

NR2A or NR2B but caused severe reduction of NR2A and NR2B protein; in addition, both subunits were retained and aggregated in the somata of CA1 cells, indicating that the NR1 subunit is necessary for the release of NR2 subunits from the endoplasmic reticulum in hippocampal pyramidal cells, and that in the absence of NR1 no functional NMDA receptor channels can be formed in CA1 cells (Fukaya et al., 2003).

The loss of NMDA receptor-mediated synaptic currents in CA1-specific knockout mice resulted in impaired LTP at Schaffer collateral to CA1 synapses. Confirming the specificity of the genetic manipulation, no changes in synaptic transmission or plasticity were found at other synaptic connections in the hippocampus. Behaviorally, the mice showed regular development and normal nonspatial learning in the water-maze. However, adult mice had impaired learning during the acquisition phase of the hidden version of the Morris water-maze and in the postacquisition probe (Tsien et al., 1996b). These mice thus provided the first direct genetic evidence that NMDA receptor-mediated synaptic plasticity at the CA1 synapses is involved in the formation of spatial memory in mice. In addition, further analysis showed a number of other cellular and behavioral deficits. The mice failed to learn an association between a conditional and an unconditional stimulus (separated by 30 seconds) in trace fear conditioning, indicating that in addition to spatial information temporal information is processed in an NMDA receptor-dependent manner in the mouse hippocampus (Huerta et al., 2000). Mice also had impaired nonspatial memory formation, including object recognition, olfactory discrimination, and contextual fear memory; interestingly, the last three deficits were rescued by keeping the mice in an enriched environment (Ramon et al., 2000). The same study showed that the enriched environment led to an increase in synapse density in the CA1 region in the knockouts (as well as in the control littermates), suggesting that NMDA receptor activity is not essential for experience-induced synaptic structural changes, and that such structural plasticity may compensate for normal synaptic plasticity at least to some extent. Further deficits were found in place cell properties in area CA1: McHugh and colleagues found a striking deficit in the coordinated firing of pairs of neurons tuned to similar spatial locations. However CA1 cells retained place-related activity, indicating that the formation of place cells as such is not NMDA receptor-dependent (McHugh et al., 1996).

CA1-specific NR1 knockout mice were also used to study the consolidation phase of learning. Shimizu et al. described a mouse model termed iCA1-KO in which gene expression in CA1 neurons could be temporally controlled (Shimizu et al., 2000). As with the previous model for NMDA receptor depletion, the  $\alpha$ -CaMKII promoter-driven Cre transgene is used to excise the floxed NR1 gene, but now it leads to simultaneous induction of a doxycycline-sensitive transcriptional activator (tTA) in the affected CA1 cells (see Box 7–1). In the absence of doxycycline, tTA is active and induces expression of the tTA-controlled transgene, which in the case of the iCA1-KO of NR1 was the GFP-tagged wild-type NR1 subunit (NR1-GFP). However, when the mice are fed doxycycline, tTA is inacti-

vated and NR1-GFP expression is switched off. Using this “on–off” mouse model, the study showed that when NR1-GFP expression was switched off in CA1 at day 1 to 6 after learning a spatial memory task retention of the acquired memory was significantly impaired compared to control mice or mice with the NR1-GFP expression switched off at post-training day 9 to 14 (Shimizu et al., 2000). Contextual fear memory was affected in a similar way. These experiments showed that memory retrieval relies on NMDA receptor-mediated synaptic transmission/plasticity for the first 6 days after learning; thereafter, retrieval becomes NR1-independent. In a follow-up study,  $\alpha$ -CaMKII promoter-Cre transgenic line with Cre expression in forebrain principal neurons was used to switch off NR1-GFP expression during memory storage, 6 months after the initial training, and at least 2 months prior to memory retrieval. The retention of 9-month contextual and cued fear memories was severely disrupted by a long (30-day) but not short (7-day) doxycycline treatment suppressing NR1-GFP expression, indicating an unexpected role for NMDA receptors in long-term memory storage (Cui et al., 2004). The proposed role of NMDA receptors in memory consolidation and storage, however, contradicts earlier pharmacological experiments (reviewed in Riedel et al., 2003). Further experiments are necessary to settle the question of NMDA receptor function in memory consolidation, storage, and retrieval.

Hippocampal CA3-specific NR1 knockout mice were generated by Cre recombinase driven from a promoter of the kainate receptor subunit KA-1 (Nakazawa et al., 2002). In this case, electrophysiological analysis of the mice revealed impaired LTP in the recurrent commissural/associational pathway but not in mossy fiber synapses of CA3 cells. The mice showed regular performance in the Morris watermaze but had clear deficits when some of the spatial guiding cues were removed or when rapid memory formation was tested in a delayed matching-to-place version of the watermaze. This led to a model proposing a critical role for the CA3 region in “filling in the blanks” (pattern completion) after partial cue removal. Similarly, CA1 pyramidal cells in these mice displayed normal place-related activity in a full-cue environment but reduced activity upon partial cue removal and increased field size in a novel environment (Nakazawa et al., 2002, 2003).

In summary, the NR1 cell-type specific knockouts unequivocally demonstrated the critical role of NMDA receptors in synaptic plasticity and learning in both CA3 and CA1 regions of the hippocampus. This work initiated a novel strategy to determine the role of specific synapses in a complex memory system.

### Mice with Point Mutations in the NR1 Subunit

Two knock-in mouse models were designed to study the role of glycine modulation in NMDA receptor function: NR1 K483Q mutation causes severe reduction of glycine affinity of the NMDA receptors, whereas NR1 D481N mutation has a milder effect (Kew et al., 2000). Mice homozygous for the

K483Q mutation do not feed and die early after birth, essentially exhibiting a phenotype similar to that of the complete NR1 knockout. This indicates that the high-affinity glycine binding site is crucial for normal NMDA receptor function. The mild reduction of glycine affinity in NR1 D481N mice was not lethal, and the mutants exhibited reduced theta burst-induced LTP and slightly impaired acquisition in the Morris watermaze.

The postulated function of the NMDA receptor with respect to synaptic plasticity in the hippocampus, and elsewhere in the brain, is to act as a Hebbian-type coincidence detection mechanism for post- and presynaptic activity owing to its dual ligand and voltage-dependent ion channel activation (see Section 7.2.3); once the receptors open,  $\text{Ca}^{2+}$  influx initiates postsynaptic signaling cascades leading to changes in synaptic efficacy. To test this model of NMDA receptor function directly, mice with altered NMDA receptor ion permeability were generated. A single asparagine residue N598 in the M2 segment of the NR1 subunit, which determines  $\text{Ca}^{2+}$  permeability, was changed to glutamine (Q) or arginine (R) (Single et al., 2000). Like NR1 knockout mice, mice exclusively expressing the mutated NR1 alleles—NR1(Q/Q) and NR1 (-/R) mice—died perinatally. Electrophysiological recordings from nucleated patches of CA1 cells in slices from NR1 (Q/Q) mice revealed the expected reduction of  $\text{Ca}^{2+}$  permeability and voltage-dependent  $\text{Mg}^{2+}$  block. Furthermore, even heterozygous NR1(+/Q) mice exhibited reduced life expectancy, and NR1(+/R) mice displayed signs of underdevelopment and died before weaning. This shows that  $\text{Ca}^{2+}$  influx via NMDA receptors remains critically important throughout life.

To address the importance of NMDA receptor-controlled  $\text{Ca}^{2+}$  influx for adult hippocampal functions, the N598R mutation was expressed conditionally in the forebrain using the Cre/lox system (see Box 7–1). First, expression of the dominant negative NR1(R) allele was inhibited by a floxed neo gene cassette in an intron of the NR1(R) allele. In these mice, the intronic neo gene can be deleted by Cre recombinase expressed, for example, from the  $\alpha$ -CaMKII promoter, resulting in activation of the NR1(R) allele. Analysis of the NR1(R) forebrain-specific mice revealed a role for NMDA receptor-mediated  $\text{Ca}^{2+}$  influx in hippocampal homeostatic and Hebbian synaptic plasticity. The developmental synaptic scaling was lacking in CA1 cells, and LTP was induced by high-frequency but not low-frequency stimulation (Pawlak et al., 2005a,b). The mortality of these mutants, unfortunately, was still elevated; to assess the role of NMDA receptor  $\text{Ca}^{2+}$  signaling for learning and memory, it is thus necessary to develop more restricted NR1(R) expression, limited, for example, to expression only in CA1 or CA3 pyramidal neurons.

### **NR2 Mutant Mice**

In agreement with the high expression of NR2A in mature compared to juvenile hippocampus, adult NR2A knockout mice showed a significant reduction of NMDA receptor-

mediated synaptic currents in CA1 neurons. Nonetheless, LTP at the hippocampal Schaffer collateral to CA1 synapses and spatial learning were only slightly impaired. This indicates that in the absence of the NR2A subunit the NR1/NR2B heteromeric receptors are generally sufficient for adult hippocampal LTP and spatial learning (Sakimura et al., 1995; Kiyama et al., 1998). The same phenotype was also observed when only the NR2A C-terminal domain was genetically deleted (Sprengel et al., 1998). The truncated NMDA receptor subunits NR2A $\Delta$ C participated in synaptic hippocampal NMDA receptor functions, as indicated by immunoisolation of synaptic NR2A $\Delta$ C-containing receptor complexes, NR2A $\Delta$ C immunogold labeling at hippocampal synapses, and the existence of spinous  $\text{Ca}^{2+}$  transients in the presence of NR2B blockers. LTP induced by a single tetanic stimulation in CA1 neurons was strongly reduced but could be restored to wild-type levels by repeated tetanic stimulation; this paradigm thus may preferentially activate NMDA receptors containing the NR2B subtype. Because the NR2A $\Delta$ C-containing receptors allowed synaptically evoked  $\text{Ca}^{2+}$  influx in dendritic spines, these results indicate that NR2A C-terminal domain-based function (e.g., a scaffold role for various cytoskeletal and signaling proteins) is critical for normal LTP induction. In juvenile (P14) mice, when NR2B-mediated LTP induction pathway was more pronounced, the NR2A $\Delta$ C mice showed no deficits in synaptic plasticity (Köhr et al., 2003). Notably, NR2A-dependent LTP as well as hippocampus-dependent spatial and associative learning are impaired in mice with forebrain-specific knockout of the transcription factor c-fos, indicating that NR2A-dependent plasticity involves activation of the c-fos pathways (note that NR2B-dependent LTP induced by repetitive tetanic stimulation was normal) (Fleischmann et al., 2003). The results from genetic mouse models, however, remain to be reconciled with pharmacological studies indicating a selective role of NR2A in LTP and NR2B in LTD (Liu et al., 2004; but see also Berberich et al., 2005). Thus, it seems most likely that the two NMDA receptor subunits play distinct roles in different synaptic plasticity paradigms by activating selective signaling pathways; however, further experimental work is necessary to determine the exact mechanisms and pathways.

NR2B knockout mice die shortly after birth owing to lack of a suckling response. In mice kept alive for several days by hand-feeding, synaptic NMDA receptor currents and LTD were abolished at CA1 synapses; this confirms that the NR2B subunit is critical for NMDA receptor function during early postnatal development (Kutsuwada et al., 1996).

Selective truncation of the NR2B C-terminal domain in mice caused the same phenotype as complete deletion of the subunit (Mori et al., 1998; Sprengel et al., 1998); homozygous NR2B $\Delta$ C mice died a few days after birth, NMDA receptor-mediated EPSCs were reduced, with an accompanying reduction in synaptic NR2B immunosignal in the dendritic regions of the hippocampus. This suggests that the NR2B C-terminal domain is important for efficient synaptic transport of the NR2B-type receptors.

A striking finding regarding the function of the NR2B sub-

unit and of NMDA receptors in general came from mice with forebrain-specific overexpression of the NR2B gene, driven from the  $\alpha$ -CaMKII promoter; these mice showed not only increased LTP at the CA3 to CA1 synapses but also enhanced associative learning and memory (Tang et al., 1999). The authors proposed that the enhanced synaptic and behavioral performance was primarily the result of the increased opening time of the NR2B receptors, leading to overall enhanced coincidence detection by NMDA receptors.

The phenotype of NR2C knockout mice relates to the prominent expression of the NR2C subunit in cerebellar granule cells: The mice show deficits in fine-tuning motor coordination. The same impairment was also observed in mice with the C-terminally truncated NR2C subunit, providing a third confirmation of the importance of the C-terminal intracellular domain for normal synaptic function of each NR subunit (Ebralidze et al., 1996; Kadotani et al., 1996; Sprengel et al., 1998). No deficits were observed in hippocampus-based functions.

The NR2D subunit shows its highest expression in the embryonic brain and declines by P2. NR2D knockout mice are viable, indicating that the subunit function is not essential for development; in addition, no synaptic or memory deficiencies have been described in NR2D knockouts (Ikeda et al., 1995).

In contrast to the NR2B-overexpressing mice,  $\alpha$ -CaMKII promoter-driven forebrain-specific overexpression of NR2D did not improve CA3 to CA1 LTP or memory performance in mice (Okabe et al., 1998). In NR2D-overexpressing mice, NMDA receptor-mediated currents in CA1 pyramidal cells had smaller amplitudes and slower kinetics, with selective impairment of LTD at juvenile and of LTP at mature Schaffer collateral to CA1 synapses. Thus, expression of NMDA receptors with NR2D-specific channel characteristics—leading to high affinity for glutamate and glycine, slow gating, and low sensitivity to  $Mg^{2+}$ —significantly altered NMDA receptor-dependent plasticity; surprisingly, these changes did not affect learning in the Morris watermaze task (Ikeda et al., 1995).

### 7.5.3 AMPA Receptor Mutant Mice

As discussed in the section about AMPA receptor trafficking (see Section 7.4.1), the two major subunits GluR1 and GluR2 appear to have distinct functions in hippocampal synaptic plasticity. Using mouse genetics, the GluR1 subunit was unequivocally identified as a key molecule in LTP at the hippocampal CA3 to CA1 connections (Zamanillo et al., 1999). The importance of the GluR2 subunit at the behavioral level is at the moment less clear, and the GluR3 subunit appears not to play a critical role in hippocampal functions.

#### GluR1 Mutant Mice

Genetic depletion of the GluR1 subunit has major effects on hippocampal functions (Fig. 7–8). CA1 pyramidal neurons showed a dramatic loss of AMPA receptor-mediated extrasynaptic currents in both the soma and the dendrites; synaptic

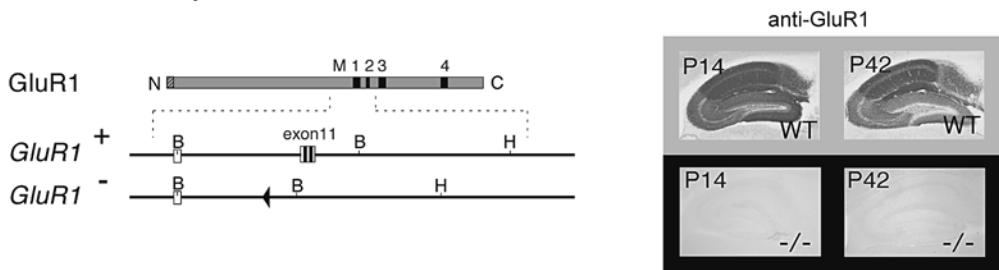

currents were only slightly reduced but showed a loss of a density scaling toward the apical dendrites (Zamanillo et al., 1999; Andrasfalvy et al., 2003). These findings demonstrated that GluR1 is necessary to establish and/or maintain an extrasynaptic AMPA receptor pool as well as distance-dependent synaptic scaling. The GluR2 subunit, in the absence of GluR1, showed a strong reduction in overall dendritic distribution and increased somatic accumulation in CA1 principal neurons when examined by immunostaining at the light microscopy level. However, consistent with the preservation of synaptic currents, synaptic GluR2 expression, as detected by immunogold labeling, was comparable to that in wild-type cells. Taken together, these data indicate that in wild-type animals a large proportion of AMPA receptors is maintained as a reserve pool at extrasynaptic sites, not immediately participating in synaptic signal transduction.

The function of the extrasynaptic pool of AMPA receptors became evident from analysis of synaptic plasticity in GluR1 knockout mice; the NMDA receptor-dependent LTP at adult Schaffer collateral to CA1 synapses was largely abolished (Zamanillo et al., 1999). Interestingly, whereas the loss of LTP in CA1 was observed after various stimulation protocols—e.g., tetanic stimulation ( $1 \times 100$  Hz or  $4 \times 100$  Hz “field” LTP) or 3-minute pairing of postsynaptic depolarization and low-frequency Schaffer collateral stimulation (“cellular” LTP)—a protocol using theta-burst frequency of pairing pre- and postsynaptic activity induced a slow-onset LTP that reached normal levels within ~20 minutes after induction. This was the first evidence that two forms of LTP coexist at the Schaffer collateral to CA1 synapses: one dependent on and the other independent of the extracellular pool of GluR1-containing AMPA receptors (Hoffman et al., 2002). Similarly, at the perforant path to dentate gyrus granular cell synapses, GluR1-independent LTP was detected in adult GluR1 knockout mice (Zamanillo et al., 1999); this indicates that in wild-type animals LTP at these synapses is at least partly GluR1-independent.

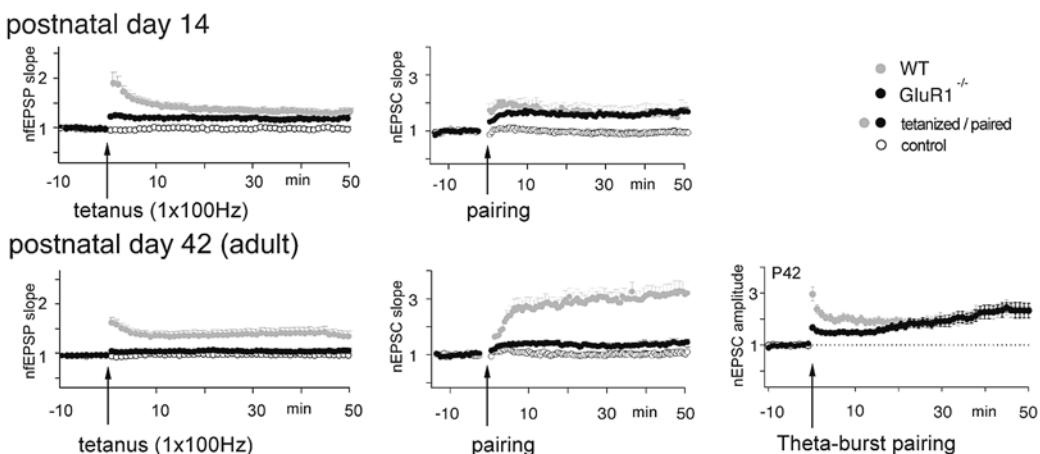

Molecular mechanisms underlying synaptic plasticity in the hippocampus also change during development. In contrast to adult GluR1-deficient mice, juvenile (2-week-old) knockout mice have normal field and cellular LTP in CA1 (Jensen et al., 2003b). This “juvenile” LTP may rely on expression of other AMPA receptor subunits, such as GluR2<sub>long</sub>, a GluR2 form with an alternatively spliced C-terminal domain (Kolleker et al., 2003) (see Section 7.3.2). The notion that GluR1-dependent function is not critical in juvenile mice is consistent with the observation that hippocampal LTP in adult GluR1 knockout mice can be rescued by transgenic forebrain-specific expression of GFP-tagged GluR1 with an onset from the second to the third postnatal week (Mack et al., 2001). This indicates that a GluR1-independent form(s) of synaptic plasticity is (are) sufficient for development of normal hippocampal synaptic circuits. Later in development, as the extrasynaptic AMPA receptor pool increases, GluR1-dependent plasticity becomes the dominant form of LTP (Jensen et al., 2003b).

Does hippocampal CA3 to CA1 LTP in the adult rely on

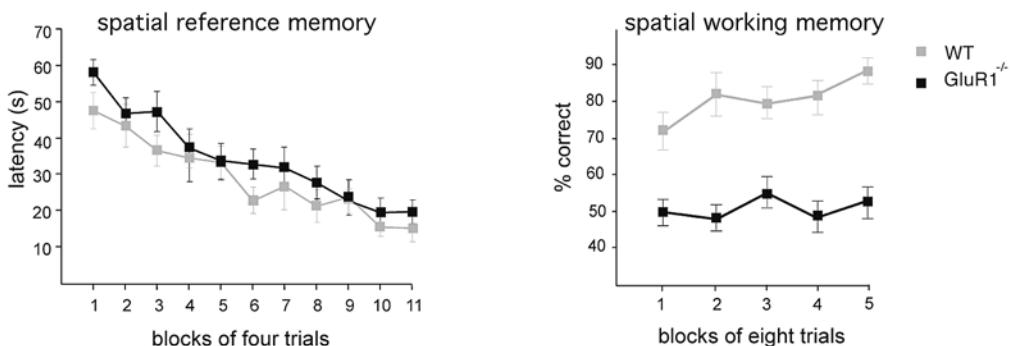

## A Functional depletion of GluR1 in the mouse

## B LTP in juvenile and adult WT and GluR1 deficient mice

## C GluR1 deficient mice are impaired in spatial working memory

**Figure 7–8.** Various forms of LTP at CA3-to-CA1 synapses revealed by analysis of GluR1-deficient mice. A. GluR1 knockout was generated by gene targeting of the M1- and M2-encoding exon 11 (Zamanillo et al., 1999). Right panel: GluR1 immunoreactivity was detected in the hippocampi of wild-type (WT) but not GluR1-deficient mice (-/-) at P14 and P42. B. Residual CA3-to-CA1 LTP is present in the GluR1-deficient mice at P14, as revealed by tetanic

stimulation and pairing LTP protocols (Jensen et al., 2003b). These two forms of LTP are absent at P42 in the GluR1-deficient mice. However, theta-burst pairing can still induce LTP at P42 in these mice (Hoffman et al., 2002). C. GluR1-deficient mice show regular learning in the hidden platform task of the Morris water-maze (left) but cannot learn the rewarded alternation in the T-maze task (Reisel et al., 2002).

any extracellular reserve pool of AMPA receptors, or does it specifically require a GluR1-containing reserve pool? A specific role for the GluR1 subunit was suggested from studies examining the function of GluR1 C-terminal phosphorylation. First, experiments in hippocampal slice cultures suggested that PKA phosphorylation of GluR1 C-tail serine 845 is necessary for synaptic insertion of GluR1-containing AMPA

receptors after LTP induction (Esteban et al., 2003); and second, gene-targeted mice carrying a mutation of GluR1 serine 845 showed reduced LTP despite normal levels of extrasynaptic AMPA receptors (Lee et al., 2003). These results provide evidence for a specific role of the GluR1 subunit in LTP at CA1 synapses.

Behavioral analysis of the GluR1-deficient mice revealed

two striking findings. First, it came as a surprise that these mice showed normal spatial reference memory in the Morris watermaze task, the paddling-pool escape task, and the appetitive elevated plus-maze and Y-maze tasks (Zamanillo et al., 1999; Reisel et al., 2002; Bannerman et al., 2003; Schmitt et al., 2004b). Importantly, the spatial learning in the watermaze and Y-maze was still dependent on hippocampal function, as bilateral hippocampal lesions in the GluR1-deficient mice profoundly impaired their performance in both tasks. These findings thus established that GluR1-dependent LTP in the CA1 region of the hippocampus is not necessary for the formation of spatial reference memory. Second, the GluR1-deficient mice did show a drastic reduction in spatial working memory during tests of nonmatching to place in a Y-maze and elevated T-maze. This impairment was partially rescued by transgenic expression of GFP-GluR1 that was largely restricted to the dorsal hippocampus of GluR1 knockout mice (Schmitt et al., 2005). These experiments thus provide a close link between hippocampal CA1 LTP and a specific form of memory formation, as a genetic LTP rescue in adult mice was paralleled by a gain of function in the behavior of the mice.

GluR1-dependent synaptic plasticity appears to be critical for a form of learning that involves processing rapid interactions between spatial cues and response requirements (Schmitt et al., 2004b). When mice were allowed to navigate through a T-maze by using textural conditional cues (all floor areas were covered with either white Perspex or wire mesh, depending on the position of the food reward) the knockout mice learned as well as wild-type mice; this is consistent with their having normal spatial reference memory. When the floor cues were present only in the start arm (not in the goal arms) of the maze, the GluR1-deficient mice again failed to learn the task. This shows that the absence of the conditional cue at the time when the place/reward association was processed critically determines whether the mice can learn. Hippocampal GluR1-dependent synaptic plasticity at the CA1 region thus contributes to a memory system that in rodents encodes both the spatial and temporal contexts associated with a particular event, a paradigm that may be analogous to human episodic memory (Schmitt et al., 2004a).

The lack of GluR1 in the brain, despite the prominent, widespread expression of the subunit, does not have major effects on general sensorimotor behavior. The GluR1 knockout mice are slightly more hyperactive, anxious, and aggressive, with only a subtle lack of motor coordination (Bannerman et al., 2004; Vekovischeva et al., 2004).

### GluR2 and GluR2/3 Mutant Mice

According to the model for NMDA receptor-dependent LTP at Schaffer collateral to CA1 synapses, it is important that AMPA receptors have low permeability for  $\text{Ca}^{2+}$ , which is determined by the presence of the Q to R edited GluR2 subunit (see Section 7.3.2); NMDA receptor-mediated  $\text{Ca}^{2+}$  influx then acts as a selective trigger for Hebbian coincidence detection of pre- and postsynaptic activity. To test this

hypothesis directly and to examine the overall role of GluR2 in synaptic transmission, mice were generated that either completely lack GluR2 or contain targeted mutations eliminating the editing of the Q codon in the M2 membrane segment.

In contrast to the GluR1-deficient mice, GluR2 knockout mice are compromised in development and overall behavior. Juvenile GluR2-deficient mice are about half the size of their wild-type littermates, and some succumb to preweaning mortality. Even though the surviving mice "catch up" in weight by 8 weeks of age, they remain impaired in several aspects of their behavior, ranging from reduced sensory stimulus processing to reduced motivation and learning; deficits are associated with hippocampus-dependent behaviors as well as behaviors associated with other brain regions, including the neocortex and cerebellum. The overall lower activity of the GluR2-deficient mice and the reduction in synaptic AMPA receptor-mediated currents (Jia et al., 1996; Meng et al., 2003) suggest that GluR2 is necessary for maintaining a steady-state level of AMPA receptor-mediated transmission, in contrast to GluR1, which is more critical for activity-dependent synaptic plasticity (see also discussion of subunit-specific AMPA receptor trafficking in Section 7.4.1).

At the cellular level, GluR1 distribution in the absence of GluR2 was unchanged in the hippocampus, indicating that GluR2 is not necessary for the extracellular AMPA receptor pool in dendrites; the aberrant receptor assemblies of GluR1/GluR3 and GluR1 or GluR3 homomeric channels are less efficiently expressed at synapses, again supporting the idea that GluR2 is necessary for synaptic stabilization of AMPA receptors (Sans et al., 2003). However, the GluR1/3-based receptors, which are permeable to  $\text{Ca}^{2+}$ , are sufficient even at their low synaptic levels to mediate CA3 to CA1 LTP; furthermore, this LTP is partially independent of NMDA receptor activation—about twofold enhanced compared to that of their wild-type littermates and nonsaturating (Jia et al., 1996). Thus, it appears that activity-dependent GluR1-based synaptic delivery of AMPA receptors is still operative, but now changes in synaptic transmission can be achieved in an atypical manner, without relying on NMDA receptor-based coincidence detection. It is unfortunate that the overall low behavioral performance of the mice makes it difficult to analyze learning under these altered synaptic conditions. One approach to getting around this problem was to analyze hippocampal place cell firing, as there is a strong correlation between Hebbian NMDA receptor-dependent LTP, place-cell function, and learning and memory. In the GluR2 knockout mice, CA1 place cells were impaired, with only 25% (down from 46%) of CA1 neurons showing detectable place fields; moreover, the remaining place cells were less precise and unstable (Yan et al., 2002). This suggests that CA1 depletion of GluR2 leads to impaired hippocampal learning and memory functions.

Mice lacking GluR2 selectively in postnatal forebrain were generated to directly circumvent the global behavioral impairments in the complete knockout animals (a floxed GluR2 gene

was again excised by CRE recombinase under control of the  $\alpha$ -CaMKII promoter (Shimshek et al., 2005, 2006). The mice showed less overall behavioral deficits but had impaired spatial reference and working memory; interestingly, LTP at the CA3 to CA1 synapses was induced to a wild-type level of potentiation and was entirely dependent on activation of NMDA receptors.. Detailed analysis of hippocampal functions in these mice revealed the following morphological and synaptic changes: loss of CA3 pyramidal cells and parvalbumin-positive interneurons in the dentate gyrus; diminished neurogenesis in the subgranular zone; reduced presynaptic fiber excitability at CA3 to CA1 synapses and reduced threshold for evoking population spikes at the CA3 to CA1 synapses.

At least some of the changes observed in the forebrain-specific GluR2 knockout mice are likely due to aberrant  $\text{Ca}^{2+}$  influx through the remaining GluR1/3 receptors; this is also supported by observations in mice with  $\text{Ca}^{2+}$ -permeable (but GluR2-containing) AMPA receptors due to genetically induced deficiency in the GluR2 Q to R editing (Brusa et al., 1995; Feldmeyer et al., 1999; Krestel et al., 2004; Shimshek et al., 2005). In these mice, AMPA receptors are stabilized by GluR2 at excitatory synapses, and the overall  $\text{Ca}^{2+}$  load during neurotransmission is larger. When the unedited GluR2 is expressed in the whole brain, the mice develop severe seizures and typically die by 3 weeks of age (Brusa et al., 1995). The severity of the phenotype correlates with the level of GluR2(Q586) expression, as mice with GluR2(Q586) expressed in the brain at only the 5% level of the endogenous GluR2 survive substantially longer and show a low tendency to epileptic attacks (Feldmeyer et al., 1999). In young mice, the deficiency of GluR2 Q to R editing induces an NMDA receptor-independent LTP at Schaffer collateral to CA1 synapses, the magnitude of which correlates with the expression level of the GluR2(Q586) subunit (Feldmeyer et al., 1999).

Interestingly, lethality and seizures do not occur in mice with GluR2(Q586) expression conditionally restricted to postnatal hippocampus, suggesting that additional expression of GluR2(Q586) in forebrain, striatum, and/or amygdala is necessary for global epileptic attacks (Krestel et al., 2004). In mice with forebrain-restricted GluR2(Q586) expression, the presynaptic fiber excitability at CA3 to CA1 synapses is unchanged, but excitatory postsynaptic responses are smaller, suggesting compensatory downscaling of the AMPA receptor-mediated  $\text{Ca}^{2+}$ -permeable currents; nonetheless, CA1 neurons are more excitable, as revealed by a lower threshold for an evoked population spike and epileptic activity in these mice; increased gliosis and mossy fiber sprouting are clear signs of recurrent seizures. Thus, in both postnatally induced forebrain-specific GluR2 knockout and editing-deficient animals, an AMPA receptor-mediated increase of a postsynaptic  $\text{Ca}^{2+}$  load induces long-term changes in hippocampal circuits affecting normal hippocampal functions and spatial learning.

GluR3 is not as highly expressed as GluR1 and GluR2 in the hippocampus. GluR3 knockout mice showed normal basal synaptic transmission in CA1; LTP at CA3 to CA1 synapses

was increased but was still fully dependent on activation of NMDA receptors (Meng et al., 2003). In addition, GluR2/GluR3 double knockout mice showed a phenotype similar to that of the GluR2-deficient mice, with general retardation of postnatal development and increased mortality, without detectable abnormalities in the gross anatomy of the central nervous system, including the hippocampus (Meng et al., 2003). Although synaptic transmission at CA1 synapses was reduced several-fold, the GluR2/3-deficient mice were competent in establishing LTD and LTP as well as depotentiation and dedepression at the Schaffer collateral to CA1 synapses. This indicates that GluR1 receptors are sufficient, in the absence of GluR2/3, to mediate the major types of synaptic plasticity in CA1 principal neurons. The overall behavioral retardation of the animals, however, prevented tests of learning and memory in the double knockout mice.

#### 7.5.4 Kainate Receptor Mutant Mice

At present, there are no reports on mice lacking the KA1 subunit; however, the other kainate receptor subunit mutants have been extremely useful in mapping kainate receptor function in different hippocampal cell types and at distinct subcellular localizations (see also Section 7.3.4).

#### KA2, GluR5, and GluR6 Knockout Mice

Genetic depletion of KA2 identified this subunit as an important functional component of both pre- and postsynaptic kainate receptors at the mossy fiber to CA3 synapses (Contractor et al., 2003). First, whereas the function of the presynaptic facilitatory kainate receptor, which is responsible for the marked frequency facilitation at the mossy fiber terminals, was normal, heterosynaptic facilitation resulting from a spillover of glutamate from CA3 collateral synapses was absent. This finding agrees with the idea that KA2 plays a role as a high-affinity glutamate-binding subunit, specifically required for sensing low concentrations of glutamate. Second, postsynaptic kainate receptor-mediated EPSCs in CA3 pyramidal cells showed faster decay. Mossy fiber LTP in these mice, however, was normal (Contractor et al., 2003).

Whereas the GluR5 subunit is prominently expressed in hippocampal interneurons, disruption of the GluR5 gene did not cause a loss or reduction of functional kainate receptors in these cells; this suggests that other kainate receptor subunits can compensate for the lack of GluR5 in hippocampal interneurons (Mulle et al., 2000). In contrast, kainate receptor-mediated enhancement of the amplitude of synaptic currents at the perforant path to CA3 synapses was abolished in the GluR5 and the GluR6 knockout animals (Contractor et al., 2000).

Gene-targeted mice lacking GluR6 revealed that the subunit plays a critical role at the mossy fiber to CA3 synapses, where postsynaptic kainate receptors mediate a small EPSC component that is completely abolished in the GluR6-deficient mice (Mulle et al., 1998). Importantly, synaptic plasticity

of mossy fiber connections is also affected; mossy fiber LTP—the expression of which is known to depend on presynaptic mechanisms—is reduced, and short-term synaptic facilitation is impaired in the absence GluR6. This suggests that kainate receptors act as presynaptic autoreceptors that mediate frequency-dependent synaptic facilitation at the mossy fiber terminals, a form of short-term plasticity in which the strength of transmission increases with repetitive stimulation (Contractor et al., 2001). In addition, several other roles for GluR6 in the hippocampus were revealed during analysis of the GluR6 knockout mice. Kainate receptor-mediated modulation of synaptic transmission between inhibitory interneurons in the stratum radiatum was impaired; however, a loss of postsynaptic kainate currents was observed only in double GluR5/GluR6 knockouts, suggesting the existence of two populations of kainate receptors in hippocampal interneurons (Mulle et al., 1998, 2000). GluR6-deficient mice also provided evidence of a functional role of GluR6-containing kainate receptors in CA1 cells, which showed reduced kainate- and domoate-induced CA1 inward currents in the mutant mice.

#### GluR5(Q636R) and GluR6(Q636R) Mutant Mice

The  $\text{Ca}^{2+}$  permeability of GluR5- and GluR6-containing receptors is controlled by site-selective RNA editing in the coding region for the channel pore-forming segment M2 (see Section 7.3.4). Mice with deficient editing of the GluR6 Q/R site show several phenotypic changes at the levels of synaptic transmission and behavior. First, LTP at medial perforant path to dentate gyrus synapses had an NMDA receptor-independent component, suggesting that, at this synapse too, kainate receptor-mediated  $\text{Ca}^{2+}$ -signaling can lead to an atypical NMDAR coincidence-deficient form of synaptic plasticity (Vissel et al., 2001). The GluR6(Q) mice were also more vulnerable to kainate-induced seizures than were their wild-type littermates. Together with the seizure-prone phenotypes of the GluR2(Q856) mice, these results provide further support for the hypothesis that increased postsynaptic  $\text{Ca}^{2+}$  influx and NMDAR coincidence-deficient synaptic plasticity lead to changes in hippocampal neuronal circuits, resulting in epileptic activity. In addition, the GluR6(Q) mice showed that GluR6-containing receptors are located on dendrites of dentate gyrus granule cells as well as on mossy fiber boutons. No phenotypic changes as yet have been found in the GluR5(Q) mice carrying the same mutation as the GluR6(Q) mice (Sailer et al., 1999).

#### 7.5.5 mGluR Mutant Mice

The role of group I metabotropic receptors in synaptic plasticity is well documented at both mossy fiber to CA3 and Schaffer collateral to CA1 synapses (see Chapter 10). Accordingly, mice lacking the mGluR1 subtype show reduced LTP at the Schaffer collateral CA1 synapse (Aiba et al., 1994) and possibly also at the mossy fiber to CA3 synapse (Conquet et al., 1994; but see also Hsia et al., 1995). Behaviorally, the

mGluR1 null mice showed impaired context-specific associative learning (Aiba et al., 1994; Conquet et al., 1994); note that the mice showed much stronger deficits in cerebellar plasticity and related behavior. Mice deficient in the mGluR5 subunit had a phenotype similar to that of the mGluR1 null mice, with reduced LTP in CA1 neurons, intact LTP at the mossy fiber to CA3 neurons, and somewhat impaired spatial learning and contextual fear conditioning. Thus, these animal models reveal that group I mGluRs play at least modulatory roles in hippocampal learning and memory.

Mice with targeted deletions of the group II/III mGluRs were also generated in a number of laboratories during the late 1990s. Among them, mice lacking the mGluR2 subtype, in agreement with its prominent expression in mossy fibers, show a loss of mossy fiber LTD (Yokoi et al., 1996). Interestingly, in the same study, no deficits were found in mossy fiber LTP or in watermaze tasks, suggesting that neither mGluR2 nor mossy fiber LTD are required for hippocampal spatial learning. Mice deficient in mGluR7 were found to be more prone to developing seizures, with a concomitant increase in population excitability of principal neurons in hippocampal slices (Sansig et al., 2001). Thus, mGluR7 may play an important role in presynaptic control of hippocampal excitability.

#### 7.5.6 Synopsis of the Section

Studies on genetic mouse mutants with altered excitatory neurotransmission in the hippocampus have greatly enhanced our understanding of the principles of glutamatergic synaptic transmission and synaptic plasticity, as well as of complex hippocampus-dependent behavior, learning, and memory. First, work with NMDA receptor mutant mice has provided important evidence for a causal link between NMDA receptor-mediated LTP at CA3 to CA1 synapses and spatial memory formation, as well as between this form of LTP and the formation of stable hippocampal place fields. In addition, NMDA receptor mutant mice have also revealed that different NMDA receptor subtypes contribute to different signaling pathways for LTP induction, such as the NR2A- and NR2B-specific pathways. During juvenile development the NR2B pathway is dominant, whereas in adult mice the NR2A pathway is more prominent.

The importance of hippocampal LTP in learning and memory, as well as the existence of subunit-specific forms of LTP in CA1 neurons were further substantiated by experiments using mice with altered AMPA receptors. Adult GluR1-deficient mice showed complete loss of field CA1 LTP, which correlated with spatial working memory impairment. The fact that spatial reference memory in these mice is intact suggests that different forms of NMDA receptor-dependent plasticity may underlie different forms of hippocampal memory. In juvenile mice, GluR1 is not essential for normal synaptic plasticity; juvenile LTP may be mediated by other AMPA receptor subunits (e.g., GluR4 and/or GluR2<sub>long</sub>). Genetic conversion of AMPA receptors to  $\text{Ca}^{2+}$ -permeable ion channels in pyrami-

dal neurons by depletion of GluR2 or by the inhibition of GluR2 Q/R site editing leads to long-term changes in hippocampal activity with increased excitability of CA1 cells and subsequent epileptic activity. This points to the critical importance of the edited GluR2 subunit, which determines the monovalent ion selectivity of the AMPA receptors in establishing and/or maintaining normal hippocampal functions and the survival of the animal. Finally, genetically modified mice showed unequivocally that kainate receptors act as important modulators of synaptic transmission in the hippocampus; their function is critical for maintaining normal synaptic transmission, especially for the dentate gyrus and CA3 neurons.

In summary, it seems clear that mouse genetics will continue to be an important source for unraveling complex molecular processes that underlie hippocampal functions. Currently, the global gene knockout strategy is being replaced by an approach aimed at generating mice deficient for receptor subtypes at specific hippocampal connections and at defined developmental stages. This will enable geneticists to study the role of glutamate receptors at distinct hippocampal connections without the interference of developmental disturbances. These new generations of mouse mutants promise to enhance our understanding of the relations between various forms of hippocampal synaptic plasticity and hippocampus-dependent learning and memory.

## **7.6 GABAergic Receptors: Structure, Function, and Hippocampal Distribution**

### **7.6.1 Introduction: Synaptic and Extrasynaptic GABAergic Receptors Mediate Tonic and Phasic Inhibition in the Hippocampus**

The flow of excitation through the hippocampus (dentate granule cells to CA3 pyramidal cells to CA1 pyramidal cells) is paced by GABA pulses from interneurons. A typical synaptic pulse of GABA (1 mM, 1 ms) initiates fast (milliseconds) point-to-point inhibition via ionotropic type A ( $\text{GABA}_A$ ) receptors forming  $\text{Cl}^-$ -permeable channels. This fast  $\text{GABA}_A$  receptor activation controls action potential frequency and inhibits dendritic  $\text{Ca}^{2+}$  spikes. Slower responses (e.g., late inhibitory postsynaptic potentials caused by opening of  $\text{K}^+$  channels), lasting 500 to 2000 ms, originate from metabotropic  $\text{GABA}_B$  receptors and extrasynaptic or perisynaptic  $\text{GABA}_A$  receptors. Both receptor types can be pre- or postsynaptic, as well as extrasynaptic or perisynaptic (reviewed in Kullmann et al., 2005). Indeed, there is likely to be substantial extrasynaptic activation of both  $\text{GABA}_A$  and  $\text{GABA}_B$  receptors via GABA spillover. Extrasynaptic GABA does not provide a clean time-dependent signal, unlike the phasic GABA pulses at the synapse. Hence extrasynaptic inhibition is termed “tonic inhibition.” Repetitive stimulation acti-

vates  $\text{GABA}_B$  receptors more effectively than single stimuli: Enough GABA has to build up and diffuse away from the cleft.  $\text{GABA}_B$  receptors are perhaps optimally activated by short bursts of inhibitory afferent activation coming from groups of interneurons. However, even the GABA released by a single interneuron—provided it fires at least three action potentials at high frequency—is sufficient to activate postsynaptic  $\text{GABA}_B$  receptors. On the other hand, extrasynaptic activation of  $\text{GABA}_A$  receptors is likely to be continually present, constituting background conductance.

The functions of background inhibitory conductances in neuronal circuits are unknown. Small, persistent tonic chloride conductances alter input resistance and membrane time constants; these in turn influence synaptic efficacy and integration. Manipulating background inhibitory currents, for example, may influence epileptic thresholds. Additionally, allosteric modulators active on  $\text{GABA}_A$  receptors, such as benzodiazepines, steroids, and general anesthetics, may be more potent on extrasynaptic than synaptic receptors because of the much lower GABA concentration outside the synapse (allosteric modulators produce effects at the receptor only at submaximal GABA concentrations).

GABA transporter activity helps set the extracellular GABA level and so governs the extent of extrasynaptic tonic and perisynaptic  $\text{GABA}_A$  receptor activation and presynaptic  $\text{GABA}_B$  activation. For example, in the hippocampus of GABA transporter-1 (GAT-1)-deficient mice, complex layers of feedback emerge: A large increase in tonic postsynaptic  $\text{GABA}_A$  conductance occurs in these mice, but the frequency of spontaneous quantal GABA release is one-third of normal (Jensen et al., 2003a).

In summary, the GABAergic system in the hippocampus has various modes. First, there is point-to-point  $\text{GABA}_A$  receptor-mediated synaptic transmission and a continually present background of extrasynaptic tonic  $\text{GABA}_A$ -mediated inhibition. In this case, interneurons act as individual units to release GABA. This mode does not provide enough GABA to activate  $\text{GABA}_B$  receptors (because of their low affinity/efficacy). Second, during oscillatory activity, with synaptic activity from many inhibitory neurons, substantially more GABA is released, allowing the concentration of GABA to build up extrasynaptically. When this diffuse mode comes into play, a new population of receptors, extrasynaptic  $\text{GABA}_B$  receptors, is recruited as well as more extrasynaptic  $\text{GABA}_A$  receptors. Specific behavioral states might use different levels of diffuse inhibitory transmission.

### **7.6.2 $\text{GABA}_A$ Receptors**

$\text{GABA}_A$  receptors are anion-permeable channels, with an  $\text{HCO}_3^-/\text{Cl}^-$  permeability ratio of approximately 0.2 to 0.4. In adult cells,  $\text{Cl}^-$  ions usually move into the cell to produce strong inhibitory hyperpolarization, as the reversal potential for  $\text{Cl}^-$  is 15 to 20 mV more negative than the resting membrane potential. The  $\text{Cl}^-$  gradient is maintained by  $\text{K}/\text{Cl}$  co-

transporters.  $\text{HCO}_3^-$  ions move out of the cells through the  $\text{GABA}_A$  receptor channel; the  $\text{HCO}_3^-$  efflux is mildly depolarizing ( $\text{HCO}_3^-$  has a reversal potential of  $-12$  mV), but this is normally offset by the  $\text{Cl}^-$  hyperpolarization. The  $\text{HCO}_3^-$  efflux is encouraged by the actions of extracellular carbonic anhydrase; in fact, these enzymes are essential for maintaining the  $\text{HCO}_3^-$  gradient. With an increased  $\text{HCO}_3^-/\text{Cl}^-$  permeability ratio, the outward  $\text{HCO}_3^-$  flux would depolarize the membrane at the resting membrane potential. Depending on the local internal  $\text{Cl}^-$  concentration,  $\text{Cl}^-$  ions can also move out after  $\text{GABA}_A$  receptor activation and depolarize the cell; this happens especially during embryonic and postnatal hippocampal development. Even in the adult hippocampus, when interneurons are strongly stimulated in the presence of ionotropic glutamate receptor antagonists, a biphasic postsynaptic GABAergic response is produced in pyramidal cells. An initial hyperpolarizing IPSP is followed by slow depolarization of the pyramidal cell. The slow depolarization causes action potential firing, and so is excitatory—it is termed a GABA-mediated depolarizing postsynaptic potential (GDSP) (Kaila et al., 1997).

$\text{GABA}_A$  receptors form as pentameric assemblies of subunits (reviewed in Ernst et al., 2003). A gene family encodes the subunits ( $\alpha 1-\alpha 6, \beta 1-\beta 3, \gamma 1-\gamma 3, \delta, \epsilon, \theta, \pi$ , and  $\rho 1-\rho 3$ ). The  $\text{GABA}_A$  receptor subunits belong to the acetylcholine receptor subunit gene superfamily; consequently, our working models of the  $\text{GABA}_A$  receptor structures are based on the extracellular domain of the nicotinic acetylcholine receptor structure. As for other brain regions, the  $\text{GABA}_A$  receptor subunit genes are differentially transcribed in the hippocampus (Fig. 7–9) (Persohn et al., 1992; Wisden et al., 1992; Sperk et al., 1997). Genes expressed at significant levels in the hippocampus are:  $\alpha 1 \alpha 2 \alpha 4 \alpha 5, \beta 1-\beta 3, \gamma 2$  and  $\delta$ . The subunits assemble into different combinations, depending on the cell-type. The large family of subunit genes produces considerable receptor diversity. These  $\text{GABA}_A$  receptors differ in their affinity for neurotransmitter and allosteric modulators, activation rate, desensitization rate, channel conductance and location on the cell (reviewed in Korpi et al., 2002).

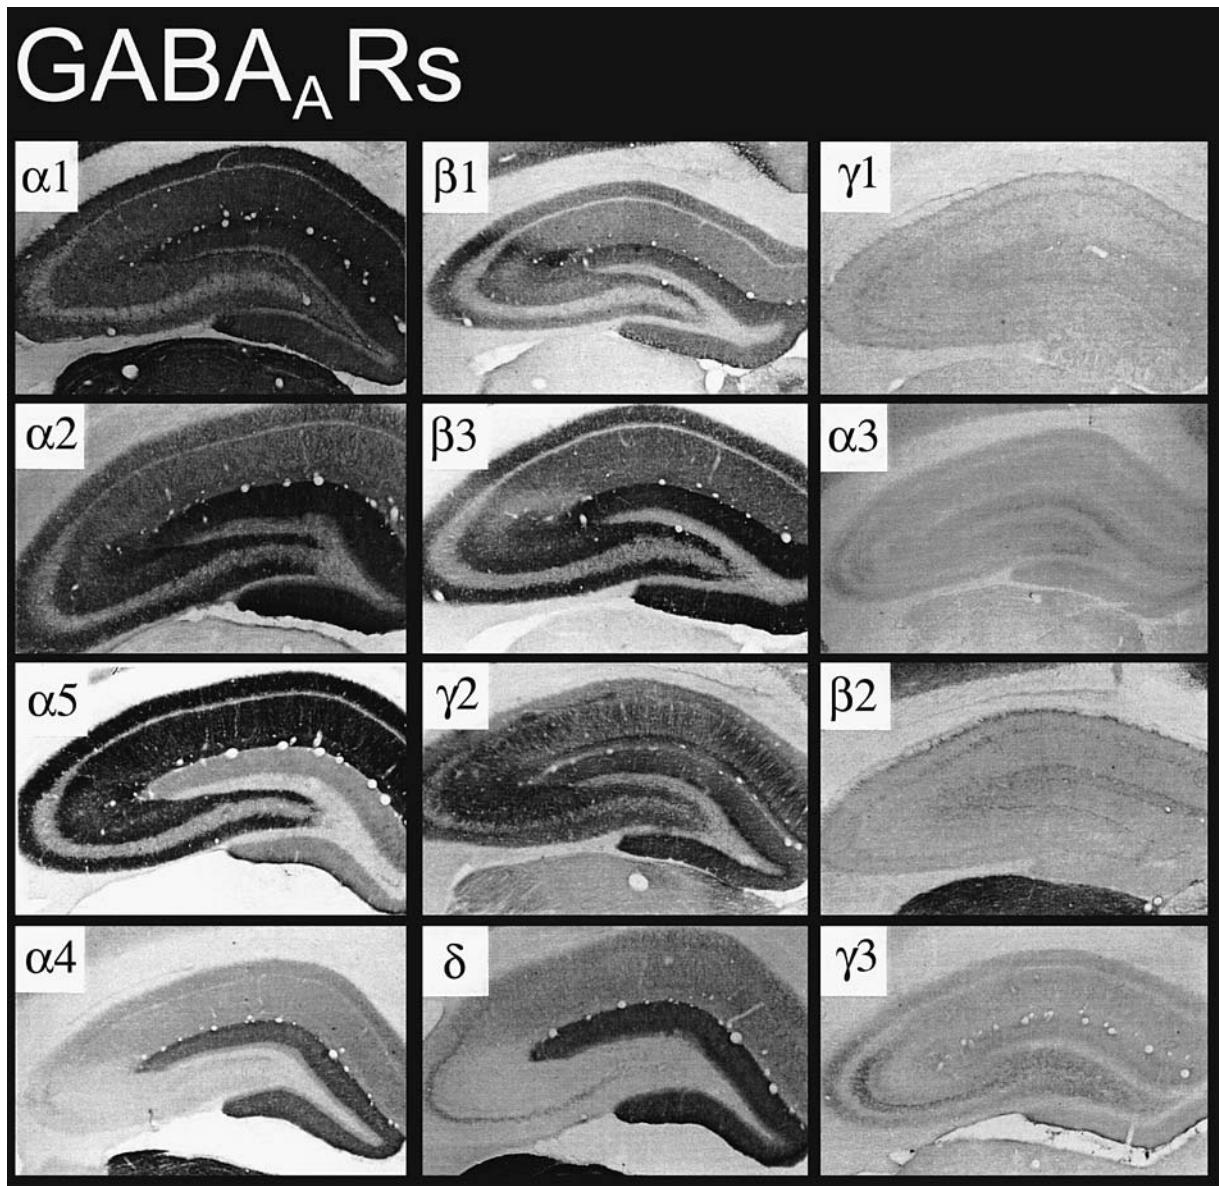

Principal  $\text{GABA}_A$  receptor subtypes relevant for hippocampal function contain:  $\alpha 1\beta\gamma 2, \alpha 2\beta\gamma 2, \alpha 3\beta\gamma 2, \alpha 4\beta\gamma 2, \alpha 5\beta\gamma 2$ , and  $\alpha\beta\delta$  (mainly  $\alpha 4\beta\delta$ ). Most hippocampal  $\text{GABA}_A$  receptors are probably  $\alpha\beta\gamma 2$  combinations, and a small number are  $\alpha\beta\delta$ : The subunit ratio in the receptor pentamer is probably  $2\alpha/2\beta/1\gamma$  or  $2\alpha 2\beta 1\delta$  (Ernst et al., 2003). Note that some receptors may contain a mixture of  $\alpha$  and  $\beta$  subunits (e.g.,  $\alpha 1\alpha 2\beta 2\gamma 2$ , and perhaps  $\alpha x\alpha 4\beta\delta$  where  $x$  is 1, 2, 3, or 5). The single channel conductance of  $\alpha\beta\gamma 2$  or  $\alpha\beta\delta$  receptors is 25 to 30 pS. As discussed in detail below, receptors with the  $\gamma 2$  subunit can be both synaptic and extrasynaptic; receptors with the  $\delta$  subunit are probably principally perisynaptic, localized around the edge of synapses (Wei et al., 2003).

The question of the function(s) of  $\text{GABA}_A$  receptor diversity has been partially addressed by pharmacological and genetic studies (reviewed in Rudolph and Mohler, 2004).

Some receptors specialize as extra or perisynaptic sensors of GABA; others enrich in particular synaptic locations. For some types of extrasynaptic or perisynaptic receptors that contain the  $\delta$  subunit, the key properties are high affinity for neurotransmitter and limited desensitization, enabling them to contribute to tonic background conductance. Another important consequence of differences in subunit expression between cells or on different parts of the same cell is that  $\text{GABA}_A$  receptor kinetics differ at different synapses (from, for example, distinct interneurons synapsing onto the pyramidal cell). This may influence the oscillation frequency of principal cells, as different interneuronal subtypes innervate different domains of pyramidal or dentate granule cells or each other (Bartos et al., 2002). In recombinant  $\alpha\beta\gamma 2$  combinations, the  $\alpha$  subunits determine receptor kinetics (Goldstein et al., 2002). The decay time constants of  $\alpha 1\beta\gamma 2$  subunits are fast, whereas those of  $\alpha 2$ - and  $\alpha 3$ -containing receptors are slower; for example, currents from recombinant  $\alpha 3\beta 2\gamma 2$  receptors decay more slowly than  $\alpha 1\beta 2\gamma 2$  receptors in response to a synaptic pulse of GABA. The  $\alpha 1$  subunit knockout mice provide direct support for this. Synaptic  $\text{GABA}_A$  receptor-mediated currents in hippocampal neurons (pyramidal and interneurons) from wild-type mice decay more rapidly than those in  $\alpha 1$  knockout mice; loss of the  $\alpha 1$  subunit in synaptically localized receptors leads to a population of synaptic receptors, probably containing the  $\alpha 2$  subunit, with slower deactivation kinetics (Goldstein et al., 2002). Differences in  $\text{GABA}_A$  receptor subunit expression between hippocampal cells and synapses likely directly influence circuit properties. Parvalbumin interneurons, for example, express mainly  $\alpha 1\beta\gamma 2$ -containing  $\text{GABA}_A$  receptors (Klausberger et al., 2002). The fast  $\text{GABA}_A$ -conveyed inhibition between these cell types helps pace the oscillation frequency in the pyramidal cell network (Bartos et al., 2002). Similarly, the mean decay time constant of the IPSC at the basket cell to basket cell synapse in the dentate gyrus is twofold faster than at the basket cell to granule cell synapse (Bartos et al., 2001). Again, this almost certainly reflects differences in receptor subunit expression.

### Distribution of $\text{GABA}_A$ Receptor Subunits in Hippocampal Dentate Granule Cells

Inhibitory terminals originate from several types of interneuron. Of the total number of inhibitory GABAergic terminals synapsing onto hippocampal granule cells, 25% occur on the cell body or axon initial segments, with the remaining 75% synapsing onto dendrites in the molecular layer (Halasy and Somogyi, 1993). At  $\text{GABA}_A$  receptors on the somatic synapses of rat dentate granule cells, there is a high probability of receptor opening ( $P_o = 0.8$ ), and all receptors are occupied by the released transmitter (reviewed in Nusser, 1999); these synapses have, on average, 26  $\text{GABA}_A$  receptors, with an average conductance of 21 pS. Rat dentate granule cells have been shown to express an extensive set of subunit mRNAs:  $\alpha 1-\alpha 5$ ,

**Figure 7–9.** Expression of GABA<sub>A</sub> receptor subunits in the rat hippocampus. Expression pattern of the 12 GABA<sub>A</sub> subunits in the adult dorsal rat hippocampus was visualized by immunohistochemistry with subunit-specific antibodies. Note: the β2 subunit staining is artificially reduced because of the low antibody concentration used. (Source: Modified from Sperk et al., 1997, with permission.)

β1–β3, and γ1–γ3, although the α3, γ1, and γ3 mRNAs are rare (Persohn et al., 1992; Wisden et al., 1992; Brooks-Kayal et al., 2001). The α2 and α4 subunit mRNAs are strongly expressed; the α1 and α5 mRNAs are at moderate levels. Of the βs, the β3 gene has the highest expression level, but β1 and β2 are also significantly expressed.

Immunocytochemical results generally agree with the *in situ* hybridization data. The α2, α4, α5, β1, β3, and δ protein staining is high in the dentate molecular layer, indicating a dendritic location on granule cells (Pirker et al., 2000; Peng et al., 2002). There is weaker staining of the granule cell soma. Many of the α subunits co-localize in the same synapses on

dentate granule cells: Double labeling immunocytochemistry shows that most of the α2-positive synapses also contains α1. Autoradiography with an α5-selective ligand, [<sup>3</sup>H]L-655,708, highlights the molecular layer of the dentate gyrus, confirming α5 protein enrichment on granule cell dendrites (Sur et al., 1999). The α4 and/or α1 and δ subunits probably assemble as perisynaptic α4βδ-, α1βδ-, or α1α4βδ-type receptors localized around the edge of the synapse (Peng et al., 2002; Wei et al., 2003). These receptors, based on analysis of their cloned counterparts, are predicted to be high-affinity and nondesensitizing, designed for their role in sensing extrasynaptic GABA and contributing to tonic inhibition.

Kullmann's group has identified presynaptic GABA<sub>A</sub> receptors on mossy fibers of dentate granule cells that inhibit axonal excitability; these receptors are tonically active in the absence of evoked GABA release or exogenous agonist application (Ruiz et al., 2003). In the presence of glutamate receptor blockers, stimulation of mossy fibers provokes monosynaptic GABA-mediated responses in their target cells; this mossy fiber-released GABA may also contribute to negative feedback via the presynaptic GABA<sub>A</sub> receptors. Alternatively, or in addition, these receptors may sense ambient GABA released from interneurons, allowing axons from granule cells to rapidly integrate the activity of surrounding neurons.

What is the identity of this presynaptic receptor? It is activated by muscimol, is antagonized by SR 95531, and has GABA responses potentiated by zolpidem (0.2 μM) (Ruiz et al., 2003), a selective agonist for α1β2γ2 receptors if used at the appropriate concentration, although at higher concentrations zolpidem also potentiates GABA's actions at α2βγ2 and α3βγ2 receptors. The zolpidem sensitivity of these presynaptic receptors suggests an α1βγ2 or α2βγ2 combination. Ruiz et al. found punctate α2 subunit immunoreactivity in rat stratum lucidum, the termination zone of mossy fibers (Ruiz et al., 2003); however, immunoreactivity for the α3 subunit was also reported at the rat mossy fibers (Pirker et al., 2000).

Several modulators of hippocampal GABA<sub>A</sub> receptors were shown to have special relevance to dentate granule cells. Neuroactive steroids modulate GABA<sub>A</sub> receptor function in the hippocampus and other brain regions. Naturally occurring steroid metabolites form locally in the brain, independently of their peripheral concentrations. 5α-Reductase transforms progesterone to 5α-DPH, which in turn is reduced by 3α-hydroxysteroid oxidoreductase to allopregnanalone. Allopregnanalone potently activates GABA<sub>A</sub> receptors. No absolute specificity of neurosteroids for particular GABA<sub>A</sub> receptor subunit combinations has been found. Many GABA<sub>A</sub> receptors are sensitive to the steroid tetrahydrodeoxycorticosterone (THDOC), but receptors with the δ subunit are particularly sensitive: 30 nM THDOC enhances the peak currents of α1β3δ GABA<sub>A</sub> receptors (with 1 μM GABA) by up to 800%; currents of other receptor isoforms (e.g., α1β3γ2) are enhanced by less (15–50%) (Mihalek et al., 1999; Wohlfarth et al., 2002; Stell et al., 2003). Thus, endogenous allopregnanalone may act on perisynaptic αβδ GABA<sub>A</sub> receptor isoforms on dentate granule cells to increase basal levels of inhibition. Mice without functional δ subunits have decreased sensitivity to the sedative/hypnotic, anxiolytic, and pro-absence effects of neuroactive steroids (Mihalek et al., 1999).

Zinc inhibits GABA<sub>A</sub> receptors. Glutamatergic neurons provide most of the extracellular zinc in the hippocampus. Zinc is stored in synaptic vesicles, notably in mossy fiber terminals; strong stimulation of mossy fibers induces co-release of glutamate and zinc into the synaptic cleft. In hippocampal neurons, zinc can reduce the amplitude, slow the rise time, and accelerate the decay of mIPSCs (e.g., Wei et al., 2003). On recombinant GABA<sub>A</sub> receptors, zinc has an inhibitory potency

3400 times higher on αβ receptors than on αβγ2 receptors (reviewed in Hosie et al., 2003). Thus the γ2 subunit lowers the sensitivity of the GABA<sub>A</sub> receptor complex to zinc. Hosie et al. suggested that the concentrations of extracellular zinc occurring in the hippocampus inhibit αβδ receptors but do not affect αβγ2 receptors (presumably α1-, α2-, α3-containing), so zinc would be a specific modulator of tonic inhibition. They hypothesized that in addition to its role in promoting synaptic targeting and single channel conductance the γ2 subunit evolved to retain the fidelity of GABAergic inhibition in the presence of zinc. Nevertheless, zinc's potency is also α subunit- and δ subunit-dependent. The IC<sub>50</sub> for zinc inhibition of α4β3δ and α4β3γ2 receptors is, in fact, similar (2 μM).

Blood alcohol levels of 1 to 3 mM can result from drinking half a glass of wine or less. Ethanol influences various channels, including the NMDA glutamate receptor; but among GABA<sub>A</sub> receptor subunit combinations, low concentrations of ethanol (about 3 mM, a concentration six times lower than the legal blood alcohol limit for driving in many states in the United States) specifically potentiate GABA responses of cloned α4β2δ receptors expressed in *Xenopus* oocytes; this effect is β subunit-dependent, as β3 subunits are needed for maximal sensitivity to ethanol (Sundstrom-Poromaa et al., 2002; Wallner et al., 2003).

### Distribution of GABA<sub>A</sub> Receptors in Hippocampal Pyramidal Cells

A pyramidal cell is covered with GABAergic terminals; a typical rat CA1 pyramidal cell receives around 1700 GABAergic synapses, with the highest density on the perisomatic region (Megias et al., 2001). Inhibition on the various domains affects different aspects of pyramidal cell function. GABA<sub>A</sub> receptor-mediated IPSCs can be generated along the whole somatodendritic domain and on the axon initial segment of CA1 pyramidal cells (Maccaferri et al., 2000). The apical dendritic trunk has a high density of GABAergic terminals relative to the rest of the dendrite (Papp et al., 2001); strong GABAergic stimulation on this apical trunk region isolates the dendritic compartment from the cell body. Inhibition on the more distal dendrites controls Ca<sup>2+</sup> spike propagation. Inhibiting the axon initial segment powerfully clamps down the pyramidal cell's activity, as this is where action potentials initiate: A typical rat CA1 pyramidal cell has more than 25 GABAergic terminals per 50 μm of the axon initial segment (AIS). Thus, GABA<sub>A</sub> receptors in the AIS deliver inhibition that controls the overall level of output activity of pyramidal cells.

Hippocampal pyramidal cells assemble many GABA<sub>A</sub> receptor subtypes (Fritschy and Brunig, 2003). By *in situ* hybridization and immunocytochemistry, rat pyramidal cells are seen to express the α1, α2, α4, β5, β1, β2, β3, γ1, and γ2 genes; expression of α3 and γ1 genes is present but weak (Wisden et al., 1992). For the α subunits, α2 mRNA is the most abundant; of the β genes, β1 and β3 are more abundant than β2; γ2 mRNA is at about the same level as α1 and β2

(Wisden et al., 1992). The *in situ* hybridization and immunocytochemical data are in agreement.  $\beta 1$  immunoreactivity is enriched at the CA2 pyramidal cell boundary (Pirker et al., 2000), as is  $\beta 1$  mRNA (Wisden et al., 1992).

As seen by immunocytochemistry with the light microscope,  $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 5$ ,  $\beta 1$ ,  $\beta 2$ ,  $\beta 3$ , and  $\gamma 2$  proteins distribute evenly on pyramidal cell dendrites and are sparser on the cell body (Sperk et al., 1997). Autoradiography with the  $\alpha 5$ -selective ligand [ $^3\text{H}$ ]L-655708 highlights the stratum radium, confirming  $\alpha 5$  protein enrichment on pyramidal cell dendrites (Sur et al., 1999). Subcellularly, the  $\alpha 5$  subunit appears predominantly extrasynaptic, with about 25% synaptic component (Brunig et al., 2002; Crestani et al., 2002). Note that the reduction in spontaneous IPSC amplitude on CA1 pyramidal cells in hippocampal slices of  $\alpha 5$  knockout mice supports the conclusion that at least some  $\alpha 5$  subunits are synaptically located (Collinson et al., 2002).

As already mentioned, the cell bodies of pyramidal cells do not heavily stain with GABA<sub>A</sub> receptor subunit-specific antibodies. However, gold-labeled antibodies combined with immunocytochemistry at the electron microscopic level have revealed GABA<sub>A</sub> subunits at synapses on the cell body; these somatic GABAergic synapses do not all have the same GABA<sub>A</sub> receptor subunit composition (Nusser et al., 1996; Somogyi et al., 1996; Nyiri et al., 2001) (see below).

GABA<sub>A</sub> receptors are also differentially sorted to specific pyramidal cell synapses. This is indicated by three levels of evidence: kinetically distinct IPSPs depending on subcellular location; GABA<sub>A</sub> receptors with different pharmacology at different synaptic inputs; and direct visualization of different receptor subunits at different synapses and extrasynaptic sites.

Different synaptic locations on pyramidal neurons have kinetically distinct IPSCs (Banks et al., 1998). At least two different IPSCs are found on CA1 pyramidal cells. A fast component (decay time constant of 9 ms) on the soma is mediated by basket cells and other interneurons; the slow component is dendritic, with a decay time constant of 50 ms, and is activated by interneurons in the stratum lacunosum-moleculare. These two decay types may be due to different receptors, although there are no subunits on the dendrite that are not on the cell body (Banks et al., 1998). In fact, a better explanation for location-dependent IPSCs is electrotonic filtering and/or the lack of voltage-clamp at the more distal recording locations (Maccaferri et al., 2000).

GABA<sub>A</sub> receptors at different GABAergic inputs onto pyramidal cells have differing sensitivities to zinc and benzodiazepines, suggestive of different subunit compositions. Zolpidem sensitivity (a selective agonist for  $\alpha 1\beta 2/3\gamma 2$  receptors if used at the appropriate concentration) was used to probe the subunit composition of synapses on the pyramidal cell body (Thomson et al., 2000). IPSPs in pyramidal cells elicited by fast-spiking basket cells (possibly corresponding to the parvalbumin-positive basket cells) were enhanced more by zolpidem than IPSCs elicited by regular spiking basket cells. Both types of synapse have IPSCs equally enhanced by

diazepam. Thus, by pharmacological inference,  $\alpha 1\beta 2/3\gamma 2$  receptors dominate postsynaptic responses in synapses formed on pyramidal cells from fast-spiking cells, whereas the  $\alpha 2$  (and  $\alpha 3$ ) subunits also contribute to receptors, together with  $\alpha 1$ , in the regular spiking basket cell to pyramidal cell synapses. This is directly supported by anatomical work (see below).

Indirect evidence for  $\alpha 4\beta\gamma 2$ -type GABA<sub>A</sub> receptors participating in synaptic transmission on the soma of CA1 pyramidal cells comes from studies on “chronic intermittent ethanol” (CIE)-treated rats. In this model, rats are exposed to intermittent episodes of ethanol and then ethanol withdrawal, producing a kindled-like state of excitability; this is accompanied by changes in GABA<sub>A</sub> receptor expression in, among other areas, the hippocampus (Cagetti et al., 2003). In CA1 pyramidal cells of CIE-treated rats, mIPSCs become insensitive to diazepam but can still be modulated by the benzodiazepine bretazenil (diazepam is active on  $\alpha 1\beta\gamma 2$  receptors, but not  $\alpha 4\beta\gamma 2$  receptors, whereas bretazenil is active on both). In CA1 pyramidal cells of control rats, mIPSCs are enhanced only slightly by the benzodiazepine “partial inverse agonist” Ro 15-4513 but are substantially enhanced by this drug in CIE-treated rats.

GABA<sub>A</sub> receptors also show differential subunit distribution at different synapses of the same pyramidal cell. On hippocampal pyramidal cells, the  $\alpha 2$  subunit is enriched in the axon initial segment but is present at only a small number of cell body synapses and synapses on dendrites (Nusser et al., 1996; Fritschy et al., 1998). The axon initial segment synapse also contains the  $\alpha 1$  subunit and possibly the  $\alpha 4$  and  $\alpha 5$  subunits. GABA<sub>A</sub> receptors at the axon initial segment are positioned to exert strong inhibitory influence over action potential generation.

Synapses formed by two types of basket cell on CA1 pyramidal cells contain distinct GABA<sub>A</sub> receptor subtypes: Only those synapses coming from parvalbumin-negative/CCK and VIP-positive basket cell interneurons contain the  $\alpha 2$  subunit; synapses from parvalbumin-positive basket cells are often  $\alpha 2$ -immunonegative (Nyiri et al., 2001). This is preferential targeting or enrichment of the  $\alpha 2$  in a particular type of synapse, not absolute selectivity. Both synapse types contain the same level of immunoreactivity for the  $\beta 2/3$  subunits; both types of synapse made by basket cells onto pyramidal cell somata also contain the  $\alpha 1$  and the  $\gamma 2$  subunits (Somogyi et al., 1996). However, the  $\alpha 1$  subunit is less abundant in the parvalbumin-negative pyramidal cell synapses than in the parvalbumin-positive ones. This work fits well with the pharmacological experiments (zolpidem sensitivity) described above. Thus, (fast-spiking) PV-basket cells probably act through  $\alpha 1\beta 2/3\gamma 2$ ,  $\alpha 2\beta 2/3\gamma 2$ , and/or  $\alpha 1\alpha 2\beta 2/3\gamma 2$  subunit-containing receptors. The subcellular location of other  $\alpha$  subunits ( $\alpha 4$  and  $\alpha 5$ ) on pyramidal cells has not yet been established by electron microscopy. Despite these differences in GABA<sub>A</sub> receptor subunit composition among synapses, paired intracellular recordings between pyramidal cells and

basket cells did not reveal significant differences in the kinetic parameters of postsynaptic responses evoked by PV- or CCK-containing basket cells (Maccaferri et al., 2000; Pawelzik et al., 2002). Different GABA<sub>A</sub> receptor subunit compositions at the synapse do not necessarily produce different kinetics.

GABA<sub>A</sub> receptors are also expressed at the dentate granule cell mossy fiber to CA3 pyramidal cell synapse, a synapse traditionally considered glutamatergic (Walker et al., 2001). Dentate granule cells can induce a partial GABAergic phenotype after seizure by expressing glutamic acid decarboxylase (reviewed in Gutierrez, 2003). The  $\alpha$ 1 and  $\beta$ 2/3 subunits were found by immunogold cytochemistry in some rat mossy fiber to CA3 synapses and co-localized with GluR2/3 AMPA receptor subunits (95% of AMPA receptor-positive mossy fiber to CA3 synapses were also GABA<sub>A</sub> receptor-positive) (Bergersen et al., 2003). What is the function of GABA release and GABA<sub>A</sub> receptor activation in mossy fiber synapses? It may be a brake on the AMPA system, although the GABAergic signal is small compared with the AMPA receptor EPSP. Note also that mossy fibers have a particularly high concentration of zinc, which when released may inhibit extrasynaptic  $\delta$  subunit-containing receptors; on the other hand, the  $\gamma$ 2 subunit may serve to reduce zinc sensitivity of the synaptic GABA<sub>A</sub> receptor complex (Hosie et al., 2003).

#### Distribution of GABA<sub>A</sub> Receptors in Hippocampal Interneurons

GABAergic interneurons and innervating principal cells also innervate each other and thus reciprocally inhibit each other. The amount of GABAergic input onto hippocampal interneurons varies with cell type, as seen from a detailed study of three types of CA1 interneuron: The ratio of GABAergic to glutamatergic inputs was about 30% for calbindin-expressing D<sub>28K</sub> cells, 20% for calretinin-expressing cells, and only 6% for parvalbumin-expressing cells (Gulyas et al., 1999). Regardless of the exact interneuronal type, GABAergic terminals onto interneurons are concentrated in the perisomatic region and on proximal dendrites; GABAergic synapses are also on distal dendrites, although at reduced density. Because of the high diversity of the interneuronal GABAergic population in the hippocampus, the available information on GABA<sub>A</sub> subunit expression in hippocampal interneurons is patchy. Based on immunocytochemistry and zolpidem sensitivity, many rat hippocampal interneurons probably use the  $\alpha$ 1 $\beta$ 2 $\gamma$ 2 receptor subunit combination. The  $\alpha$ 1 immunoreactivity is found in all parvalbumin-positive interneurons and about half of calretinin-positive cells but in no calbindin-containing cells (Gao and Fritschy, 1994; Klausberger et al., 2002); much of the  $\alpha$ 1 immunoreactivity on parvalbumin-positive cells is attributable to extrasynaptic receptors. The  $\alpha$ 1 immunoreactivity is found in most NPY- and some somatostatin-containing cells, but not in CCK- or VIP-positive cells (Gao and Fritschy, 1994). However, at least 40% of hippocampal interneurons do not express the  $\alpha$ 1 subunit and so probably use other types of

GABA<sub>A</sub> receptor. For example, as seen by the single-cell reverse transcription-polymerase chain reaction (RT-PCR), the most prominently expressed GABA<sub>A</sub> receptor subunit genes in rat dentate basket-like cells are  $\alpha$ 2,  $\beta$ 3, and  $\gamma$ 2 (Berger et al., 1998), although by immunocytochemistry there is only weak (Fritschy and Mohler, 1995) or no (Sperk et al., 1997)  $\alpha$ 2 subunit immunoreactivity detectable in this cell type. Some other interneurons (unidentified) in the polymorph cell layer of the dentate gyrus may assemble multiple GABA<sub>A</sub> receptor types: Such cells are immunoreactive for the  $\alpha$ 3,  $\beta$ 1, and the  $\delta$  subunits as well as for the  $\alpha$ 1,  $\alpha$ 2, and  $\gamma$ 2 subunits (Fritschy and Mohler, 1995; Pirker et al., 2000). The  $\alpha$ 3-positive cells in the hilus may be mossy cells. Some  $\alpha$ 3-positive cells (small cells, three to five parallel dendrites) are present in the stratum oriens of the CA1 region (Brunig et al., 2002). Peng et al (2002) and Wei et al (2003) reported  $\delta$  subunit immunoreactivity in scattered, unidentified interneurons throughout the hippocampus. Double-labeling studies are needed to confirm subunit co-expression and interneuron type.

#### GABA<sub>A</sub> Receptor Subtypes and Network Oscillation Frequency in the Hippocampus

Modeling predicts that IPSC kinetics between basket cell–basket cell groupings and between basket cells and principal cells strongly influence network oscillations in the gamma frequency range, although models differ in their assumption of the actual values of IPSC parameters (reviewed in Bartos et al., 2002). Empirically, synapses in the hippocampus differ with respect to their IPSC kinetics; the kinetics of interneuron–interneuron IPSCs are always faster than interneuron–principal cell IPSCs (Bartos et al., 2002). For example, the time course of the GABAergic postsynaptic conductance change at basket cell to basket cell synapses in the dentate gyrus is fast (decay time constant 1.8 ms), whereas basket cell to granule cell synapses are slower (decay time constant 5.2 ms). The differing subunit combinations between cell types can explain the differing IPSC kinetics; the predominant receptor subtype on many hippocampal interneurons is  $\alpha$ 1 $\beta$ 2 $\gamma$ 2, and this receptor subtype has faster decay kinetics than those of the  $\alpha$ 2 $\beta$ 2 $\gamma$ 2 receptors enriched at some synapses on pyramidal and dentate cell bodies. Whether these IPSC kinetic differences are really due to the distinct GABA<sub>A</sub> receptor subunit compositions at specific synapses or have some other explanation remains to be tested. Indeed, the decay time constants between basket cell–basket cell pairs vary among hippocampal regions (DG faster than CA3, in turn faster than CA1), although they are always faster than the corresponding interneuron–principal cell IPSCs. Factors in addition to subunit composition that might affect IPSC kinetics include the phosphorylation status of the GABA<sub>A</sub> receptors; synaptic geometry (differing distances of receptors from transmitter release sites); and differences in GABA reuptake kinetics via transporters. These factors could be synapse- and cell type-dependent.

### 7.6.3 GABA<sub>B</sub> Receptors

The GABA<sub>B</sub> receptors consist of seven transmembrane-domain proteins, GABA<sub>B</sub>R1, and GABA<sub>B</sub>R2 (reviewed in Bettler et al., 2004). Most GABA<sub>B</sub> receptors are heterodimers of GABA<sub>B</sub>R1 and GABA<sub>B</sub>R2. Inactivation of the GABA<sub>B</sub>R1 gene in mice removes all biochemical and electrophysiological GABA<sub>B</sub> responses, demonstrating that GABA<sub>B</sub>R1 is an essential component of all GABA<sub>B</sub> receptors. The lack of the GABA<sub>B</sub> response causes generalized epilepsy (Prosser et al., 2001; Schuler et al., 2001). There are two R1 versions, GABA<sub>B</sub>R1a and GABA<sub>B</sub>R1b, produced by different promoters of the GABA<sub>B</sub>R1 gene; the proteins differ in their N-termini, the first 147 amino acids in GABA<sub>B</sub>R1a being replaced by an equivalent region in GABA<sub>B</sub>R1b differing in 18 amino acids. In many neurons, such as pyramidal cells and dentate granule cells, GABA<sub>B</sub> receptors are formed as heteromers of GABA<sub>B</sub>R1 and GABA<sub>B</sub>R2 in a stoichiometric 1:1 ratio. Most GABA<sub>B</sub> receptors are likely to be GABA<sub>B</sub>R1a/GABA<sub>B</sub>R2 or GABA<sub>B</sub>R1b/GABA<sub>B</sub>R2 heteromers. In the GABA<sub>B</sub>R complex, the GABA<sub>B</sub>R1 subunit binds GABA and all competitive GABA<sub>B</sub> ligands, whereas the GABA<sub>B</sub>R2 subunit is essential for the translocation of GABA<sub>B</sub>R1 subunits to the cell surface and for targeting of the receptor to distal dendrites (Pagano et al., 2001; Gassmann et al., 2004); the GABA<sub>B</sub>R2 subunit contributes to activating the G protein but is not absolutely essential, as GABA<sub>B</sub>R2 knockout mice still have (atypical) electrophysiological GABA<sub>B</sub> responses (Gassmann et al., 2004).

GABA<sub>B</sub> receptors act through G proteins to, for example, open K<sup>+</sup> channels (GIRK type), inhibit high-voltage-activated Ca<sup>2+</sup> channels (P/Q- and N-type) and inhibit/stimulate adenyl cyclase; the opposite effects on cAMP production might be due to different G proteins (Bettler et al., 2004). GABA<sub>B</sub> receptor effects on K<sup>+</sup> channels are mainly postsynaptic and cause long-lasting membrane hyperpolarization, which can take up to 200 ms to peak and 450 to 2000 msec to decay. In contrast, Ca<sup>2+</sup> effects are mainly presynaptic. GABA<sub>B</sub> receptors can act as inhibitory autoreceptors to block GABA release from interneurons (Poncer et al., 2000); the resulting disinhibition plays an important role in the induction of LTP (see Chapter 10). In CA1 pyramidal cells of mice lacking the GABA<sub>B</sub>R2 subunit, GABA<sub>B</sub> receptors inhibit rather than activate K<sup>+</sup> channels, but whether this is physiologically relevant is unclear—it may be a side effect of GABA<sub>B</sub>R1 having no proper partner (Gassmann et al., 2004).

In keeping with the long-term effects produced by GABA<sub>B</sub> receptor activation, various signaling proteins, including transcription factors, may link to the GABA<sub>B</sub> receptor complex, forming a signaling scaffold. Examples include the direct interactions between the C-terminal tails of GABA<sub>B</sub>R1 and GABA<sub>B</sub>R2 with two related transcription factors, CREB2 (ATF4) and ATF $\zeta$  (Nehring et al., 2000; White et al., 2000); both these transcription factors activate target genes with CRE sites in their regulatory regions. On cultured hippocampal

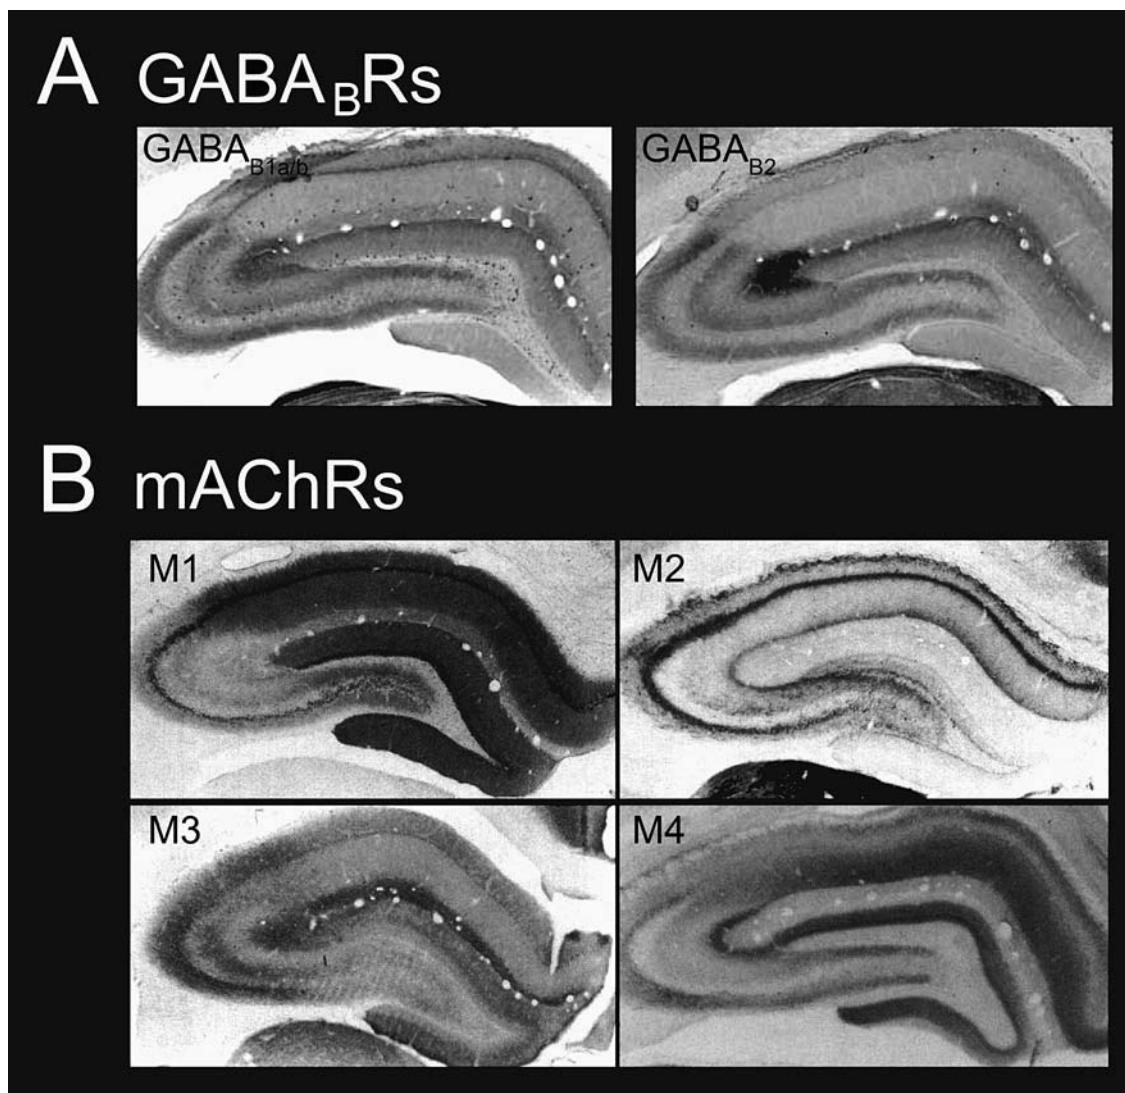

neurons, immunocytochemistry shows that GABA<sub>B</sub> receptors and ATF4 co-cluster in the soma and at the dendritic membrane surface. This suggests a model in which activation of the receptor releases the transcription factors, which then translocate to the nucleus to activate/repress target gene expression. NGF and BDNF genes are candidate target genes (White et al., 2000).

#### Distribution of GABA<sub>B</sub> Receptors in Hippocampal Principal Cells

Both GABA<sub>B</sub>R1 and GABA<sub>B</sub>R2 are expressed in hippocampal pyramidal cells and dentate granule cells, as shown by *in situ* hybridization and immunocytochemistry (Fig. 7–10A) (Kulik et al., 2003). Most GABA<sub>B</sub> receptors are on dendrites. There is a differential subcellular distribution of GABA<sub>B</sub> receptors on hippocampal pyramidal cells: GABA<sub>B</sub>R1b immunoreactivity is enriched on distal dendrites (stratum lacunosum-moleculare) of rat pyramidal cells, whereas the GABA<sub>B</sub>R1a form is found predominantly on the cell body. The somatic receptors are probably not functional; electron microscopy with gold particle-tagged antibodies shows that the strong somatic labeling results from GABA<sub>B</sub> receptor immunoreactivity in the endoplasmic reticulum (Kulik et al., 2003). On dentate granule cells, GABA<sub>B</sub> receptor immunoreactivity is enriched in the molecular layer, suggesting a dendritic location. Throughout the hippocampus, GABA<sub>B</sub>R2 immunoreactivity corresponds to the sum of the R1a and R1b patterns. The subunits co-localize in the same intracellular compartments. The targeting of GABA<sub>B</sub> receptors to distal dendrites requires the GABA<sub>B</sub>R2 subunit; in mouse hippocampal neurons lacking GABA<sub>B</sub>R2 the soma of pyramidal cells and dentate granule cells become prominently labeled by a GABA<sub>B</sub>R1 antibody, whereas in wild-type animals cell bodies have only weak, diffuse staining, and GABA<sub>B</sub>R1 immunoreactivity is distributed throughout the neuropil (Gassmann et al., 2004).

#### Distribution of GABA<sub>B</sub> Receptors in Hippocampal Interneurons

GABA<sub>B</sub> receptor responses are detected on some interneurons and are similar to those of principal cells (Mott et al., 1999). Both GABA<sub>B</sub>R1a- and GABA<sub>B</sub>R1b-like immunoreactivity is found on subsets of hippocampal GABAergic interneurons (Kulik et al., 2003; Gassmann et al., 2004); however, these interneurons do not stain with an antibody recognizing the GABA<sub>A</sub> receptor  $\beta$ 2/ $\beta$ 3 subunits. This implies that GABA<sub>A</sub> and GABA<sub>B</sub> receptors may be on distinct interneuronal cell populations, or that these GABA<sub>B</sub>-expressing interneurons use GABA<sub>A</sub> receptors with the  $\beta$ 1 subunit (Fritschy et al., 1999). Not all hippocampal interneurons seem to have GABA<sub>B</sub> receptors; there are some in the dentate hilus border region in which GABA<sub>B</sub>-activated K<sup>+</sup> currents are not produced (Mott et al., 1999). By double labeling for glutamic acid decarboxyl-

**Figure 7–10.** Expression of GABA<sub>B</sub> and mAChR receptors in the hippocampus.

A. Immunohistochemistry with subunit-specific antibodies was used to visualize the expression pattern of GABA<sub>B</sub> receptor subunits. (Source: Modified from Kulik et al., 2003, with permission.) B. Immunohistochemistry with mAChR type-specific antibodies in the adult rat hippocampus. (Source: Modified from Levey et al., 1995, with permission.)

lase 67 (GAD67) mRNA, Kulik et al., estimated that only 50% of GABAergic interneurons contain GABA<sub>B</sub> receptor immunoreactivity (Kulik et al., 2003).

#### Subcellular Localization of GABA<sub>B</sub> Receptors in Hippocampal Neurons

Presynaptic GABA<sub>B</sub> receptor subunits are localized to GABAergic and putative glutamatergic axon terminals. Functional GABA<sub>B</sub> receptors can be found, for example, on mossy fiber terminals, where they provide heterosynaptic depression (Vogt and Nicoll, 1999). The subunits are found at the extrasynaptic membrane but also at the presynaptic membrane specialization. GABA<sub>B</sub> receptors on inhibitory synaptic

terminals autoinhibit GABA release. Presynaptic GABA<sub>B</sub> receptors on glutamatergic terminals likely function as heteroreceptors regulating glutamate receptor release (Kulik et al., 2003).

Postsynaptically, the most intense labeling for GABA<sub>B</sub> receptor subunits was found in CA1 and CA3 pyramidal cell spines associated with glutamatergic terminals (Kulik et al., 2003). The functional relevance of this is unclear. In dendritic shafts, the GABA<sub>B</sub> receptor subunits localize to the extrasynaptic membrane, with no association with inhibitory synapses. Thus, activation of these receptors requires GABA spillover. Activation of GABA<sub>B</sub> receptors depends on transients in the ambient GABA concentration and may serve to detect enhanced and/or simultaneous activity of GABAergic

interneurons, as occurs in population oscillations when many interneurons fire simultaneously.

## 7.7 Trafficking of GABA Receptors and Hippocampal Synaptic Function

How GABA<sub>A</sub> receptor subunits/subtypes target GABAergic synapses, and differentially target between synapses on the same hippocampal cell (e.g., the  $\alpha 2$  subunit enriched in the axon initial segment of pyramidal cells) is not well understood. In vivo most GABA<sub>A</sub> receptors on hippocampal neurons are located opposite GABAergic terminals, not opposite glutamatergic terminals. How does this selective targeting occur? There is evidence that targeting of GABA<sub>A</sub> receptors to specific domains of hippocampal neurons is partially cell-intrinsic. In cultured hippocampal neurons, 40% of pyramidal axon initial segments have enrichment of the  $\alpha 2$  subunit, as seen by co-staining with the axon-specific type II voltage-gated Na channel (Brunig et al., 2002), and a similar proportion is seen in vivo (Nusser et al., 1996). Thus, specific innervation patterns on the hippocampal pyramidal cells (e.g., from the axo-axonic interneurons in vivo) are not required to establish  $\alpha 2$  enrichment at the axon initial segment during development.

### 7.7.1 Role of Gephyrin in GABA<sub>A</sub> Receptor Localization

Placing GABA<sub>A</sub> receptors at synapses requires specific proteins that interact directly or indirectly with the  $\gamma 2$  subunit. For example, targeting some GABA<sub>A</sub> receptor subtypes to GABAergic terminals involves the microtubule-binding protein gephyrin. In hippocampal neurons *in vitro* and *in vivo*, gephyrin either helps convey some GABA<sub>A</sub> receptor subtypes to the synapse or anchors them there; this requires the  $\gamma 2$  subunit (Kneussel et al., 1999; Brunig et al., 2002). Without the  $\gamma 2$  subunit, no GABA<sub>A</sub> receptors are found in synapses in the developing or adult hippocampus (Gunther et al., 1995; Essrich et al., 1998; Schweizer et al., 2003); and without gephyrin, much reduced numbers of some synaptic GABA<sub>A</sub> receptor subtypes, especially  $\alpha 2$ -containing, are found. Some receptor clusters, especially those containing the  $\alpha 1$  subunit, persist in hippocampal gephyrin knockout neurons (Levi et al., 2004). Gephyrin, however, does not bind the  $\gamma 2$  GABA<sub>A</sub> receptor subunit intracellular loop directly, as it does for the glycine  $\beta$  receptor subunit. The identity of the missing link(s) between gephyrin and GABA<sub>A</sub> receptor subunits is unknown.

As mentioned above, the targeting of  $\gamma 2$ -containing receptors to hippocampal synapses must depend on both the  $\alpha$  subunit and the  $\gamma 2$  subunit. According to some investigators  $\alpha 5\beta\gamma 2$  receptors seem largely extrasynaptic and not co-localized with gephyrin (Crestani et al., 2002), and when  $\alpha 6\beta\gamma 2$  receptors (normally found only in cerebellar granule cells) are

ectopically expressed in hippocampal pyramidal cells, these receptors remain extrasynaptic (Wisden et al., 1992). The determinants of synaptic/extrasynaptic GABA<sub>A</sub> receptor location may be cell type-specific and subunit-specific. In hippocampal “fireball” interneurons, the  $\alpha 3$  subunit is extrasynaptic (not co-localized with gephyrin); whereas in interneurons described as “small multipolar,”  $\alpha 3$  immunoreactivity clusters with that of gephyrin (Brunig et al., 2002). Thus, in addition to gephyrin, other clustering proteins must contribute to the synaptic localization of selected GABA<sub>A</sub> receptor subtypes.

### 7.7.2 Role of Dystrophin-associated Protein Complex in GABA<sub>A</sub> Receptor Function

The dystrophin-associated protein complex (DAPC) connects the cytoskeleton to the extracellular matrix via a transmembrane link. The DAPC’s integrative role has been best studied in muscle and Duchenne muscular dystrophy. However, DAPC components are also expressed in both neurons and glia, and some that are not found at excitatory synapses seem to be specialized for GABAergic synaptic function (Kneussel et al., 1999; Brunig et al., 2002; Levi et al., 2002; Fritschy and Brunig, 2003). Because the DAPC binds intracellular and extracellular components, it could function as an organizer of GABAergic synaptic structure in the hippocampus. The DAPC comprises dystroglycan (extracellular  $\alpha$  subunits and transmembrane  $\beta$  subunits derived from a common precursor protein by cleavage). The  $\alpha$ -dystroglycan binds laminin and agrin and the transmembrane  $\beta$ -dystroglycan. The  $\beta$ -dystroglycan binds the intracellularly located dystrophin and/or related utrophin. Dystrophin (Dp) is a cytoskeletal protein of the  $\alpha$ -actinin/ $\beta$ -spectrin family. The main brain isoform of dystrophin is Dp71. Dp71 binds to  $\alpha$ -dystobrevin. Dystrophin and  $\alpha$ -dystobrevin each bind up to two syntrophins (pleckstrin homology domain and PDZ-containing proteins). The PDZ domain of the syntrophins serves as an adaptor to bind membrane channels, receptors, kinases, and other signaling proteins. Dystrophin and dystroglycan selectively associate with subsets of GABAergic synapses in the hippocampus (Kneussel et al., 1999; Levi et al., 2002). Dystrophin immunoreactivity is present in the CA1 and CA3 regions but not in the dentate gyrus; extensive co-localization between the  $\alpha 2$ ,  $\gamma 2$ , and dystrophin immunoreactivities was observed in the soma and dendrites of hippocampal pyramidal cells; but the axon initial segment, which was prominently stained for GABA<sub>A</sub> receptor subunits, was negative for dystrophin staining (Kneussel et al., 1999). Similarly,  $\beta$ -dystroglycan is present at only a subset of GABAergic synapses in cultured hippocampal neurons, including synapses positive for  $\alpha 1$ ,  $\alpha 2$ ,  $\gamma 2$ , and  $\beta 2/3$  subunits (Levi et al., 2002). However, many clusters of glutamic acid decarboxylase, gephyrin, and  $\gamma 2$  subunits were not co-localized with  $\beta$ -dystroglycan, which, like dystrophin, is present only in a subset of GABAergic synapses. There is no interaction between the gephyrin and DAPC sys-

tems. The number and size of gephyrin-immunoreactive clusters were unaffected by the absence of dystrophin in *mdx* mice; hippocampal neurons from gephyrin knockout mice have normal dystroglycan and dystrophin immunoreactive clusters.

### 7.7.3 Plasticity of GABA<sub>A</sub> Receptor Expression at Hippocampal Synapses

It is important to keep in mind that, as for ionotropic glutamate receptors, GABA<sub>A</sub> receptor expression on the surface of hippocampal cells is dynamic; receptors rapidly recycle and leave from or insert into the synapse (reviewed in Kittler and Moss, 2003). For some inhibitory hippocampal synapses, a direct relation exists between the number of synaptic GABA<sub>A</sub> receptors and the strength of the synapse (reviewed in Nusser, 1999). As for glutamate receptors at excitatory synapses, neurons probably recycle GABA<sub>A</sub> receptors as an important strategy for setting their degree of excitability. GABA<sub>A</sub> receptors constitutively internalize by clathrin-dependent endocytosis; this requires interactions between the  $\beta$  and  $\gamma 2$  subunits and the AP2 adaptin complex. Again, as for glutamatergic synapses, the properties of inhibitory GABAergic synapses alter with activity through changes in GABA<sub>A</sub> receptor properties or receptor number.

#### Plasticity in GABA Receptor Expression in Dentate Granule Cells

Dentate granule cells exhibit pronounced plasticity in their patterns of gene expression; although their phenotype is predominantly glutamatergic, after prolonged seizure activity granule cells can display a partial GABAergic phenotype by expressing glutamic acid decarboxylase (reviewed in Gutierrez, 2003). Moreover, seizure activity in the hippocampus—for example, pilocarpine-induced epilepsy or kindling—causes changes in GABA<sub>A</sub> receptor subunit expression in dentate granule cells (Brooks-Kayal et al., 1998). There are also long-term changes in receptor number. After kindling, the amplitudes of elementary synaptic GABA<sub>A</sub> currents on dentate granule cells increased 66% owing to a corresponding 75% increase in GABA<sub>A</sub> receptor number in GABAergic synapses on granule cell somata and axon initial segments, as assessed with immunogold labeling with an antibody to the  $\beta 2$  and  $\beta 3$  subunits (Nusser et al., 1998a); immunostaining of granule cells with  $\alpha 1$ ,  $\alpha 2$ , and  $\gamma 2$  subunit antibodies was also increased. This demonstrates directly that under these conditions the efficacy of GABAergic synapses is enhanced by the insertion of extra GABA<sub>A</sub> receptors postsynaptically. Using single-cell mRNA amplification, Brooks-Kayal et al. (1998) studied the relative changes in GABA<sub>A</sub> receptor subunit expression in isolated dentate granule cells from normal rats and chronically epileptic rats in which temporal lobe epilepsy was produced by pilocarpine injection. The largest changes found were a marked decrease in  $\alpha 1$  and a strong increase in  $\alpha 4$

subunit mRNA levels, as well as increases in  $\beta$  and  $\delta$  subunit transcript levels (Brooks-Kayal et al., 1998).

Other forms of stimulation eliciting GABA<sub>A</sub> receptor plasticity in dentate granule cells include ethanol, steroids, and prenatal handling. Expression of the  $\alpha 4$  subunit gene seems particularly plastic with regard to ethanol and steroid treatments. Chronic *in vivo* administration and withdrawal of progesterone, which mimics hormonal changes of the menstrual cycle, increases the expression of hippocampal  $\alpha 4\beta\delta$  receptors (Smith et al., 1998a,b); long-term treatment and withdrawal from ethanol (in CIE-treated rats) elevates hippocampal  $\alpha 4$  mRNA and protein in CA1 pyramidal cells (Mahmoudi et al., 1997). Brief traumatic stress during infancy can permanently alter expression of GABA<sub>A</sub> receptors in dentate granule cells of the adult hippocampus (Hsu et al., 2003). In adult rats that have experienced two episodes of separation from their mothers and human handling, dentate granule cells recorded *in vitro* significantly reduced responses to zolpidem application; by single-cell RNA amplification,  $\alpha 1$  subunit mRNA levels decrease in handled individuals, whereas those of the  $\alpha 2$  subunit increase.

### 7.8 Genetic Analysis of GABA Receptor Function in the Hippocampus

#### 7.8.1 GABA<sub>A</sub> Receptor Mutant Mice

The widespread expression of most GABA<sub>A</sub> receptor subunit genes makes it difficult to attribute behavioral changes in knockout animals specifically to changes in the hippocampus (reviewed in Rudolph and Mohler, 2004). Nevertheless, various studies on genetically engineered mice have provided insight into the role of GABA<sub>A</sub> receptors in hippocampal function.

Expression of the  $\alpha 5$  gene is highly enriched in pyramidal cells of the hippocampus compared with other brain regions, making the knockout phenotype relatively easy to interpret as “hippocampal” (Collinson et al., 2002). Homozygous  $\alpha 5$  subunit knockout mice show no overt phenotypic abnormalities, breed normally, and have no spontaneous seizures. However, in a “matching-to-place” watermaze task, in which the hidden platform is moved between trials,  $\alpha 5$  knockout mice had enhanced performance compared with their wild-type littermates, whereas performance in non-hippocampal-dependent learning and anxiety tasks was unaltered. In the CA1 region of hippocampal slices from  $\alpha 5$  knockout mice, the IPSC amplitude was decreased and paired-pulse facilitation of field EPSP amplitudes was enhanced. In complementary data, mice engineered to express  $\alpha 5$  subunits with a histidine to arginine mutation at position 105 of  $\alpha 5$  have a fortuitous CA1-specific knockdown of the  $\alpha 5$  subunit expression (Crestani et al., 2002). In these  $\alpha 5$  CA1 knockdown mice, trace fear conditioning (a hippocampal-dependent process) is selectively

enhanced. These combined data suggest that  $\alpha$ 5-containing GABA<sub>A</sub> receptors contribute to cognitive processes by controlling a component of synaptic transmission in CA1 (Collinson et al., 2002).

In terms of network properties,  $\gamma$  oscillations (20–80 Hz) are modified in  $\alpha$ 5 knockout hippocampal slices (Towers et al., 2004). The peak power of oscillations evoked by kainic acid was significantly greater in  $\alpha$ 5 knockout than in wild-type slices; however, the frequency change of  $\gamma$  oscillations that normally occurs with increasing network drive was absent in  $\alpha$ 5 knockout slices. The enriched expression of the  $\alpha$ 5 subunit in the hippocampus has therapeutic potential. The drugs L-655,708 (partial inverse agonist at the BZ site) and “43” (a thiophene analogue and a full inverse agonist at the BZ site) are  $\alpha$ 5 $\beta$  $\gamma$ 2-selective modulatory ligands (Chambers et al., 2003); “43” can increase, relatively selectively, neuronal activity in the hippocampus; “43” enhances cognitive performance in rats in the delayed matching-to-place Morris watermaze. In principle, it and similar  $\alpha$ 5 subunit-selective drugs are potential “cognition enhancers” in humans.

Further useful information on hippocampal signaling has also been gleaned from some of the other GABA<sub>A</sub> receptor subunit knockouts. The  $\delta$  subunit knockout mice were instrumental in showing the selective contribution of the  $\alpha$ 4 $\delta$ -containing GABA<sub>A</sub> receptors to extrasynaptic tonic inhibition on dentate granule cells (Stell et al., 2003). In the hippocampus of  $\alpha$ 1 subunit knockout mice, synaptic GABA<sub>A</sub> receptor-mediated currents (pyramidal and interneuronal) decay more slowly than those from wild-type mice (Goldstein et al., 2002). Loss of the  $\alpha$ 1 subunit in synaptically localized receptors leads to a population of synaptic receptors with slower deactivation kinetics, in which the  $\alpha$ 1 subunit is probably replaced by an  $\alpha$ 2 or  $\alpha$ 3 subunit, thus confirming the role of  $\alpha$  subunits in determining GABA<sub>A</sub> receptor kinetics.

### 7.8.2 GABA<sub>B</sub> Receptor Mutant Mice

Two independent GABA<sub>B</sub>R1 knockout lines were established (Prosser et al., 2001; Schuler et al., 2001). Although both lines show a loss of GABA<sub>B</sub> responses in hippocampal pyramidal cells, demonstrating the absolute requirement for the GABA<sub>B</sub>R1 subunit in forming GABA<sub>B</sub> receptors, the genetic background of the two lines dramatically affects their mortality. The responsible strain-dependent modifier genes have not been identified.

Balb/c GABA<sub>B</sub>R1 knockout mice (BALB/c ( BALB/c, F1) generated from BALB/c embryonic stem cells have spontaneous epileptiform activity but are otherwise viable. In addition, the mice are hyperalgesic, show hyperlocomotor activity, and are severely impaired in passive avoidance learning (Schuler et al., 2001). The second line—genetic background 129SVJ  $\times$  C57Bl6/J,—GABA<sub>B</sub>R1 knockout mice have spontaneous generalized seizures and die after several seizure events; an increased ictal discharge pattern of epileptiform activity

was observed in hippocampal slices from mice that had repetitive seizures (Prosser et al., 2001).

A knockout mouse line has also been made for the other GABA<sub>B</sub> receptor subunit gene, GABA<sub>B</sub>R2 (Gassmann et al., 2004). Adult GABA<sub>B</sub>R2 knockout mice (BALB/c) display several episodes of spontaneous seizures per day. The recorded seizures are exclusively clonic. This is in contrast to GABA<sub>B</sub>R1 knockout mice (BALB/c), in which additionally absence-type and spontaneous tonic-clonic seizures occur with low frequency. GABA<sub>B</sub>R2 knockout mice exhibit impaired passive avoidance learning, similar to GABA<sub>B</sub>R1 knockout mice. Thus, the GABA<sub>B</sub>R2 subunit is needed for functional GABA<sub>B</sub> receptors in vivo.

## 7.9 Cholinergic Receptors

### 7.9.1 Introduction: Muscarinic and Nicotinic Receptors

Cholinergic neurotransmission modulates glutamatergic and GABAergic transmission in the hippocampus, and cholinergic projections into the hippocampus regulate the hippocampal theta rhythm *in vivo* (reviewed in Kimura, 2000). The neurotransmitter acetylcholine activates both metabotropic G protein-coupled muscarinic receptors and neuronal nicotinic receptors constituting ligand-gated cation channels. Acetylcholine is delivered to the hippocampus primarily by cholinergic neurons projecting from the medial septum/diagonal band complex; in addition, infrequent choline acetyl transferase (ChAT)-positive interneurons in the hippocampus produce local acetylcholine (ACh).

Activation of muscarinic receptors on both principal cells and interneurons causes a variety of cellular effects, including inhibition of K<sup>+</sup> currents, membrane depolarization, and IP<sub>3</sub> production (reviewed in Wess, 2004). A prominent effect of muscarinic agonists on pyramidal cells is the potentiation of NMDA-induced currents (Marino et al., 1998). Muscarinic effects on hippocampal function can be modulated by activation of autoreceptors on cholinergic terminals of the afferents from the septo-hippocampal pathway, with a resultant reduction in hippocampal ACh release.

Nicotinic receptors are used for fast transmission at the nerve–muscle synapse and at autonomic nervous system ganglia; however, in the brain, nicotinic receptors play modulatory roles—an interesting case of a fast-ligand-gated neurotransmitter receptor working as a modulator. The timing of nicotinic receptor activation depends on activity in the medial septum–diagonal band complex (Ji et al., 2001). Presynaptic nicotinic acetylcholine receptors (nAChRs) can increase the probability of neurotransmitter release, increasing the fidelity of synaptic transmission. Postsynaptic nAChRs can increase the depolarization and Ca<sup>2+</sup> signal associated with successful transmission, helping initiate intracellular cas-

cades. On the other hand, nicotinic activity can strongly excite GABAergic interneurons, thus regulating the excitability of circuits. To quote Ji et al., “the location of nAChR activity and the moment-by-moment change in that activity can tip the balance in favor or against the induction of synaptic plasticity” (Ji et al., 2001).

Nicotinic acetylcholine receptors in the hippocampus are important for learning and memory. In addition to findings from mice lacking distinct nicotinic acetylcholine receptor genes (see Section 7.8.3), evidence for this role comes also from behavioral pharmacology showing that infusion of the nicotinic receptor antagonist mecamylamine into the ventral hippocampus impairs memory performance in rats; conversely, injection of nicotine and nicotinic receptor agonists improves memory performance (reviewed in Levin et al., 2002). In the ventral hippocampus, cholinergic transmission thus boosts memory-related functions. In contrast, the cholinergic tone in the dorsal hippocampus is associated with anxiolysis (reviewed in File et al., 2000).

### 7.9.2 Hippocampal Muscarinic Receptors

Five subtypes (M1–M5) of muscarinic receptors exist: M1, M3, and M5 couple to Gq/G11 G proteins; M2 and M4 prefer Gi/Go (reviewed in Wess, 2004). Muscarinic receptors are “classic” G protein-coupled receptors that are distantly related, if at all, to metabotropic glutamate and GABA<sub>B</sub> receptors. As seen by *in situ* hybridization and immunocytochemistry, M1 is the most prominent muscarinic receptor in the hippocampus. The M1 gene is abundantly expressed in CA1 and CA3 pyramidal cells, dentate granule cells, and scattered interneurons; M1 protein is on somata and dendrites (Buckley et al., 1988; Levey et al., 1995). In CA1 pyramidal cells, M1 and the NR1a NMDA receptor subunits co-localize and may directly interact via an intracellular signaling scaffold (Marino et al., 1998). This may explain how muscarinic agonists potentiate NMDA-induced currents (see above). Mice lacking the M1 gene show various cellular and behavioral phenotypes related to hippocampal functions (see below), confirming the importance of M1 in the hippocampus.

M2 and M4 couple to the Gi family and share similar ligand-binding properties, making it difficult to distinguish pharmacologically between the two subtypes. However, studies with M2 and M4 knockouts revealed that various physiological functions are mediated by a mixture of M2 and M4 activation (Wess, 2004) (see below). M2 is expressed mostly in interneurons in the oriens/alveus border; the M2 protein is on the GABAergic terminals of the interneurons and might account for the observation that presynaptic muscarinic receptors depress inhibitory responses in the hippocampus (Levey et al., 1995). M2 is not found in pyramidal cells or dentate granule cells. In contrast, M4 mRNA and protein are mainly in CA pyramidal cells; they have lower expression in the dentate granule cells, with CA3 pyramidal cells containing slightly more M4 than CA1 cells.

In the hippocampus, M3 mRNA and protein have distributions similar to those of M4 mRNA (see above) (Buckley et al., 1988; Levey et al., 1995). M5 mRNA is restricted to CA1 pyramidal cells, but the expression is weak (Vilaro et al., 1990); M5 protein has not been detected in the hippocampus.

### Muscarinic Receptor Mutant Mice

M1 knockout mice exhibit a mild reduction in hippocampal LTP (Schaffer-CA1 synapse) in response to theta burst stimulation (Anagnostaras et al., 2003). M1 knockouts have normal or enhanced memory for tasks involving contextual fear conditioning and the Morris watermaze, but they are impaired in non-matching-to-sample working memory and consolidation (win-shift radial arm and social discrimination learning). The conclusion drawn from these mice was that M1 receptors are not essential for memory formation or initial stability of memory in the hippocampus but are more likely to contribute to processes requiring interactions between the neocortex and hippocampus. A possible substrate for binding distant populations of cells is  $\gamma$  oscillations. Muscarine-induced  $\gamma$  oscillations are absent in hippocampal slices (CA3 area) from M1 knockout mice but are still present in the M2 to M5 knockouts (Fisahn et al., 2002). These muscarine-induced  $\gamma$  oscillations depend on M1-mediated depolarization of CA3 pyramidal cells by activation of the mixed Na<sup>+</sup>/K<sup>+</sup> current ( $I_h$ ) and the Ca<sup>2+</sup>-dependent nonspecific cation current ( $I_{cat}$ ).

M2 knockout mice have significant performance deficits in passive avoidance tests. The increase in hippocampal ACh induced by local administration of scopolamine was markedly reduced in M2 knockout mice and completely abolished in M2/M4 double knockouts (as measured by *in vivo* microdialysis), probably due to a lack of M2 and M4 autoreceptors on septal-hippocampal afferents (Tzavara et al., 2003). In M2 and M4 knockouts, and to a much greater extent in M2/M4 double knockouts, the increase in hippocampal ACh triggered by exposure to a novel environment was more pronounced than in wild types (both amplitude and duration).

### 7.9.3 Hippocampal Nicotinic Receptors

Nicotinic acetylcholine receptors are ligand-gated cation channels of the superfamily that also includes the GABA<sub>A</sub> receptors; and like the GABA<sub>A</sub> receptors, they are pentameric assemblies of subunits. Neuronal nicotinic receptor subunit genes comprise  $\alpha 2$  to  $\alpha 10$  and  $\beta 2$  to  $\beta 4$  subtypes. In the hippocampus, prominent neuronal nicotinic receptors are  $(\alpha 4)_2(\beta 2)_3$ ,  $(\alpha 3)_2(\beta 4)_3$ , and  $(\alpha 7)_5$  (Zoli et al., 1998; Fabian-Fine et al., 2001). The  $\alpha 7$  receptors are fast-inactivating nonsselective cation channels with high Ca<sup>2+</sup> permeability. The  $(\alpha 4)_2(\beta 2)_3$  receptors are mainly permeable to Na<sup>+</sup> and K<sup>+</sup> and are the main targets for nicotine. Both the  $\alpha 7$  and  $(\alpha 4)_2(\beta 2)_3$  receptors can be pre- and postsynaptic. Although the  $(\alpha 4)_2(\beta 2)_3$  and  $(\alpha 3)_2(\beta 4)_3$  receptors are expressed on pyramidal cells, their function is not clear.

The  $\alpha 7$  gene is expressed in many hippocampal cell types, including interneurons, dentate granule cells, and pyramidal cells (Fabian-Fine et al., 2001). Many GABAergic and glutamatergic synapses in the hippocampus contain  $\alpha 7$  receptors; postsynaptically,  $\alpha 7$  receptors are on dendritic spines in a perisynaptic annulus. The large  $\text{Ca}^{2+}$  entry through  $\alpha 7$  nicotinic receptors may play a key role in synaptic plasticity, evoking transmitter release (e.g., from mossy fiber terminals) and/or triggering  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release from internal stores (Khiroug et al., 2003). In hippocampal principal neurons, nicotinic  $\alpha 7$  receptors mediate activation of  $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase and the ERK/MAPK cascade, resulting in sustained phosphorylation of the transcription factor CREB. Presynaptic  $\alpha 7$  receptors enhance the probability of hippocampal LTP, presumably via  $\text{Ca}^{2+}$  entry through these receptors (Dajas-Bailador and Wonnacott, 2004). Interestingly,  $\beta$ -amyloid peptide ( $\text{A}\beta_{1-42}$ ) antagonizes  $\alpha 7$  receptors on hippocampal neurons (Liu et al., 2001), suggesting that in patients with early Alzheimer's disease this antagonist effect could be an additional factor that contributes to cognitive defects. This also provides indirect support for the role of the  $\alpha 7$  subunit in cognition under normal conditions. In hippocampal interneurons,  $\alpha 7$  receptors constitute 38 pS, inwardly rectifying channels that produce strong excitatory effects, including generation of action potentials.

### Nicotinic Receptor Mutant Mice

Strong pharmacological evidence suggests that nicotinic transmission is essential for healthy cognition and learning; but as is often the case with knockouts of modulatory systems, studies on nicotinic receptor subunit knockout mice have failed to provide convincing support for this conclusion (see the informed commentary by Champiaux and Changeux, 2002, for possible reasons). Thus, despite the proposed roles of  $\alpha 7$  receptors in hippocampal function alluded to above, mice lacking the  $\alpha 7$  subunit have no deficits in hippocampal learning tasks (Paylor et al., 1998). Thus, either there is compensation (always a possibility), or the  $\alpha 7$  receptors regulate behavioral effects too subtle to pick up with current techniques. Similarly, young adult  $\beta 2$  knockout animals performed normally in spatial learning (Morris watermaze) and Pavlovian fear conditioning (reviewed in Champiaux and Changeux, 2002). However, the performance of aged  $\beta 2$  knockout mice was significantly impaired in the watermaze compared with age-matched wild-type mice. These deficits were mainly attributed to increased neurodegeneration in hippocampal and neocortical areas of  $\beta 2$  knockout brains.

Instead of studying loss of function, dominant-negative mutations can sometimes provide more insight into receptor function. Non- $\alpha 7$  nACh responses (e.g., from  $\alpha 4\beta 2$  receptors) are more difficult to characterize on central neurons, so knock-in mice with hypersensitive  $\alpha 4$  subunit-containing receptors have been used to amplify the effect of these recep-

tors (Fonck et al., 2003). In these mice, the  $\alpha 4$  subunits have a leucine to serine mutation in the channel pore-lining region of TM2, a 9' position that renders  $\alpha 4$  receptors hypersensitive to agonists. Homozygous animals die soon after birth (the same lethal phenotype was also observed for knock-in mice with an L250T mutation in the  $\alpha 7$  subunit gene that increases the  $\alpha 7$  currents) (Orr-Urtreger et al., 2000). However, mice heterozygous for the  $\alpha 4$  TM2 mutation survive but show increased anxiety. In these mice, the hippocampus is hypersensitive to nicotine; much lower doses of nicotine are needed to elicit increases in the amplitude of the electroencephalography trace; and compared with wild-type mice, a large (threefold) nicotine-induced increase in power density at  $\vartheta$  frequencies (7 Hz) occurs (Fonck et al., 2003). Thus  $\alpha 4$ -containing nicotinic receptors could contribute to oscillatory network behavior in the wild-type hippocampus.

### ACKNOWLEDGMENTS

We thank Peter H. Seuberg for long-term support. We also gratefully acknowledge our collaborators Per Andersen, David Bannerman, Øvind Hvalby, Vidar Jensen, Nick Rawlins, and Bert Sakmann. W.W. thanks Hannah Monyer for long-term support. The work in P.O.'s laboratory was funded in part by Deutsche Forschungsgemeinschaft, the German Israeli Foundation, and the Human Frontier Science Program. The work in W.W.'s laboratory was funded by the Volkswagen Stiftung, the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Schilling Foundation (grant to Prof. H. Monyer). The work in R.S.'s laboratory was funded in part by the Deutsche Forschungsgemeinschaft and Volkswagen Stiftung.

# Local Circuits

## 8.1 Overview

Local circuits play a critical role in determining the pattern of output from discrete brain regions receiving multiple inputs over time. Individual neurons have been proposed to act as integrators of multiple afferent inputs and/or coincidence detectors for these inputs depending on the compartmental organization of intrinsic membrane conductance and the type of synaptic input received. However, within a brain region, it is common to find the pattern of inputs, and subsequent outputs, of a subpopulation of neurons affecting the behavior of the population as a whole. This property of discrete brain regions is governed by the organization of local circuit connections between homogeneous and heterogeneous cell types. The aim of this chapter is to demonstrate the basic principles involved in local circuits in general and to review evidence for the organization of local circuits in the hippocampus.

### 8.1.1 Neuronal Classification Issues

Hippocampal neurons are divided into two major classes: principal cells (which form the major output pathway from hippocampal subregions) and interneurons (which are thought to be mainly local-circuit neurons). Interneurons are considerably less abundant (< 10%) than spiny principal neurons, such as granule and mossy cells in the dentate gyrus and pyramidal neurons in the CA1 and CA3 areas. As yet (and in contrast to the neocortex), there is relatively little evidence that hippocampal principal neurons fall into many distinct subclasses. However, despite their relatively small numbers, recent technical and conceptual progress has indicated an astonishing variety of interneuron classes (for review see Freund and Buzsaki, 1996). Apart from highlighting the diversity of interneuronal subtypes, these data have also revealed an equally bewildering complexity of interneuronal organiza-

tion. Some “interneurons,” for example, show properties that are traditionally associated with principal, projection neurons. Certain classes of hippocampal interneurons establish a commissural axon collateral or even project to extrahippocampal targets (Toth and Freund 1992), and others have been shown to have dendritic spines (Gulyas et al., 1992). Thus, some degree of caution is warranted when using the term local-circuit neuron and the associated morphological parameters as a synonym for interneuron. Conversely, virtually all excitatory hippocampal projection neurons have a local axonal arbor and could therefore be also considered bona fide local-circuit neurons.

Problems also arise when attempting to establish a more functionally oriented operational definition of interneurons. Although traditionally interneurons have been viewed as subserving an inhibitory function, recent anatomical studies indicate that the interneurons that selectively innervate other interneurons may have a net disinhibitory effect on principal cells (for review see Freund and Buzsaki, 1996). Moreover,  $\gamma$ -aminobutyric acid (GABA)ergic inhibitory postsynaptic potentials (IPSPs) may be depolarizing, for example during early development (Cherubini et al. 1991). GABAergic interneurons may also have pacemaker-like properties that are generally not associated with an inhibitory function.

Hippocampal interneurons can be defined operationally as GABAergic nonprincipal cells (Buckmaster and Soltesz 1996). Within this catch-all definition various attempts have been made to subclassify hippocampal interneurons based on their anatomical, electrophysiological, or neurochemical properties, including the following.

1. Dendritic morphology
2. Laminar position
3. Neuropeptide content
4. Type of calcium-binding proteins expressed
5. Efferent connectivity

6. Intrinsic conductance and firing properties
7. Participation in specific circuits

A number of these classification schemes have their undisputed merits, often facilitating the discrimination of interneurons into nonoverlapping subclasses; however, this is not always possible owing to common properties shared by otherwise distinct interneurons. For example, with respect to useful classification schemes, several extensive quantitative electron microscopic studies have provided compelling evidence that hippocampal interneurons show striking differences in their efferent connectivity properties (e.g., Gulyas et al., 1993a). However, combining this property with others in the above list leads to classification difficulties: Basket and axo-axonic (chandelier) cells both contain parvalbumin (Kosaka et al., 1987) but show clear-cut differences with respect to their efferent target profile. In addition, attempts to classify hippocampal interneurons based on their membrane and firing properties also cause problems (e.g., Lacaille and Williams, 1990; Mott et al., 1997). In short, it has, as yet, proved impossible to find a set of physiological parameters that allows a meaningful classification scheme of hippocampal interneurons to be established. For the future, the current inadequacy of this approach could be addressed by either finding more suitable criteria or, ideally, adopting a multiparametric, and therefore integrated, approach to refine the existing classification schemes, similar to efforts being made in neocortical areas (Gupta et al., 2000).

### **8.1.2 Input Specificity of Extrinsic Afferents**

All hippocampal subfields receive an abundance of extrinsic afferents, which can be grouped into three broad classes: (1) glutamatergic inputs (e.g., originating in the entorhinal cortex and other ipsilateral and contralateral hippocampal subregions); (2) the septo-hippocampal GABAergic projection; and (3) several pathways from brain stem and forebrain nuclei, releasing neurotransmitters that are often referred to as “neuromodulators,” among them acetylcholine, dopamine, serotonin, and norepinephrine.

As far as excitatory, glutamatergic afferent pathways are concerned, it appears that most of them show a high degree of laminar selectivity. Entorhinal afferents target the distal apical dendrites of granule and pyramidal cells, whereas commissural/associational fibers innervate the proximal dendrites of granule cells and the apical and basal dendrites of pyramidal neurons in the strata radiatum and oriens of the CA3 and CA1 subfields. In addition, submammillary and thalamic nucleus reunions pathways also show a high degree of laminar specificity. This laminar specificity of inputs can have powerful effects on shaping any consequent output from the target population.

Hippocampal principal cells show a marked distribution pattern of intrinsic conductance. In general, conductance that favors slower postsynaptic responses (e.g.,  $I_h$  and voltage-

operated calcium channels) is preferentially located on distal dendritic compartments (Magee, 1998; Wei et al., 2001). The distribution of such conductance has profound effects on the integrative and coincidence-detection abilities of target neurons, suggesting that inputs with different laminar profiles are handled differently by neurons in the target regions. In addition, the high degree of laminar specificity of glutamatergic input to hippocampal subregions is also accompanied by specificity in interneuron targets. The axon domains of interneurons targeted by a specific pathway often match remarkably to the axon domains of that specific pathway (see Figs. 8–2 and 8–5, later in the chapter). This suggests that where compartment-specific excitatory inputs are present a specific feedforward inhibitory local circuit is also co-activated to control those compartments (see also Section 8.1.3). Thus, the architecture exists to provide specific target region responses to specific inputs at both the cellular compartmental level and local circuit levels.

With respect to target cell selectivity, there are, as yet, no data that suggest any clear biases toward particular target neurons for glutamatergic pathways. In contrast, the GABAergic septal projection has no obvious laminar innervation pattern (Freund and Antal, 1988) but does have a precise target cell preference. Synapses are formed exclusively with GABAergic interneurons, among them subpopulations co-localizing parvalbumin, calbindin, calretinin, somatostatin, and cholecystokinin (CCK) (Freund and Buzsaki, 1996). Interestingly, the cholinergic afferents, also forming part of the septo-hippocampal pathway, do not appear to have any particular target cell or laminar preference. Cholinergic axons branch profusely in all hippocampal layers and establish synaptic contacts with both principal cells and interneurons. This widespread, nonspecific influence over target areas is also seen to some extent for other neuromodulatory inputs. Noradrenergic afferents from the locus coeruleus do not appear to have a particular target cell preference but are particularly dense in areas that receive mossy fiber input (i.e., in the hilus of the dentate gyrus and stratum lucidum of the CA3 area). One branch of the serotonergic raphe-hippocampal projection also shows this lack of specificity. Most transmitter-containing boutons in this pathway (> 75%) do not appear to make synaptic specializations and show no obvious association with particular target cells or a domain-specific innervation pattern (Oleskevich et al., 1991). Less specific data are available for dopaminergic and noradrenergic projections to the hippocampus. In general, although most hippocampal neurons express dopamine receptors, mesohippocampal projections are predominantly to area CA1. Terminals are found in all fields from the stratum oriens to the molecular layer (Gasbarri et al., 1997), with projections from the ventral tegmental area favoring the temporal hippocampus and nigral projections favoring septal CA1 fields (Gasbarri et al., 1994). In contrast, noradrenergic fibers from the locus coeruleus project mainly to the dentate gyrus and stratum lacunosum-moleculare (Swanson & Hartman, 1975; Samson et al., 1990).

Dense axonal varicosities are seen in the inner molecular layer, granule cell layer, and hilus (Ishida et al., 2000).

### 8.1.3 Subcellular Domain Specificity in Hippocampal Circuits

The pattern of co-lamination of specific extrinsic pathway inputs and their preferred interneuronal targets suggests a general pattern of organization whereby different interneurons control the activity of different principal cell compartments. Evidence for this division of labor by interneuron subtypes can also be found when considering other interneuron subtypes. Axo-axonic cells show remarkably high-target specificity for axon initial segments (Somogyi et al., 1985; Buhl et al., 1994b; Martinez et al., 1996). Conversely, basket cells clearly favor somata and proximal dendritic shafts of their postsynaptic targets (Gulyas et al., 1993; Halasy and Somogyi, 1993; Han et al., 1993). Thus, it appears that despite the spatial mixing of postsynaptic target domains at least some GABAergic cells maintain a remarkable degree of specificity for particular membrane compartments. It is interesting, however, to note that domain specificity and postsynaptic target cell selectivity are not necessarily linked. Although hippocampal basket cells appear to be invariably domain-specific, an individual basket cell may provide divergent innervation to both principal cells as well as other interneurons (Sik et al., 1995; Cobb et al., 1997).

### 8.1.4 Patterns of Local Circuit Connectivity

The previous two sections dealt predominantly with the pattern of input to local hippocampal circuits. These patterns involve two elements: the input profile directly onto local principal neurons and the concurrent activation of interneurons generating a feedforward inhibitory signal (Fig. 8–1A). Feedforward inhibition serves to impose a temporal framework on a target area on the basis of inputs received. The extra delay associated with an additional synapse in the circuit ensures that the feedforward inhibitory synaptic event does not impinge on the initial, direct extrinsic synaptic event in principal neurons. However, further extrinsic influence of the target principal cells is reduced for a time equal to the effective period of the feedforward inhibitory synaptic potential. Some interneurons receive input only from extrinsic afferents and can therefore participate only in feedforward inhibition. Examples are cells associated with the perforant path in the molecular layer of the dentate gyrus and neurogliaform cells in area CA1 (Han et al., 1993; Vida et al., 1998). Feedforward inhibition can account for most of the input from extrinsic sources. For example, the mossy fiber axons in area CA3 make roughly 10 times as many contacts with CA3 interneurons as with the far more numerous CA3 principal cells (Acsady et al., 1998).

If principal neurons fire, a number of interneurons receive synaptic excitation. Such interneurons include basket cells,

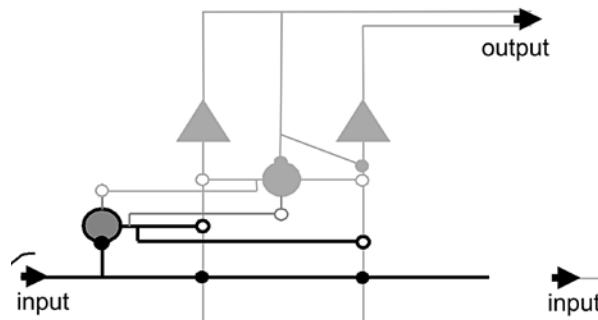

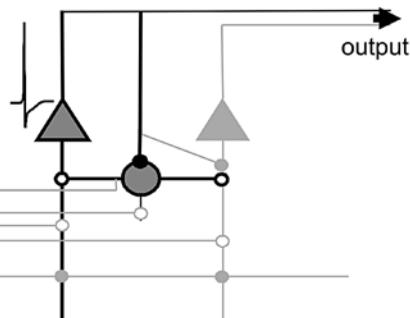

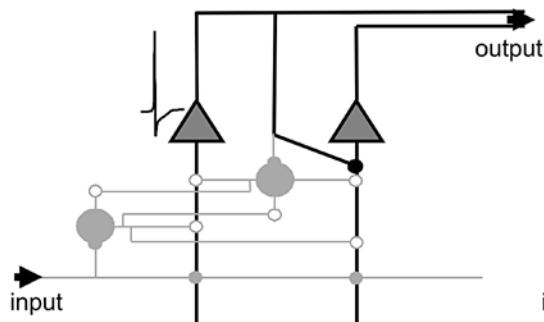

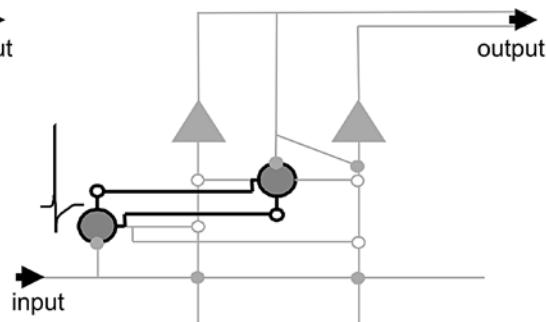

bistratified cells, and oriens and lacunosum-moleculare cells. The strength of excitatory synaptic innervation is such that there is a high probability that the target interneuron will fire an action potential (see Section 8.3). In turn, interneurons target local principal cells, thus providing a feedback inhibitory circuit (Fig. 8–1B). As with feedforward inhibition, these local feedback circuits can account for most of the local output from principal neurons. In area CA1, excitatory neurons have a strong preference for interneurons as targets (e.g., Gulyas et al., 1998). Thus, generation of an output action potential from a hippocampal subregion is followed rapidly by a period of marked local inhibition. Many interneurons can be involved in both feedforward and feedback inhibition (e.g., Buzsaki, 1983; Frotscher et al., 1984), providing a functional link between afferent input patterns and any resulting output from the target area.

In addition to circuits involving both principal excitatory neurons and inhibitory interneurons, there are many examples of interneuron–interneuron synaptic interactions (see Sections 8.2.6 and 8.3.5). Most interneurons that target principal cells, such as basket and bistratified cells, also target other interneurons. There is evidence of a broad heterogeneity of interneuron–interneuron connections, with single presynaptic interneurons innervating other interneurons with different postsynaptic targets (e.g., the distal dendritic or perisomatic compartments of pyramidal cells) (Tamas et al., 1998). Unlike feedforward and feedback inhibition, this mutual inhibition (Fig. 8–1D) can be relatively weak. For example, CA1 basket cells are 25 times more likely to form synapses with principal cells than are other basket cells. However, there are also distinct subclasses of interneurons that appear to target other interneurons exclusively (Freund and Buzsaki, 1996). Networks of such interneurons, coupled with interneurons that have principal cells as targets, massively enrich the dynamics of local circuit responses to an afferent input. In particular, recurrent pathways provide a mechanism by which rhythmic patterns of activity can be generated in interneuron circuits and projected onto principal cells, thus generating network oscillatory activity (Whittington et al., 1995) (see Chapter 11).

The occurrence of recurrent connections is not limited to interneurons. Recurrent excitation is also seen in hippocampal local circuits (Fig. 8–1C). In the hippocampus there are probably few, if any, neurons without local axon collaterals synapsing on neighboring neurons. In general, principal neurons recurrently excite other local (or neighboring) principal neurons as well as interneurons. Only dentate granule cells in rodents appear to be wired differently (see Section 8.2.1).

### 8.1.5 Circuit Specific Receptor Distribution

The basic principles of connectivity for interneurons described above also have a correlate in the types of GABA receptor expressed at specific target sites. Thus, receptors that

**A. Feedforward inhibition****B. Feedback inhibition****C. Recurrent excitation****D. Mutual inhibition**

**Figure 8–1.** Basic local circuit interactions. *A*. Feedforward inhibition. Axon collaterals from excitatory afferent fibers contact local interneurons. The additional synaptic delay compared to direct afferent excitation onto principal cells provides a time-dependent sequence of excitation and inhibition from single afferent inputs. *B*. Feedback inhibition. Axon collaterals from local principal cells contact local interneurons, providing a period of inhibition of principal cell activity following the generation of an output. Interneuron populations involved in *A* and *B* are not always mutually exclusive.

*C*. Recurrent excitation. Axon collaterals from local principal cells also contact other local principal cells, providing an excitatory mechanism for concerted, temporally coordinated population output. *D*. Mutual inhibition. Some interneuron subtypes contact other interneurons as well as principal cells, and some interneurons contact other interneurons exclusively. This pattern of connectivity can serve to impart spatiotemporally coordinated patterns of excitation and inhibition in the local circuit leading to rhythm generation. Filled circles, excitatory synapses; open circles, inhibitory synapses.

contain  $\alpha 5$  subunits are enriched in the dendritic regions of the hippocampal subfields and therefore are associated with distinct presynaptic sources, such as the class of dendrite-targeting bistratified cells (Sperk et al., 1997; Thomson et al., 2000). Conversely,  $\alpha 1$  and  $\alpha 2$  subunits containing GABA<sub>A</sub> receptors predominate in the perisomatic domain of pyramidal neurons (Nusser et al., 1996; Nyiri et al., 2001). Those receptor complexes with an  $\alpha 2$  subunit are primarily found on the axon initial segment and are, by default, associated with presynaptic terminals of axo-axonic cells, which provide the near-exclusive innervation of this neuronal compartment. The somata of pyramidal neurons, the postsynaptic target of basket cells, are decorated with both  $\alpha 1$  and  $\alpha 2$  subunit-containing GABA<sub>A</sub> receptors (Nusser et al., 1996). Interestingly, there is an even greater refinement of the input-specific recep-

tor distribution, as  $\alpha 1$ -containing receptors are matched with the terminals of parvalbumin-positive basket cells, whereas those with an  $\alpha 2$  subunit are associated with synapses established by CCK-positive basket cells (Nyiri et al., 2001).

Apart from the domain-specific distribution of GABA<sub>A</sub> receptor  $\alpha$  subunits, there is also evidence of remarkably selective expression across cell classes. Immunocytochemical double-labeling studies have revealed that all parvalbumin- and most NPY-positive interneurons express GABA<sub>A</sub> receptor  $\alpha 1$  subunits, whereas calbindin-, vasoactiveinhibitory peptide (VIP)-, and CCK-containing neurons are immunonegative for  $\alpha 1$  (Gao and Fritschy, 1994). In view of the different molecular pharmacology of GABA<sub>A</sub> receptors containing, for example,  $\alpha 1$ ,  $\alpha 2$ , or  $\alpha 5$  subunits, it is thus likely that specific inhibitory microcircuits are differentially modulated by those allosteric

modulators of GABA<sub>A</sub> receptors that show a subunit-dependent pharmacological profile. Indeed, paired recordings from identified interneurons in the CA1 area have shown that IPSPs mediated by bistratified cells were not enhanced by zolpidem, a benzodiazepine type 1 agonist requiring an α1 subunit. However, they were powerfully enhanced by diazepam, which is consistent with evidence that these synapses are associated with α5 subunit-containing GABA<sub>A</sub> receptors (Thomson et al., 2000). Conversely, and as predicted, zolpidem potentiated the IPSPs mediated by fast-spiking basket cells.

Some classes of glutamate receptors are also distributed nonrandomly. Although the GluR1 subunit of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors seems fairly evenly dispersed (Molnar et al., 1993), GluR2 subunits are lacking in interneurons (Leranth et al., 1996), giving interneuronal AMPA receptors a significant permeability for calcium (Burnashev et al., 1992) (see Chapters 6, 7, and 10). Metabotropic glutamate receptors also show a highly specific distribution. For example, mGluR1a-containing receptors are enriched in somatostatin-containing O-LM cells (Baude et al., 1993). These cells, along with other horizontal interneurons with cell bodies in the stratum oriens, appear to be the only class of hippocampal interneurons that exclusively mediate feedback inhibition (Blasco-Ibanez and Freund, 1995; Maccaferri and McBain, 1995).

Just as for GABA<sub>A</sub> and glutamate receptors, there is a similar degree of specificity in the expression of receptors that mediate responses of ascending modulatory fiber tracts, among them the cholinergic and serotonergic systems. With respect to the latter, the subpopulation of GABAergic CCK-positive basket cells express high levels of ionotropic serotonin (5HT)-3 receptors (Morales et al., 1998). Likewise, metabotropic 5HT-2 receptors are enriched in GABAergic interneurons (Morilak et al., 1994). A similar picture is beginning to emerge with respect to the distribution of cholinergic receptor subtypes. For example, fast postsynaptic nicotinic responses have been recorded in GABAergic interneurons but are absent in pyramidal neurons (Jones and Yakel, 1997; Alkondon et al., 1998; Frazier et al., 1998), suggesting that nicotinic cholinergic responses are mediated indirectly via changes in interneuronal activity. However, more recent evidence has shown that nicotinic receptors on glutamatergic terminals may serve to modulate plastic changes at excitatory synapses (Fabian-Fine et al., 2001; Ge and Danni, 2005). Muscarinic acetylcholine receptors may also show a high degree of specificity in their expression patterns. Postsynaptic m2 receptors, for example, are predominantly found in a subset of GABAergic interneurons, whereas at the presynaptic level m2 receptors are enriched in the perisomatic terminals of basket and axo-axonic cells (Hajos et al., 1998).

As yet, too little is known about the precise cellular and subcellular distribution of most hippocampal neurotransmitter receptor systems to extract any general functional and/or organizational principles. The examples listed above provide no more than a sketchy picture. Hopefully, with the use of single-cell polymerase chain reaction (PCR) and subunit-

specific antisera, a complete description may disclose clearer rules that govern the cell type-specific and/or circuit-specific distribution of receptor proteins.

### 8.1.6 Convergence and Divergence

In common with neocortical areas, the hippocampal formation is characterized by a high degree of neuronal interconnectivity. This is due to a multitude of converging inputs and diverging outputs; that is, an individual neuron is generally targeted by multiple afferents (convergence), whereas the efferent output of a single neuron contacts multiple postsynaptic target neurons (divergence). A hippocampal neuron may receive several thousand synaptic contacts that originate from distant brain areas (e.g., the septum or entorhinal cortex) or, conversely, arise from neighboring excitatory and/or inhibitory local-circuit neurons (Buhl et al., 1994a; Freund and Buzsaki 1996). In turn, hippocampal principal and interneurons give rise to extensive axonal systems that arborize locally and/or project to distant, extrahippocampal targets.

Using light-microscopic bouton counts and correlated electron microscopy, it is possible to determine the degree of divergence of individual hippocampal neurons (Halasy et al., 1996). Such estimates indicate that most hippocampal interneurons contact well in excess of 500 postsynaptic target neurons. In addition, it has been estimated that approximately 25 basket cells may innervate a single pyramidal neuron (Buhl et al., 1994a). This massive divergence of inhibitory axons and convergence of multiple inhibitory neuronal inputs onto single pyramidal cells underpins the ability of GABAergic neurons to synchronize hippocampal population activity.

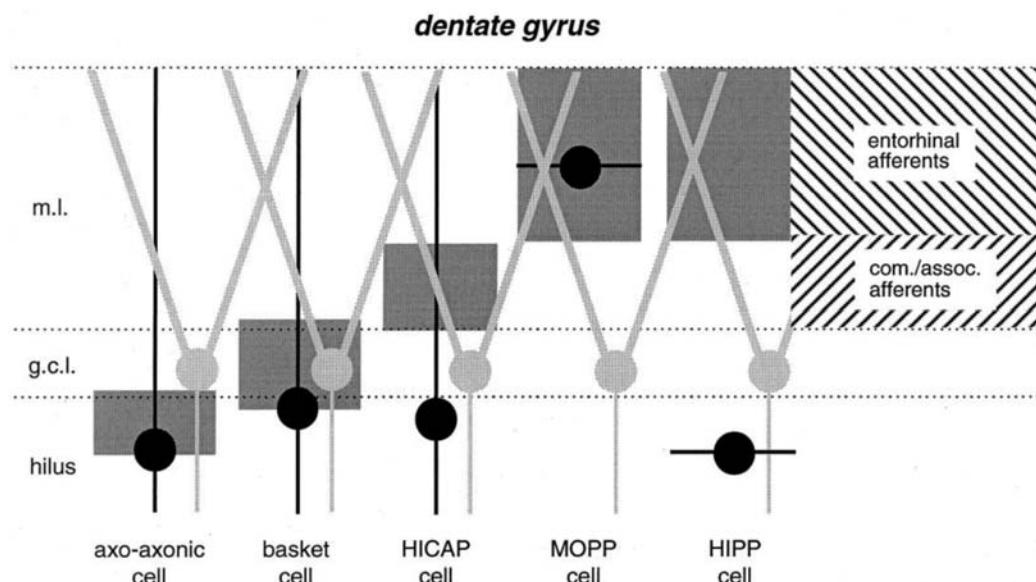

## 8.2 Dentate Gyrus

Granule cells are the principal neuronal type of the dentate gyrus. Their sole efferent projection, the mossy fiber pathway, forms the second link of the so-called tri-synaptic loop by targeting CA3 pyramidal cells. Granule cells also form connections with interneurons, mossy cells (excitatory neurons in the hilus) and, in some epilepsy models, other granule cells (Dashtipour et al., 2002). Thus, within the dentate gyrus, granule cells may function as elements in circuits generating feedforward and feedback inhibition as well as homo- and heterogeneous recurrent excitatory circuits.

### 8.2.1 Inputs to the Dentate Gyrus

There is, as yet, little evidence for target cell specificity of excitatory inputs to the dentate granule cells. However, there is abundant evidence for subcellular domain specificity. The main perforant path input to the dentate gyrus from entorhinal stellate cells targets the distal apical dendrites of granule cells, whereas commissural/associational fibers innervate the

**Figure 8-2.** Basic organization of interneuron output fields in the dentate gyrus. Subcellular domain specificity of dendrite-targeting interneurons co-organizes with afferent inputs. M.l., molecular layer; G.c.l., granule cell layer; HICAP, hilar commissural/associa-

tion pathway-associated interneuron; MOPP, molecular layer perforant path-associated interneuron; HIPP, hilar perforant path-associated interneuron. Shaded regions mark the axonal arbors for each cell type.

proximal dendrites (Blackstad 1958; Buhl and Dann, 1991; Deller et al., 1996). This target domain specificity is precisely reflected in the preferred interneuron targets for these dentate gyrus inputs (Fig. 8-2). MOPP (molecular layer perforant path-associated) cells receive excitatory inputs only from the perforant path projection; there is no recurrent feedback from innervated granule cells. HIPP (hilar perforant path-associated) cells also receive inputs from the perforant path, whereas HICAP (hilar commisural/association pathway-associated) cells receive external inputs from the commisural/association pathway (Han et al., 1993).

Other afferent input pathways also show some degree of specificity. The submammillary projection forms a dense plexus of axons in the border regions of the granule and molecular layer (Magloczky et al., 1994). In addition, the noradrenergic inputs from the locus coeruleus appear to target areas receiving mossy fiber input—the hilus and stratum lucidum of area CA3 (Loy et al., 1980; Oleskevich et al., 1989). In terms of neuronal subtypes, the serotonergic raphe–hippocampal projection demonstrates the highest degree of target cell specificity. One part forms large synaptic boutons that form synapses predominantly with GABAergic interneurons, avoiding principal cells (Halasy et al., 1992). Within this group of interneurons there is specificity for distinct subsets.

The serotonergic input preferentially targets calbindin-, calretinin-, somatostatin-, and neuropeptide Y-containing cells (i.e., those with an efferent target profile for the dendritic domain of principal neurons) (Miettinen and Freund, 1992). In contrast, the other part of the raphe projection conforms to the notion of modulatory inputs exerting a diffuse action (as

with septal projections). Most transmitter-containing boutons in this part of the raphe projection (> 75%) do not appear to make synaptic specializations and show no obvious domain-specific innervation patterns or association with particular target cells (Oleskevich et al., 1991).

### 8.2.2 Granule Cell Projection to Area CA3

Granule cell axons aggregate in a distinct bundle of unmyelinated axons above the CA3 pyramidal cell layer, termed the stratum lucidum because of its characteristic light-microscopic appearance. Here they form three distinct types of synaptic terminal: the large en passant mossy boutons (4–10  $\mu\text{m}$ ), filopodial extensions of large mossy boutons (0.5–2.0  $\mu\text{m}$ ), and smaller en passant-type terminals (0.5–2.0  $\mu\text{m}$ ) (Acsady et al., 1998). The characteristic mossy terminals exclusively innervate hilar mossy cells and CA3 pyramidal neurons, forming a multitude (30–40) of synaptic junctions (release sites) with a single thorny excrescence on each innervated CA3 or hilar neuron (Chicurel and Harris, 1992). Conversely, filopodial extensions and en passant-type terminals selectively target hilar and CA3 area interneurons (Acsady et al., 1998). The total number of mossy terminals along the trajectory of completely labeled granule cell axons is relatively small (10–18), and it has been suggested that a single granule cell may contact no more than 11 to 15 CA3 pyramidal cells and a somewhat smaller number of hilar mossy cells (Acsady et al., 1998). Thus, in contrast to other cortical areas, there appears to be only a modest degree of excitatory convergence and divergence in the mossy fiber output. Moreover, due to

the low firing probability of granule cells *in vivo* (Jung and McNaughton, 1993) the statistical likelihood of coincident activity among afferent inputs to a single target neuron seems relatively low. In addition, single spike transmission at the mossy fiber synapse is also rare, whereas transmission in response to spike trains in granule cells is robust (Geiger and Jonas, 2000; Henze et al., 2002).

### 8.2.3 Granule Cell–Interneuron Connections

In the CA3 area granule axons do not appear to display a preference for particular subtypes of GABAergic interneurons (Acsady et al., 1998). Thus, they make contact with substance P receptor-containing interneurons, interneurons positive for mGluR1a (a marker for somatostatin-containing interneurons with a dendritic innervation pattern, among them O-LM cells in the CA areas), and parvalbumin-labeled interneurons, which innervate the perisomatic region of their target cells. They do, however, contact, via en passant or filopodial terminals, interneurons in considerably larger numbers than pyramidal neurons; and it has been estimated that, compared to other cortical principal cells, granule cells innervate GABAergic targets ~10 times more frequently. The smaller mossy terminals on interneurons typically establish no more than a single synaptic release site (Acsady et al., 1998). Therefore, the substantially greater degree of mossy fiber convergence onto GABAergic neurons appears to be counterbalanced by a comparatively lower strength of unitary connections. It must be emphasized, however, that in general the absolute strength (in terms of amplitude and/or conductance) and kinetics of unitary granule cell-to-interneuron connections are comparable to pyramidal-to-interneuron connections in other hippocampal regions (Miles, 1990; Scharfman et al., 1990; Gulyas et al., 1993a,b; Buhl et al., 1994a,b; Geiger et al., 1997; Ali and Thomson, 1998; Ali et al., 1998).

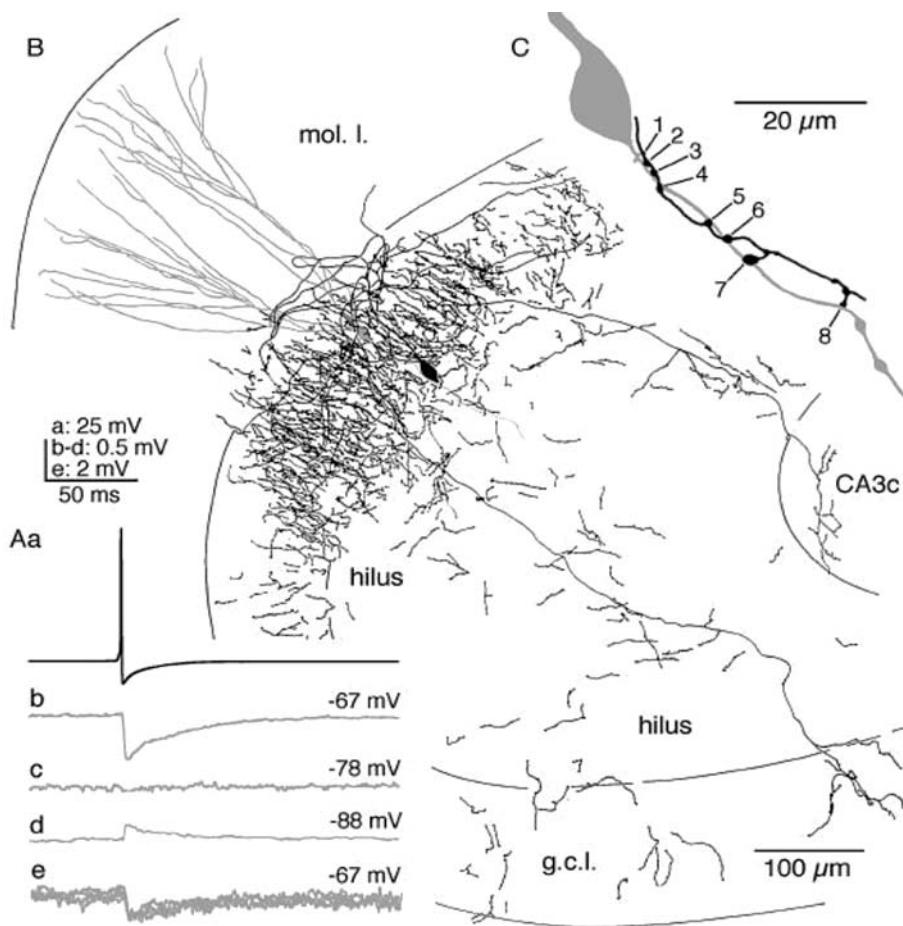

As yet, relatively little is known with respect to putative differences in the innervation of dentate interneurons. Such differences are apparent in the hippocampal CA1 area (Ali and Thomson, 1998; Ali et al., 1998); and based on their dendritic architecture it seems reasonable to assume that certain subtypes of dentate gyrus interneurons, such as those with their dendritic arbor restricted to the outer two-thirds of the molecular layer (MOPP cells) (Han et al., 1993), are unlikely to receive a significant degree of recurrent excitatory granule cell input. In contrast, others, such as a class of interneurons that have their dendrites largely confined to the hilar region (HIPP cells) (Han et al., 1993), are predisposed to mediate recurrent input from granule cell collaterals. Indeed, their neurochemical equivalent, mGluR1a-containing neurons, have been shown to receive granule cell synapses, whereas it has been demonstrated in the CA1 area that their counterparts, mGluR1a/somatostatin-containing O-LM cells, are exclusively innervated by recurrent collaterals of CA1 pyramidal neurons (Blasco-Ibanez and Freund, 1995; Maccaferri and McBain, 1995).

### 8.2.4 Interneuron–Granule Cell Connections

Dentate interneurons all release the amino acid transmitter GABA. However, beyond this unifying characteristic, they constitute a heterogeneous class of neurons. Dentate interneurons differ with respect to their content of neuropeptides, calcium-binding proteins, and somatodendritic architecture as well as their axonal arborization pattern (Freund and Buzsaki, 1996). The latter feature in particular has been a useful guide to subdividing hippocampal interneurons into distinct subclasses.

The advent of intracellular labeling techniques has facilitated the near-complete visualization of interneurons, revealing axonal arbors with highly complex but distinct ramification patterns. As in all other hippocampal areas, several classes of GABAergic interneurons target distinct domains of their postsynaptic target neurons. Thus, axo-axonic cells, frequently referred to as chandelier cells, have an absolute target preference for the initial segment of granule and mossy cells (Somogyi et al., 1985; Han et al., 1993; Halasy and Somogyi, 1993; Buhl et al., 1994b). A specific example of this target preference for granule cells is shown in Figure 8–3C. In contrast, basket cells direct their efferent output toward the somata (78%) and proximal dendrites (22%) of granule cells (Halasy and Somogyi, 1993). Whereas these two types of interneuron appear to account for most of the inhibitory synapses in the perisomatic region, the axonal arbors of several other interneuron classes occupy distinct strata in the dentate molecular layer, innervating either proximal or distal segments of postsynaptic dendrites (Halasy and Somogyi, 1993; Han et al., 1993). Interestingly, as we have seen (Fig. 8–2), the target zones of these GABAergic axons overlap with the laminar distribution of the major excitatory pathways. Axons of the HICAP cells co-stratify with the commissural/associational afferents in the inner third of the dentate molecular layer, as demonstrated in Figure 8–4 (lower neuron), whereas two additional classes of dendrite-targeting neuron, HIPP and MOPP cells, innervate the outer two-thirds of the molecular layer, co-laminating with the perforant path input, as shown in Figure 8–4 (Han et al., 1993). It thus appears that distinct types of neuron have evolved that selectively and locally modulate the dendritic integration of a distinct set of glutamatergic afferents. Interestingly, this division of labor is even more refined, as those interneuron classes with overlapping terminal fields, such as HICAP and axo-axonic cells (Fig. 8–3), are further specialized to participate in feed-forward or feedback inhibitory microcircuits, respectively (Han et al., 1993). However, other types of dendrite-targeting neurons show no apparent laminar preference (Soriano et al., 1993).

Although only a small number of dentate interneurons, such as somatostatin-positive cells, have a long-range commissural projection (Bakst et al., 1986; Schwerdtfeger and Buhl, 1986; Sik et al., 1997), virtually all of those that do have extensive axonal arbors (Han et al., 1993; Buckmaster and

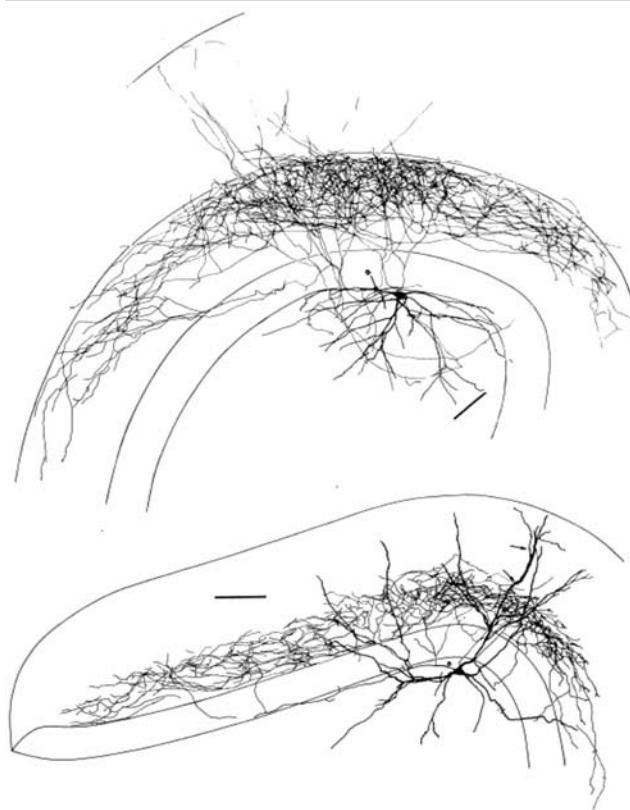

**Figure 8-3.** Pattern of axo-axonic cell axonal arborization. A. Action potential in an axo-axonic cell (Aa) generates a short-latency IPSP in a granule cell (Ab) with reversal potential around -80 mV (Ac–e). B. Axon of the axo-axonic cell innervates the

granule cell layer, the hilus, and the tip of area CA3c. C. Location of eight synaptic junctions on the initial axonal segments of a granule cell whose responses are shown in Ab–e. (Source: Adapted from Buhl et al., 1994a, with permission.)

Schwartzkroin, 1995a,b; Sik et al., 1997). Individual axons have been shown to ramify extensively, filling both dentate blades and extending in excess of 3 mm along the septo-temporal axis (Sik et al., 1997). Although it appears that interneurons generally establish more than a single synaptic junction with a target neuron, the total number of release sites appears to be relatively small. In one instance, correlated light and electron microscopic analysis of a synaptically connected axo-axonic-to-granule cell pair revealed a total of eight sites of membrane apposition with an equivalent number of synaptic release sites that mediated the unitary interaction (Buhl et al., 1994a), with other light microscopic estimates being in a similar range. Because the granule cell axon initial segment received an additional 40 unlabeled synapses, it is—in view of the virtually exclusive innervation of this target domain by axo-axonic cells—reasonable to assume a convergence factor in the range of six. Clearly, however, there are too few data to extract any general rules as, for example, in one instance 36 VIP-positive boutons originating from a single axon collateral were counted on a single spiny substance P-positive dendrite in the hilus (Sik et al., 1997).

The relatively low number of interneurons and the modest number of release sites that characterize unitary connections are in stark contrast to estimates of the total bouton number established by individual GABAergic axons, ranging from approximately 10,000 to 75,000 (Sik et al., 1997). Accordingly, these data suggest a large degree of synaptic divergence, with individual interneurons occupying a large volume fraction of an entire hippocampus, perhaps in the range of 25%, and innervating up to 10,000 postsynaptic target neurons. Conversely, unitary inhibitory interactions appear to be relatively weak (Scharfman et al., 1990; Buhl et al., 1994a). Electron microscopic studies of individual biocytin-labeled axons consistently show a greater number and/or density of unlabeled inhibitory terminals converging on postsynaptic target structures, suggesting that several neurons of a given type converge on a postsynaptic neuron. It therefore appears that at least some of the GABAergic circuitry in the dentate gyrus is laid out to affect information processing at highly specific sites, such as dendritic segments, but generally at the level of neuronal populations it simultaneously affects several thousands of target cells.

**Figure 8-4.** Domain specificity of axons in the dentate gyrus. Upper neuron: Reconstruction of a HIPP cell illustrating axonal fields closely associated with the distal granule cell dendritic termination zone for perforant path inputs from the entorhinal cortex. Bar = 0.1 mm. Lower neuron: Reconstruction of a HICAP cell demonstrating an axonal field distribution different from that of the HIPP cell. In this case the HICAP cell axonal field was associated with the proximal dendritic termination zone associated with commissural and associational pathways. Bar = 0.1 mm. (Source: Adapted from Han et al., 1993, with permission.)

### 8.2.5 Granule Cell-Local Excitatory Neuron Connections

Apart from dentate and CA3 interneurons, granule cells also innervate hilar mossy cells, both with large mossy terminals, impinging on mossy cell thorny excrescences as well as smaller terminals, contacting conventional spines on mossy cell dendrites (Frotscher et al., 1991; Acsady et al., 1998). However, in contrast to principal cells in other hippocampal and cortical areas, granule cells in rodents do not establish recurrent excitatory feedback to themselves, perhaps owing to the spatial segregation of granule cell dendrites (rodent granule cells lack basal dendrites) and their axons, which do not enter the molecular layer. Only certain pathological conditions, such as temporal lobe epilepsy, favor aberrant sprouting of mossy fibers into the dentate molecular layer and the de novo formation of recurrent feedback loops. Interestingly, in adult rhesus monkeys and humans a sizable proportion of granule cells extend basal dendrites into the hilar region, thereby pro-

viding the spatial proximity of dendrites and recurrent axons that might be expected to encourage monosynaptic granule cell–granule cell synapses (Seress and Mrzljak, 1987; Buhl and Dann, 1991). However, whether and to what extent primate granule cells are interconnected—and if so, what consequences it would have for their processing capabilities—remains to be established. Moreover, it is, as yet, unclear whether there is an archetypical mammalian blueprint for the dentate gyrus microcircuit and whether primates or rodents conform more closely to this ancestral blueprint.

### 8.2.6. Interneuron-Interneuron Connections

With the notable exception of axo-axonic cells, which exclusively innervate excitatory principal cells, the other interneuron types described above appear to have no particularly bias for a specific type of target neuron, innervating both principal neurons and interneurons (Sik et al., 1997). Immunocytochemical data, however, suggest an additional class of interneurons that are specialized to innervate other interneurons. A subpopulation of VIP-positive nonprincipal cells innervate substance P receptor-immunopositive hilar interneurons as their major postsynaptic target, and an additional subclass of VIP neurons with a projection to the molecular layer innervate several types of GABAergic neurons (Hajos et al., 1996). The functional role of these interneuron-targeting interneurons, which may include disinhibition or the synchronization of GABAergic networks, awaits experimental investigation.

## 8.3 Areas CA3 and CA1

The cornu ammonis is usually delineated into areas CA3 and CA1, with some researchers also distinguishing area CA2 (between area CA3 and CA1) (see Chapter 3). In the classic hippocampal trisynaptic circuit, activity is projected from the dentate gyrus (see Section 8.2) to CA3 and then from CA3 via Schaffer collaterals to CA1. However, direct input to areas CA3 and CA1 also originate from the entorhinal cortex, nucleus reunions, and neuromodulatory regions (see below).

### 8.3.1 Inputs to CA3 and CA1

With one exception, the stratum radiatum giant cells (Gulyas et al., 1998), the principal neurons in the hippocampal subfields, constitute a relatively homogeneous population of glutamate-releasing pyramid-shaped neurons. In the CA1 and CA3 areas pyramidal neurons bear numerous spines, with estimates being as high as 30,000 (Bannister and Larkman, 1995; Trommald et al., 1995), and most of these spines receive a single excitatory synapse. Although single-cell-labeling studies indicate that all pyramidal neurons have a local axonal arbor, most excitatory synapses in the hippocampal subfields are of extraneous origin, arriving from a multitude of sources,

such as a different hippocampal subfield, the contralateral hippocampus, the entorhinal cortex, the submammillary body (Magloczky et al., 1994), and the nucleus reuniens thalamus (Wouterlood et al., 1990). More diffuse neuromodulatory inputs are seen from septal cholinergic axons (Frotscher and Lenrath, 1985; Lenrath and Frotscher, 1987) and interneuron-targeting raphe axons (Freund et al., 1990).

In contrast to the mossy fiber synapse(s) on the thorny excrescences of CA3 pyramidal neurons, the amplitude of unitary excitatory inputs to area CA1 is weak (< 2 mV) (Miles and Wong, 1986; Sayer et al., 1990; Malinow, 1991) and well below spike threshold. Although there are, as yet, no accurate estimates of the number of release sites at unitary connections established by an afferent excitatory axon, a wealth of indirect evidence suggests that the number of contact sites is small (see Chapters 3 and 6). First, the trajectory of incoming axons is often perpendicular to that of pyramidal dendrites, not dissimilar to the geometrical arrangement of parallel fibers and cerebellar Purkinje cells, thus decreasing the statistical likelihood of synaptic encounters on an individual target cell. Second, so-called single-fiber stimulation experiments generally yield low-amplitude responses, which are commensurate with the release of relatively few quanta of transmitter. These experiments involving paired recordings of CA3-to-CA1 pyramidal pairs (i.e., activation of a single Schaffer collateral) have revealed small-amplitude unitary excitatory responses, with quantal analysis providing evidence that the low quantal content was due to a small number of synaptic release sites rather than a low release probability (Sayer et al., 1990; Larkman et al., 1991; Malinow, 1991; Bolshakov and Siegelbaum, 1995). Synaptic CA3–CA1 responses have been attributed to as little as a single release site (e.g., Turner et al., 1997). Ultimately, however, correlated physiological and electron microscopic approaches are needed to resolve this important issue.

### **8.3.2 Pyramidal Cell-Interneuron Connections**

Local connections between pyramidal neurons and interneurons form the physiological substrate for feedback inhibition in the hippocampal network. The efficacy of recurrent inhibition can be readily demonstrated, as action potentials in CA3 pyramidal neurons can frequently elicit IPSPs in neighboring pyramidal cells. These IPSPs are generated by the local network of inhibitory cells, which in turn have been synaptically activated by the excitatory feedback of the presynaptic pyramidal neuron. Accordingly, both GABA<sub>A</sub> and AMPA/kainate receptor antagonists are effective in abolishing disynaptic IPSPs (Miles, 1990). Apart from demonstrating the presence of inhibitory local feedback circuits, these data show that excitatory postsynaptic potentials (EPSPs) evoked by individual pyramidal neurons must be sufficiently strong to trigger action potentials reliably in postsynaptic interneurons. More direct evidence in support of this notion has been obtained with intracellular recordings of synaptically coupled pyramidal cell-to-interneuron pairs (Miles, 1990). These data show

that in such unitary interactions the probability of spike transduction can be as high as 60%, with mean EPSP amplitudes varying between 0.2 and 4.0 mV (Miles, 1990; Gulyas et al., 1993b). Similar values were reported for the CA1 area (Buhl et al., 1994a; Ali and Thomson, 1998; Ali et al., 1998). Multidisciplinary studies using paired recordings and post hoc correlated light and electron microscopic analysis demonstrate that pyramidal cell-to-interneuron connections in the CA3 and CA1 regions are generally established by one presynaptic bouton establishing no more than a single synaptic junction (Gulyas et al., 1993b; Buhl et al., 1994a). Quantal analysis of such interactions revealed a relatively high release probability (0.76) and, not surprisingly in view of the presumed small number of release sites, a sizable quantal amplitude (0.70 mV). Thus, it appears that a small number of synaptic junctions with a large quantal amplitude and a low failure rate, perhaps boosted by active dendritic conductance (Traub and Miles, 1995; Martina et al., 2000), is sufficient to guarantee relatively reliable spike transmission at pyramidal-to-interneuron connections.

Using paired recordings in conjunction with intracellular labeling techniques, at least three classes of interneurons have been conclusively identified as postsynaptic targets of local axon collaterals of pyramidal neurons: basket, bistratified, and O-LM cells (Gulyas et al., 1993b; Buhl et al., 1994a; Ali and Thomson, 1998; Ali et al., 1998). At least in the CA1 area, the overall probability of obtaining such a connection with paired recordings is substantially higher than that for pyramidal cell pairs. Moreover, there are marked differences depending on the type of postsynaptic interneuron. Thus, the probability of obtaining a pyramidal-to-basket cell connection is in the range of 1:22; that of finding a pyramidal-to-bistratified cell pair is 1:7; and pyramidal cell-to-O-LM cell interactions are most readily encountered (1:3) (Ali et al., 1998). Although, as a general rule, physiological estimates from paired recordings are prone to some degree of experimental bias, these differences appear to be sufficiently clear-cut to suggest not only that pyramidal neurons in the CA1 area have a marked target preference for inhibitory interneurons, but that there is a distinct bias toward favoring different subclasses of interneurons.

Hippocampal interneurons receive fewer excitatory synapses than principal neurons, with the numbers varying considerably depending on the class of cell (Gulyas et al., 1999). Parvalbumin-positive cells with a perisomatic efferent target profile (axo-axonic and basket cells) receive, on average, approximately 15,000 excitatory synapses, whereas the group of dendrite-targeting calbindin-positive interneurons (e.g., bistratified cells) receive in the range of 2600 excitatory inputs. The class of interneuron-targeting calretinin-positive interneurons are targeted by even fewer, in the order of 1700 excitatory synapses (Gulyas et al., 1999). Because it is unknown how many of the excitatory inputs to interneurons are from neighboring pyramidal neurons, it is not possible to calculate convergence factors for feedforward and recurrent pyramidal cells inputs. However, even if the proportion of recurrent inputs were as low as 10%, it (e.g., in the case of par-

valbumin-positive cells) suggests that approximately 1500 neighboring pyramidal cells converge on a single interneuron. Accordingly, this conservative estimate suggests that the concomitant activity of no more than 1% of the local pyramidal cell population, with an average quantal amplitude of 0.7 mV, would be required to elicit 10 mV recurrent EPSPs in an interneuron. Thus, it seems likely that only a small fraction of feedforward and/or recurrent excitatory inputs is required to be simultaneously active (see below) to drive interneurons to their firing threshold.

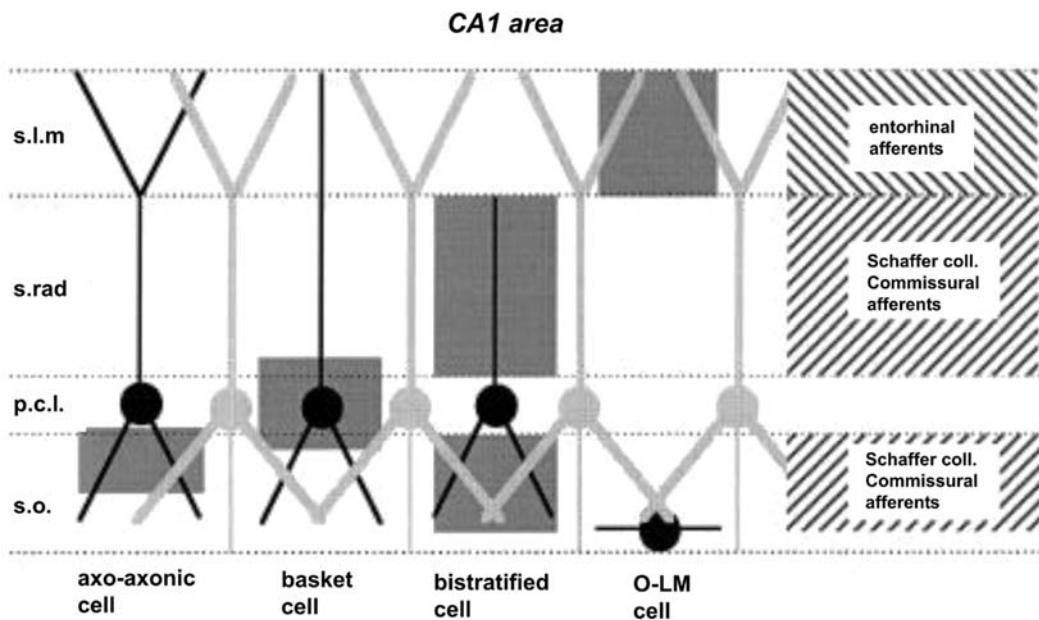

It appears to be a general rule that EPSPs on hippocampal interneurons, regardless of whether they originate locally or in a different (hippocampal) brain area, have faster kinetic properties than excitatory inputs on principal neurons (Miles, 1990; Lacaille, 1991; Gulyas et al., 1993b; Buhl et al., 1994a, 1996; Ali and Thomson, 1998; Ali et al., 1998). There are several reasons for this: First, interneurons have comparatively short membrane time constants, in part due to their expression of Kv3 potassium channel subtypes (Lien and Jonas, 2003); second, active dendritic conductance may counterbalance the electrotonic slowing of synaptic potentials; third, the molecular composition of interneuronal AMPA receptors endows them with faster single-channel kinetics (Geiger et al., 1997); fourth, the contribution of an NMDA receptor-mediated component, which would slow EPSP kinetics, appears to be relatively small (Buhl et al., 1996). It is conceivable that all these factors act in unison to accelerate spiking in interneurons and thereby minimize the delay of disynaptic IPSPs, also explaining the well known observation that recurrent inhibition is effective in curtailing EPSPs evoked using electrical stimulation of afferent fibers. Moreover, fast EPSPs in interneurons improve the precision of spike timing by decreasing the temporal jitter of action potentials, a factor that is of considerable importance for the network activity during inhibition-based brain rhythms.

Excitatory unitary interactions in the adult hippocampus may show both frequency-dependent depression and facilitation of the postsynaptic response magnitude; that is, during repetitive presynaptic activity, successive action potentials elicit EPSPs with a gradually decremental or incremental amplitude (Miles and Wong, 1986; Miles, 1990; Deuchars and Thomson, 1996; Ali and Thomson, 1998; Ali et al., 1998). In general, unitary EPSPs in interneurons of the CA3 area show a greater tendency to facilitate, perhaps related to the greater propensity of CA3 neurons to fire bursts of action potentials. Moreover, evidence suggests that short-term plasticity of unitary excitatory connections may be target-dependent (i.e., determined by the postsynaptic neuron) (Ali and Thomson, 1998; Ali et al., 1998). The finding is particularly intriguing because what in essence is considered a presynaptic phenomenon is determined by the type of postsynaptic neuron. Thus, upon repetitive activation, the unitary responses evoked by CA1 pyramidal cells in CA1 basket and bistratified cells invariably exhibit gradual depression of their amplitudes, whereas those evoked in O-LM cells strongly facilitate (Ali and Thomson, 1998; Ali et al., 1998). The biophysical proper-

ties of the target cell may also affect the integration of unitary synaptic potentials, determining, for example, whether successive events will show response summation, thereby leading to an overall amplitude increase of the compound potential despite the fact that the input may show frequency-dependent depression. Because of their brief membrane time constants, unitary EPSPs in hippocampal interneurons generally show modest, if any, response summation, even with brief interevent intervals, whereas EPSPs evoked in pyramidal cells exhibit an incremental increase of the compound potential (Miles, 1990). Accordingly, pyramidal cells are often viewed as integrators (i.e., their output reflects the sum of inputs), whereas interneurons have been termed coincidence detectors, as their activation is strongly dependent on the temporal coherence of their inputs, showing only a significant degree of response summation with (near) synchronous inputs (Konig et al., 1996).

### 8.3.3 Interneuron–Pyramidal Cell Connections

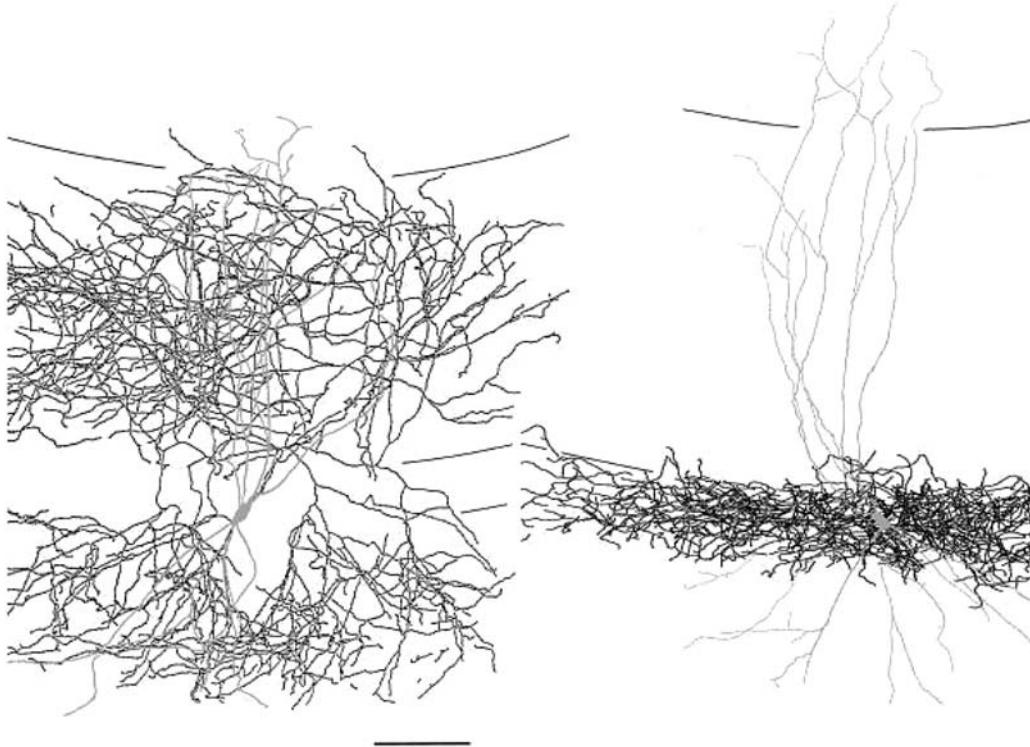

As is the case in the dentate gyrus, a variety of intracellular labeling studies have provided evidence that GABAergic interneurons in the CA1 and CA3 regions are morphologically diverse and can be classified with respect to their laminar position, somatodendritic morphology, and most importantly efferent connectivity (Gulyas et al., 1993a,b; Buhl et al., 1994a,b, 1995; McBain et al., 1994; Sik et al., 1994, 1995; Halasy et al., 1996; Vida et al., 1998; Vida and Frotscher, 2000; but see Parra et al., 1998). A general scheme for interneuronal connectivity is illustrated in Figure 8–5 (compare with Fig. 8–2). Although there are region-specific variations, it appears that the fundamental principles in the organization of interneuron microcircuitry are similar in all hippocampal regions and indeed in all cortical areas (Somogyi et al., 1998). Thus, axo-axonic and basket cells in the CA1 and CA3 subfields target the perisomatic domain, with the former almost exclusively innervating the axon initial segment of principal cells and the latter forming synapses on somata and proximal dendrites (Gulyas et al., 1993a,b; Buhl et al., 1994a,b, 1995). Likewise, several classes of dendrite-targeting interneurons have their axonal arbor co-laminating with afferent excitatory inputs. The axons of bistratified cells in the CA1 area co-stratify with the Schaffer collateral/commissural input (Buhl et al., 1994b). The remarkable delineation of axonal fields between perisomatic targeting (basket cell) and dendrite targeting (e.g., bistratified) interneurons is illustrated in Figure 8–6. O-LM cells in both hippocampal subfields selectively innervate the perforant path termination zone in the stratum lacunosum-moleculare (Gulyas et al., 1993a,b; McBain et al., 1994); and mossy fiber-associated interneurons have their axons restricted to the stratum lucidum of the CA3 region and, as the name suggests, have been proposed to modulate selectively the granule cell output to the CA3 region (Vida and Frotscher, 2000). As in the dentate gyrus, more than a single type of interneuron may be associated with a particular pathway, such as OL-M cells and perforant-path associated interneurons at the stratum radia-

**Figure 8-5.** Basic anatomical organization of interneuron output fields in area CA1. As with the dentate gyrus, dendrite-targeting interneurons show a great deal of specificity when associating with termination fields for afferent inputs of differing anatomical origin. S.l.m., stratum lacunosum moleculare; S.rad., stratum radiatum; P.c.l., pyramidal cell layer; S.o., stratum oriens; O-LM cell, oriens-lacunosum moleculare cell.

**Figure 8-6.** Compartmental target specificity for interneurons in area CA1. Left-hand neuron: Axonal and dendritic arborizations of a bistratified neuron demonstrating the near absence of input to perisomatic compartments but dense arborization in the stratum radiatum and the stratum oriens (associated with Schaffer collateral

commissural afferents). Right-hand neuron: Axonal and dendritic arborizations for a basket cell illustrating the high precision of axons for the perisomatic compartments and complete absence of projections to dendritic fields. Bar = 0.1 mm.

tum/lacunosum-moleculare border (Vida et al., 1998). However, their dendritic architecture suggests that interneurons with a similar efferent target profile may be preferentially involved in either feedforward or recurrent inhibitory microcircuits. Indeed, for O-LM cells compelling anatomical and physiological data show that they exclusively mediate recurrent inhibition onto pyramidal cells (Blasco-Ibanez and Freund, 1995; Maccaferri and McBain, 1995). Again, as in the dentate gyrus, there may be input selectivity for at least some of those interneurons involved in feedforward inhibitory circuits. For example, in view of their dendritic architecture, bistratified cells presumably receive commissural/associational afferents and are less likely to process a significant proportion of direct entorhinal input (Halasy et al., 1996).

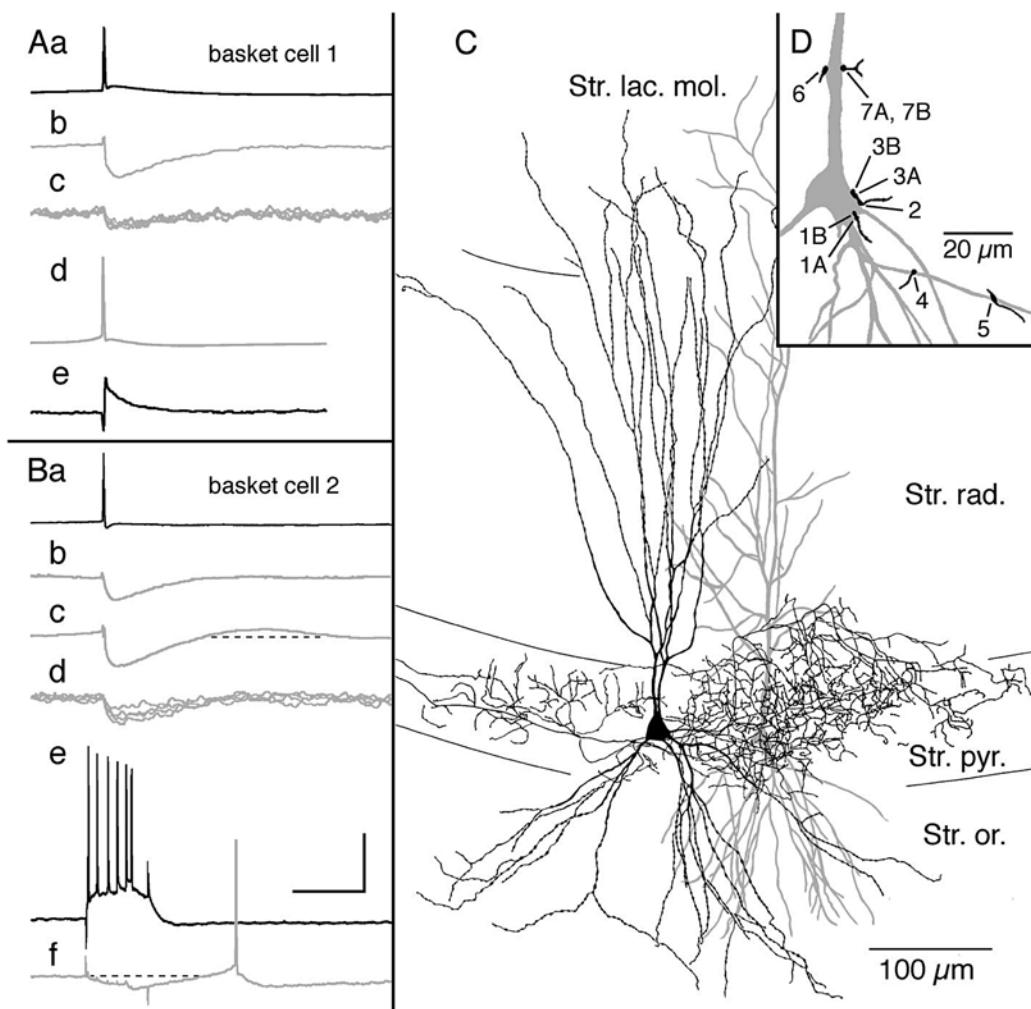

Interneurons in the CA3 and CA1 subfields have axonal arbors of varying size. Neurogliaform and O-LM cells have the most compact axonal arbors (Gulyas et al., 1993a,b; Sik et al., 1995; Ali and Thomson, 1998; Vida et al., 1998), generally spanning less than 1 mm, whereas axo-axonic, basket, bistratified, and trilaminar cells have considerably larger axonal trees, with *in vivo* estimates for basket cell axon arbors being in the range of 1 mm, approximately 2 mm for a bistratified cell, and about 2.5 mm for a trilaminar interneuron (Sik et al., 1995). The available evidence suggests that axonal arbors tend to be relatively symmetrical in all hippocampal planes. Moreover, apart from having extensive local axonal arbors, several types of hippocampal interneuron have extra-areal projections. Axons of perforant path-associated interneurons in the CA1 area cross the hippocampal fissure and spread into the outer molecular layer of the dentate gyrus (Vida et al., 1998). Back-projecting cells in the CA1 region appear to have even larger axonal arbors, extending throughout all hippocampal subfields (Sik et al., 1994); and a subset of GABAergic calbindin-positive interneurons with an as yet unknown morphology project to the medial septum (Toth and Freund, 1992).

Electron microscopic data show that individual terminal boutons of most hippocampal interneurons usually establish a single synaptic junction per bouton, although occasionally a double junction is seen (Buhl et al., 1994a,b, 1995; Halasy et al., 1996; Vida et al., 1998). Thus, light-microscopic bouton counts are generally thought to be a reasonable approximation of the total number of synaptic contact sites established by a single inhibitory axon. Such estimates for a variety of interneurons labeled *in vitro*, among them basket, axo-axonic, neurogliaform and bistratified cells as well as Schaffer collateral and perforant path-associated interneurons, are consistently above 5000 and can be as high as ~13,000 (Gulyas et al., 1993a,b) (Halasy et al., 1996; Miles et al., 1996; Vida et al., 1998). Not surprisingly, *in vivo* estimates are substantially higher, approximately twofold, with basket cell axons having bouton counts up to 12,000 (Sik et al., 1995). Likewise, bouton counts for individual bistratified, trilaminar, and O-LM cells were in the range of 15,000 (Sik et al., 1995). However, despite the large total number of boutons per axon, relatively

few are associated with individual postsynaptic target neurons, providing further anatomical evidence for the divergent nature of inhibition (see Section 8.1.6). Correlated light and electron microscopic analysis of unitary inhibitory interactions revealed that hippocampal basket cells establish 2 to 12 synaptic junctions, whereas dendrite-targeting interneurons (e.g., bistratified cells) form 5 to 17 contacts with an individual pyramidal neuron (Buhl et al., 1994a,b; Miles et al., 1996; Tamas et al., 1997). Although there are relatively few published examples with electron microscopic counts of unitary release site numbers, several light microscopic estimates obtained from O-LM, bistratified, Schaffer collateral-associated, and axo-axonic cells confirm the above data (Gulyas et al., 1993a,b; Vida et al., 1998; Maccaferri et al., 2000). Thus, it seems reasonable to assume that the efferent output of most hippocampal interneurons distributes onto approximately 1000 to 2000 target neurons.

Connectivity estimates of hippocampal neurons have been obtained with paired recordings. On average, CA1 basket cells contact approximately 22% of pyramidal neurons within the confines of their axonal arbor, with the connection probability dropping from 54% for immediate neighbors to 5% for longer-range connections (Ali et al., 1999). Although there is an inevitable experimental bias with this approach, earlier quantitative anatomical data showed a surprising degree of agreement with estimates obtained from paired recording. Calculations based on pyramidal cell and basket cell terminal densities, taking an average number of synaptic release sites into account, suggest that CA1 basket cells contact approximately 28% of nearby target cells, with the connection probability plummeting to 4% toward the peripheral extent of the axonal arbor (Halasy et al., 1996).

Although it is probable that thousands of pyramidal cells converge on each inhibitory interneuron, for a number of reasons the convergence factors in the reciprocal direction are substantially smaller. First, as pyramidal cells are innervated by many classes of GABAergic neurons, each subpopulation supplies no more than a fraction of the total GABAergic input. Accordingly, cell class-specific convergence factors are inversely related to the number of interneuron types. Second, pyramidal cells receive fewer inhibitory than excitatory inputs, although the exact ratio is unknown. Although there are currently no data on the number of inhibitory inputs onto dendrites, electron microscopic estimates suggest that pyramidal cell somata receive in the range of 120 synapses and axon initial segments in the range of 100 to 200 (Kosaka 1980; Buhl et al., 1994). Third, unitary inhibitory interactions are generally mediated by several synaptic release sites, as illustrated in Figure 8–7. Accordingly, current estimates suggest that approximately 25 basket cells and even fewer axo-axonic cells (2–10), converge on a single pyramidal neuron (Li et al., 1992; Buhl et al., 1994). It therefore follows that, in contrast to presynaptic pyramidal cell input, a disproportionately large fraction of inhibitory neurons (at least 10%) must be active during neuronal population activity. Rhythmic network oscil-

**Figure 8-7.** Basket cell morphology and effects on principal cells in area CA1. *A*, Single action potentials in basket cells (*Aa,d*) elicit short latency IPSPs in principal cells. Average of > 100 single IPSPs is shown in *Ab*, but individual IPSPs showed a great deal of amplitude variability (*Ac*). Hyperpolarization of pyramidal cells resulted in depolarizing IPSPs with a reversal potential, indicating a chloride-mediated event (*Ae*). *B*, Some IPSPs were followed by a distinct

depolarizing membrane potential episode (*Bc*) that was sufficient to generate action potentials (*Be,f*). *C*, Axonal and dendritic fields of a single basket cell overlaid with a single target pyramidal neuron. Axon collaterals were limited to the perisomatic region. *D*, Expanded view of the pyramidal neuron somatic region showing 10 inhibitory synaptic connections. lations, for example, require sustained GABAergic input from a specific source, such as fast perisomatic inhibition originating from basket or axo-axonic cells. Indeed, simultaneous multielectrode recordings of pyramidal cells and interneurons during rhythmic electroencephalographic (EEG) activity in the intact, behaving animal show that at least some interneurons fire considerably and consistently faster than neighboring pyramidal neurons, whereas others (e.g., the so-called anti-theta cells) may actually decrease their firing rate (Freund and Buzsaki, 1996).

Currently, our appreciation of the amazing morphological, neurochemical, and physiological complexity of GABAergic interneurons at the reductionist level contrasts with our relative lack of understanding of their functional role in the hippocampal network as a whole. There is a modest amount of

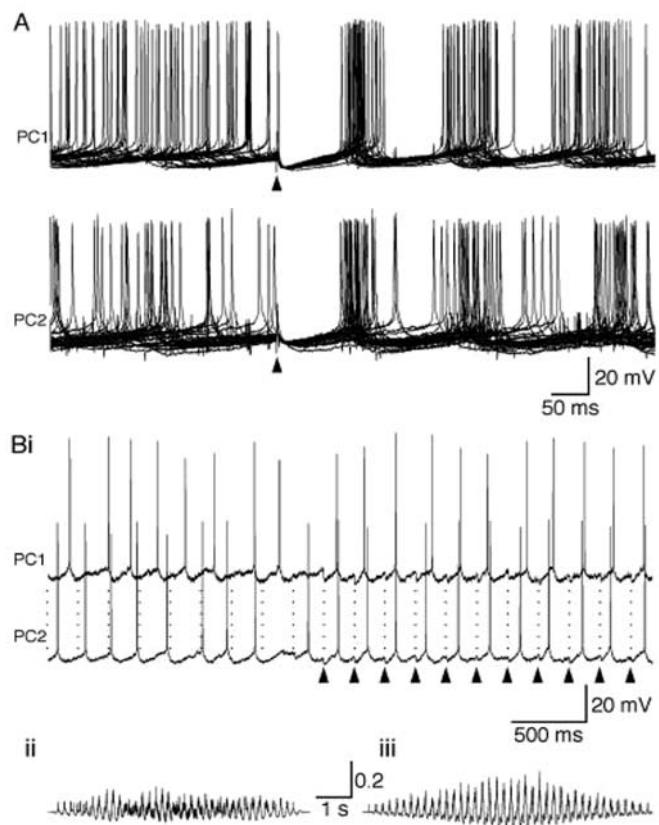

data illustrating the behavior of identified interneurons in the intact, behaving animal, showing, for example, phase-locked discharge of basket cells and O-LM cells during theta EEG activity (Buzsaki et al., 1983; Skaggs et al., 1996; Klausberger et al., 2003). A number of studies have attempted to address the functional role of interneurons at the cellular level. Paired interneuron-to-pyramidal cell recordings have revealed that all unitary inhibitory interactions have relatively fast kinetics and are (as yet without exception) mediated by GABA<sub>A</sub> receptors (Miles and Wong, 1983; Lacaille et al., 1987; Buhl et al., 1994a; 1995; Ouadou and Lacaille, 1997; Vida et al., 1998; Thomson et al., 2000). In addition, the activation of GABA<sub>B</sub> receptors may either require high-frequency tetanic stimulation of a unitary inhibitory connection or, alternatively, the concomitant activation of multiple GABAergic inputs (Mody

et al., 1994; Thomson and Destexhe, 1999). Although this may suggest overall uniformity in function, it is also clear that unitary hippocampal interactions differ with respect to the molecular composition and associated pharmacological properties of differentially distributed and domain-specific GABA<sub>A</sub> receptor subunits (Thomson et al., 2000). IPSPs evoked by fast-spiking basket cells are more potentiated by the  $\alpha 1$  subunit-selective benzodiazepine zolpidem than are IPSPs elicited by regular-spiking basket cells. It has been proposed that fast-spiking basket cells are parvalbumin-positive and associated with postsynaptic receptors carrying an  $\alpha 1$  subunit. Conversely, regular spiking basket cells may be the electrophysiological signature of CCK-positive basket cells and target perisomatic synapses with a predominance of GABA<sub>A</sub> receptors containing  $\alpha 2$  subunits (Thomson et al., 2000). In addition, bistratified cells may be associated with dendritically located  $\alpha 5$  subunits, and indeed bistratified cell-mediated unitary IPSPs are diazepam-sensitive but not zolpidem-sensitive (Thomson et al., 2000). Recent data from transgenic animals indicate that the molecular heterogeneity of GABA<sub>A</sub> receptors is indeed reflected in different functional roles, such as anxiety (Low et al., 2000). Moreover, work in intact animals suggests that neuroactive steroids may act as endogenous modulators to regulate the function of GABA<sub>A</sub> receptors with different subunit compositions differentially (Smith et al., 1998).

Apart from differences in their molecular pharmacology, the function of GABA<sub>A</sub> receptors may differ with their subcellular location. Because of the shunt and/or membrane polarization resulting from the opening of GABA<sub>A</sub> receptor channels, other domain-specific conductance may also be affected. Thus, unitary interactions mediated by dendrite-targeting interneurons, such as bistratified and O-LM cells, have slower kinetics and smaller amplitudes/conductance levels when measured at the level of the cell body. Some of this effect has been attributed to dendritic filtering (Buhl et al., 1994a,b; Miles and Freund, 1996; Maccaferri et al., 2000). Although there are, as yet, no compelling hippocampal data to demonstrate differences in the local versus somatic integration of compartmentalized excitatory and inhibitory inputs, there is at least evidence suggesting that domain-specific GABAergic inputs interact with local conductance. In the hippocampal CA3 area, microstimulation experiments have revealed that inhibitory inputs onto the dendrites of pyramidal neurons are effective in suppressing calcium-dependent spikes, and perisomatic inhibitory cells inhibit the repetitive discharge of sodium-dependent action potentials (Miles et al., 1996). However, the local interaction of unitary IPSPs and voltage-gated conductance can be even more complex. Basket and axo-axonic cells (i.e., interneurons with a perisomatic innervation pattern) have been shown to interact with intrinsic subthreshold membrane oscillations (Cobb et al., 1996). By resetting their phase, repetitive IPSPs originating from a single presynaptic interneuron are effective in phase-locking subthreshold oscillations, with the entrainment of oscillatory activity being most effective in the theta frequency band.

Moreover, as pyramidal neurons have a propensity to fire during the most depolarized part of the oscillatory waveform (Buhl et al., 1995), rhythmic unitary IPSPs are therefore also strikingly effective in pacing the discharge of postsynaptic pyramidal neurons—without, however, necessarily affecting the neuronal firing rate (Cobb et al., 1997). These authors demonstrated that the output from an individual interneuron not only may pace spontaneous action potential generation in multiple pyramidal cells but also synchronize these paced outputs, as shown in Figure 8–8. In view of the widespread divergence of basket and axo-axonic cell axons, it is reasonable to assume that the temporally coherent discharge of relatively few interneurons with a perisomatic termination pattern is sufficient to synchronize hippocampal population activity. Although they do not prove a causal relation, *in vivo* studies

**Figure 8–8.** Single IPSPs can synchronize ongoing pyramidal cell outputs. A. Overlaid responses from two concurrently recorded principal cells (PC1, PC2) receiving a single IPSP at the time illustrated by the arrow. Rebound from the IPSP generates action potentials in a time-dependent manner such that both pyramidal cells discharge within a small time window. B. Entrainment of theta-frequency pyramidal cell output by successive IPSPs from a single interneuron (Bi). Two pyramidal cells (PC1, PC2) were concurrently recorded and action potentials elicited in a single interneuron at times indicated by the arrows. Cross correlations between the two pyramidal cells are shown before interneuron firing (Bii) and during (right-hand side) single, repetitive interneuron firing (Biii). (Source: From Cobb et al., 1995, with permission.)

are clearly consistent with this notion, as they demonstrate a close temporal correlation of interneuron and principal cell activity during theta and gamma EEG activity (Bragin et al., 1995; Ylinen et al., 1995).

### 8.3.4 Pyramid–Pyramid Local Connections

In contrast to the dentate gyrus, principal neurons in the CA1 and CA3 subfields are interconnected with recurrent excitatory axon collaterals, thus increasing the computational complexity of local information processing. Pyramidal cells in the CA3 area are not only the source of major efferent fiber tracts, such as the Schaffer collateral pathway, they also give rise to several local axon collaterals, which emanate from the main axon in the stratum oriens. Axonal side branches branch further, with most of them remaining in the stratum oriens and the remainder penetrating the pyramidal cell layer and arborizing in the stratum radiatum (Gulyas et al., 1993a,b; Sik et al., 1993; Li et al., 1994). The terminal arbors in the CA3 area are generally large, frequently occupying several millimeters in the transverse and septo-temporal axis, indicating a large degree of divergence. Bouton counts of individual axons suggest that the number of hippocampal synaptic terminals is in the range of 10,000 to 60,000, with a sizable proportion remaining in the CA3 area. Quantitative studies suggest that CA3 pyramidal cells contact at least some of their postsynaptic targets randomly (i.e., in proportion to their occurrence in the neuropil) (Sik et al., 1993). Although there are no anatomical studies to provide reliable estimates with respect to pyramidal-to-pyramidal cell convergence, divergence, and number of synaptic release sites, physiological data provide evidence that CA3 pyramidal cells may be synaptically interconnected (Miles and Wong, 1986; Miles et al., 1996), with the connection probability of neighboring neurons being in the range of 2% (Miles and Wong, 1986). In general, unitary pyramidal-to-pyramidal cell EPSPs have small amplitudes, ranging between 1 and 2 mV, which fluctuate in amplitude and show apparent postsynaptic response failures, suggesting that they may be mediated by a small number of release sites (Miles and Wong, 1986). Thus, only a small proportion of unitary EPSPs (4%) are of sufficient strength to trigger action potentials in a postsynaptic neuron. Interestingly, however, when presynaptic pyramidal cells fire a salvo of several action potentials so as to mimic their physiological burst firing pattern, postsynaptic responses show a substantial degree of augmentation, and the incidence of burst-to-spike transduction can be as high as 35% (Miles and Wong, 1986). Indeed, experiments in disinhibited slices show that a single CA3 pyramidal neuron can trigger synchronous population discharges (Miles and Wong, 1983). Thus, despite the connection probability being relatively low, there is a sufficient degree of divergence and convergence to allow rapid, reliable synchronization of network activity.

As in area CA3, pyramidal neurons in the CA1 area emit local axon collaterals. The latter, however, establish smaller local axonal arbors and remain confined to the strata oriens and alveus, where they establish synaptic contacts with neigh-

boring pyramidal cells and interneurons (Buhl et al., 1994a,b; Deuchars and Thomson, 1996; Ali and Thomson, 1998; Ali et al., 1998). The degree of pyramidal cell interconnectivity is approximately 1% and thus markedly lower than in the CA3 area (Deuchars and Thomson, 1996), which may also explain why the isolated CA1 area is less prone to develop seizure-like activity in the presence of GABA<sub>A</sub> receptor antagonists. Unitary responses tend to be relatively small (0.17–1.5 mV) and show paired-pulse depression, suggesting that a small number of synaptic release sites with a high release probability underlies the modest unitary responses. Indeed, correlated light and electron microscopic analysis of a single pyramidal-to-pyramidal cell pair showed that a unitary EPSP with a mean amplitude of 1.5 mV was mediated by a total of two synaptic release sites (Deuchars and Thomson, 1986). Both synaptic contacts were established on two third-order basal dendrites, suggesting that despite some degree of dendritic filtering even relatively distal excitatory quantal inputs can evoke measurable somatic responses.

### 8.3.5 Interneuron–Interneuron Connections

Reciprocally connected GABAergic interneurons comprise one of the key substrates for the generation of gamma frequency network oscillations. This finding has underscored the pivotal role of GABAergic neurons for the generation of EEG rhythms (Whittington et al., 1995). In principle, GABAergic inputs on hippocampal GABAergic neurons can be subdivided into three major categories.

- Extrinsic sources, particularly the septo-hippocampal GABAergic projection
- Output of interneurons, such as basket cells, which innervate principal cells and other interneurons in approximately random proportions
- Several subpopulations of interneurons that appear to have special, exclusive innervation of other interneurons

Regarding the septo-hippocampal GABAergic input, combined immunocytochemical and tracing studies have shown that, in contrast to the cholinergic input, this projection is highly selective in terms of targeting GABAergic interneurons, albeit with no apparent preference for particular subtypes (see Section 8.1.2) (Freund and Antal, 1988; Miettinen and Freund, 1992). The earlier *in vivo* observation that stimulation of the medial septum facilitates granule cell activity (Bilkey and Goddard, 1985) can be most parsimoniously explained by the inhibition of inhibitory interneurons (i.e., a disinhibitory mechanism). More direct evidence in support of this notion was obtained with a series of elegant *in vitro* experiments using a combined septo-hippocampal slice preparation (Toth et al., 1997), demonstrating a disinhibitory effect of septal stimulation on CA3 pyramidal cell activity. Thus, theta frequency activity in the medial septum diagonal band complex is likely to entrain hippocampal population activity by rhythmically releasing pyramidal neurons from a background of tonic inhibitory activity, thereby allowing them to fire while inhibition is maximally suppressed.

In contrast to the septal GABAergic projection, many interneurons in areas CA3 and CA1 target specific subcellular domains, but they appear to have no apparent specificity for innervating either principal cells or interneurons, contacting them in what has been referred to as a “quasi-random” fashion (i.e., based on the statistical distribution of postsynaptic elements in the neuropil) (Freund and Buzsaki, 1996). In the case of parvalbumin-positive basket cells, it has been estimated that they contact not only approximately 1500 pyramidal cells (see above) but also a proportionally smaller number (in the range of 60) parvalbumin-positive neurons (Sik et al., 1995). These anatomical data are corroborated by paired recordings of synaptically coupled and anatomically identified interneurons, revealing their divergent output to both excitatory and inhibitory neurons (Cobb et al., 1997; Ali et al., 1999). In addition, these studies not only demonstrate directly that basket cells are interconnected, they established the existence of synaptic coupling across interneuronal classes, such as between basket cells and trilaminar interneurons. Thus, the efferent output of basket cells not only directly (i.e., monosynaptically) affect inhibitory and excitatory hippocampal neurons, the output is likely to occur almost synchronously in all target neurons, an assumption with important implications for their putative role in hippocampal rhythmogenesis. Experimental findings and computational simulations provide compelling evidence for a synchronizing role of perisomatic fast IPSPs during gamma frequency network oscillations (Whittington et al., 1995; Wang and Buzsaki, 1996; Traub et al., 1997; Fisahn et al., 1998). It follows that the discharge of interneurons such as basket cells, with a widely divergent output, is phase-locked with the population rhythm, as they are the source of the phasic IPSPs (Andersen and Eccles, 1962). Indeed, in the awake rat the firing of putative interneurons is phase-locked to the underlying gamma rhythm (Bragin et al., 1995), and the discharge of identified basket cells was found to be temporally correlated with both gamma and theta activity (Ylinen et al., 1995). Despite the importance of GABAergic mechanisms for the generation of synchronous network behavior, it should be stressed that other synaptic as well as nonsynaptic factors, such as fast excitation and electrical coupling (see below), appear to have different but equally important roles in hippocampal rhythmogenesis (Traub et al., 1996, 2000; Fisahn et al., 1998; for a comprehensive review see Traub et al., 1999).

Unlike basket cells, a second major group of GABAergic interneurons, comprising at least three neurochemically distinct subclasses, exclusively innervate other GABAergic interneurons (for detailed review, see Freund and Buzsaki, 1996). These cells demonstrate that, in addition to subcellular domain specificity, interneurons may exhibit a high degree of target cell selectivity. The three subtypes are (1) a class of calretinin-positive neuron that innervates calbindin-positive dendrite-targeting cells, CCK/VIP-positive basket cells, and other calretinin-positive cells (Gulyas et al., 1996); (2) an interneuron-selective GABAergic cell that contains VIP and contacts calbindin-positive cells; and (3) a group of VIP-positive interneurons that show a preference for the somato-

statin/mGluR-positive class of O-LM cells (Acsady et al., 1996a,b). It thus appears that distinct subsets of GABAergic interneurons selectively modulate the activity of several other types of interneuron, such as O-LM cells, which in turn have an efferent projection to the termination zone of entorhinal afferents in the stratum lacunosum-moleculare. Although a number of suggestions have been made as to their functional relevance there are, as yet, no experimental or modeling data to attribute specific functional roles to interneuron-selective interneurons during hippocampal information processing.

### 8.3.6 Gap Junction Connections

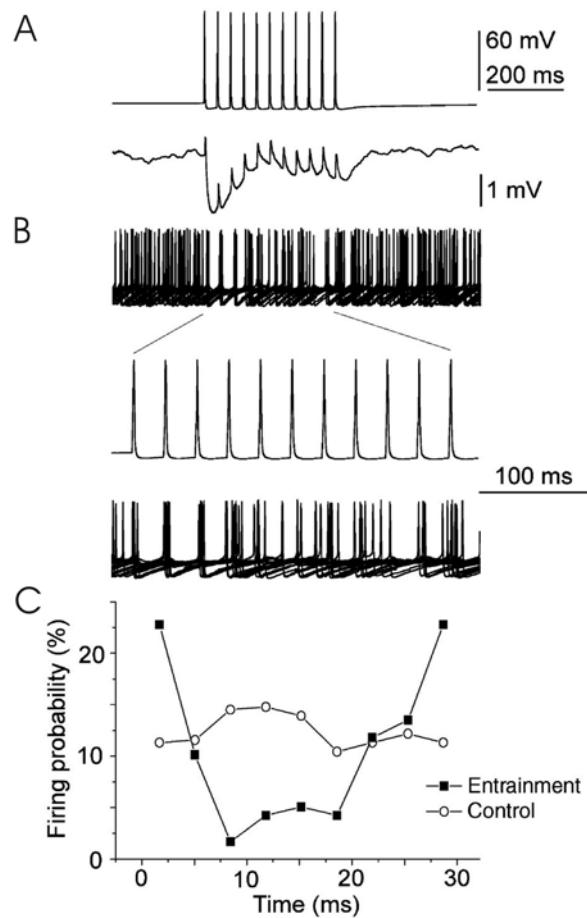

As already mentioned, during oscillatory network activity at gamma frequency, fast perisomatic IPSPs have a major role in pacing and synchronizing population activity. In view of their kinetics, however, experimental and computational data suggest that the upper limit of fast inhibition-based rhythms may not exceed ~80 Hz. Yet, in awake animals hippocampal sharp waves are accompanied by a high-frequency (~200 Hz) EEG oscillation with a high degree of spatiotemporal coherence (Buzsaki et al., 1992; Ylinen et al., 1995). As this ultrafast rhythm, frequently referred to as “ripples,” is unlikely to be generated by phasic inhibition, it seems likely that a fundamentally different synchronizing mechanism is at work. Indeed, hippocampal slices maintain a fast ripple-like oscillatory activity pattern that remains after blockade of synaptic transmission but is abolished by a variety of gap junction uncoupling agents (Draguhn et al., 1998). Interestingly, gap junction blockers are also effective in abolishing pharmacologically induced gamma oscillations (Traub et al., 2000). It therefore appears that gap junction-mediated electrical coupling may have a strong role in the synchronization of gamma frequency oscillations as well as the generation of ultrafast neuronal population activity.

Gap junctions are the morphological correlate of electrical synapses, and anatomical studies have clearly demonstrated their presence in the adult mammalian hippocampus (Kosaka, 1983; Fukuda and Kosaka, 2000). Interestingly, however, these data have so far provided evidence for gap junctions only between the dendrites of GABAergic interneurons. There is compelling evidence for electrically coupled interneurons in the neocortex; and, intriguingly, these data also point to specific coupling between members of the same neuronal class (Galarreta and Hestrin, 1999; Gibson et al., 1999; Tamas et al., 2000). This may also apply for the hippocampus, where gap junctions have been identified between the dendrites of parvalbumin- and calretinin-positive interneurons (Gulyas et al., 1996; Fukuda and Kosaka, 2000), although these findings do not rule out the occurrence of heterologous connections.

Modeling studies have suggested that parameter heterogeneity in interneuronal circuits (e.g., differences in firing rates and/or kinetics of inhibitory conductance) destabilizes synchronous population activity (Wang and Buzsaki, 1996; White et al. 1998). However, when interneurons in such networks are interconnected with both chemical and electrical

synapses (i.e., GABAergic synapses and gap junctions), their conjoint action tends to improve population coherence (White et al., 1998). Indeed, data from connexin36-deficient mice (a recently cloned neuronal gap junction-forming protein) (Condorelli et al., 1998) not only showed that GABAergic interneurons are electrically “uncoupled,” they demonstrated that the presumed lack of gap junctions between interneurons results in impaired gamma frequency oscillatory network activity (Hormuzdi et al., 2001). With respect to the underlying mechanism, recordings of neocortical basket cell pairs showed an apparent synergistic effect of concurrent synaptic and nonsynaptic communication between interneurons (Fig. 8–9). With both mechanisms in place, action potential generation in one interneuron produced a biphasic membrane potential change in the coupled neuron: initial transient depolarization followed by IPSP-mediated hyperpolarization. Repeated action potential generation provided a powerful subthreshold membrane potential oscillation that influenced spike firing (Tamas et al., 2000).

Although this mechanism may account for establishing synchrony in the interneuronal network at gamma frequencies, it is unlikely to explain the generation of ultrafast ripple activity. Modeling studies suggest that when pyramidal cells are coupled by gap junctions in soma or dendrites the somatodendritic compartment, in conjunction with the gap junction, acts as a low-pass filter. The effect is to slow the kinetics of spikelets to such an extent that it is difficult, based on our current understanding of the biophysical properties of pyramidal neurons, to explain the emergence of ultrafast synchronous network activity (Draguhn et al., 1998; Traub and Bibbig, 2000). Moreover, despite numerous electron microscopic studies, there is, as yet, no ultrastructural evidence of gap junctions between the somatodendritic domain of hippocampal pyramidal neurons. However, putative axo-axonal gap junctions between pyramidal cells can allow spikes to produce either a spikelet in the postjunctional axon or, if above threshold, an action potential that may antidromically invade the parent cell body and/or rapidly propagate (provided there is a sufficient degree of interconnectivity) through the axonal plexus, thereby prompting the generation of coherent, ultrafast oscillatory activity as an emergent property of the axonal pyramidal network (Traub et al., 1999). These simulations indicate that as few as 2.5 to 3.0 gap junctions per axon may be sufficient, perhaps explaining why possible axo-axonal gap junctions have also gone unnoticed by anatomists. Indeed, intracellular labeling studies using time-lapse confocal microscopy have shown dye coupling between axons of hippocampal pyramidal neurons, thus providing experimental evidence for this notion (Schmitz et al., 2001). Moreover, electrophysiological studies have revealed the occurrence of spikelets in principal neurons following, for example, the antidromic activation of CA1 pyramidal cell axons (Kandel and Spencer, 1961; Taylor and Dudek, 1982; Schmitz et al., 2001). Ultimately, however, a more direct approach—such as paired recordings in conjunction with post hoc correlated

**Figure 8–9.** Synchrony via both gap junctional and IPSP-mediated interactions. *A*, Trains of presynaptic action potentials in one interneuron (top trace) generate a decrementing IPSP and spikelets in a connected interneuron (lower trace). *B*, Presynaptic action potential generation reduced the postsynaptic firing frequency and synchronized these action potentials with those from the presynaptic cell (bottom trace). *C*, Temporal correlation of postsynaptic firing probability in the postsynaptic cell during one action potential cycle in the presynaptic cell. Control condition is with no drive to either cell pair. Entrainment condition is as illustrated in *B*. (Source: Adapted from Tamas et al., 2000, with permission).

electron microscopy of the sites of interaction—is needed to resolve this intriguing issue.

#### 8.4 Summary

Local circuits in the hippocampus are comprised of excitatory connections from principal cells to interneurons and mainly inhibitory interneuronal connections onto principal cells. A smaller number of connections are made up of mutual inhibitory interneuronal interconnectivity and recurrent excitatory connectivity between principal cells. The pattern of local connectivity is diverse and represents a rich tapestry of prospective strategies for modifying initial responses to inputs

and post hoc responses to continued input activity on the basis of previously generated outputs.

The diverse profile of anatomical, pharmacological, and electrophysiological properties of local circuit connections can, to some extent, be reduced to a few basic properties. First, afferent activity invariably co-activates not only local principal cells but also local inhibitory interneurons. This organizing principle offers a mechanism by which any initial input can organize the response to any subsequent input, with the specific temporal profile being a consequence of the kinetics of interneuronal synaptic postsynaptic responses and their compartmental localization onto principal cells. Second, efferent activity also co-activates local inhibitory interneurons. There is some (but by no means complete) overlap between interneurons receiving feedforward and feedback signals. This organizing principle allows local circuits to modify responses to afferent activity further on the basis of whether an output is generated. Third, interconnectivity within either principal cell populations or local interneuron populations provides a mechanism by which spatially discrete patterns of input (and subsequent output) may influence populations of neurons outside the active area.

Taken together these three principles provide a form of architecture that seems unsuited to the classic notion of point-to-point neuronal communication. Instead, time appears to play a more critical role in governing neuronal output than space: Activation of feedforward circuits favors responses to inputs after a period of quiescence (governed by the duration of influence of feedforward inhibitory postsynaptic potentials). Activation of feedback circuits provides a further temporal constraint on subsequent outputs, effectively providing a short-term "history" of a local circuit's output. Convergence, divergence, and recurrent connectivity effectively spread these temporal influences spatially within the target neuronal population. If one considers the property of "bias" in principal neuronal responses to input (i.e., differences in afferent excitatory synaptic weights and/or tonic membrane potential heterogeneity), local circuit architecture can be seen to serve as an ideal mechanism by which to "read out" this bias as a specific pattern of outputs.

Local circuits of the type described in this chapter therefore provide a substrate for converting blanket (relatively unstructured) inputs into specific spatiotemporal profiles of output on the basis of the history of each principal neuron in the target population. Thus, a deeper insight into the role of the hippocampus as a region involved in aspects of learning and memory can be obtained by taking into account the organization of local patterns of neuronal interconnectivity.

## ACKNOWLEDGMENTS

This work was conceived, and the first draft entirely written, by the late E.H. Buhl. Professor Buhl died during the revision of this chapter, and we dedicate it to his memory.

# Structural Plasticity

## 9.1 Overview

The hippocampal formation has been described as a relatively late-developing brain region. Rather than having a fixed, immutable structure, as might be implied by the earlier anatomical and physiological chapters, it is in fact known to undergo several structural changes throughout life that are traditionally described as “developmental”. Numerous reports have demonstrated that the hippocampal formation is capable not only of substantial reorganization when damaged but also dramatic structural change when intact. It appears to undergo dynamic modifications continually in the form of dendritic extension and retraction as well as synapse formation and elimination.

Perhaps the most basic of all structural changes is the addition of new neurons, a phenomenon known as neurogenesis. Although this process was once believed to be restricted to the embryonic or early postnatal period, neurogenesis is now recognized to be a substantial process in some regions of the adult brain. In fact, the dentate gyrus of the rat adds thousands of new neurons every day throughout adulthood (Cameron and McKay, 2001), raising intriguing questions about the regulation and functional significance of this phenomenon.

The incorporation of new neurons into preexisting circuitry results in a cascade of structural changes that further increase the structural plasticity of this region. For example, new neurons elaborate axons and dendrites (Hastings and Gould, 1999; Markakis and Gage, 1999; Cameron and McKay, 2001) and undergo synaptogenesis (Kaplan and Hinds, 1977; Markakis and Gage, 1999). These progressive events are typically followed by a series of regressive phenomena, such as cell death (Gould et al., 1999a, 2001; Dayer et al., 2003), which likely involves process retraction and synapse elimination. Coincident with the growing acceptance of adult neurogenesis as a significant phenomenon in the mammalian brain,

numerous studies have identified factors and conditions that regulate its occurrence. This information has suggested possible functions for adult-generated neurons.

This chapter begins by discussing the types of structural plasticity in the hippocampal formation and then concentrates on the evidence revealing that new neurons are formed in the dentate gyrus throughout life. It then reviews the literature related to the modulation of neurogenesis in the dentate gyrus by hormones and by experience and finally focuses on the role these new cells may play in hippocampal function. The possibility that new cells participate in certain types of learning and in the modulation of anxiety and stress responses is explored. Some recent evidence suggesting unusual properties of immature neurons is considered in light of the hypothesis that a continual influx of these unique cells to hippocampal circuitry has important functional consequences.

## 9.2 Dendritic and Synaptic Plasticity in the Hippocampal Formation

### 9.2.1 Naturally Occurring Structural Plasticity

For more than a century, neuroanatomists have speculated about the capacity of the adult brain to change its structure (see Stanisch and Nitsch, 2002 for review). Evidence accumulated over the past several decades has identified the hippocampus as a region with a large degree of structural plasticity. These studies together indicate that the fine, and sometimes even the gross, structure of the hippocampal formation is constantly changing under normal conditions. Far from being a structurally static region, the hippocampal formation is a dynamic area whose synapses and dendrites are undergoing continuous rearrangement.

## 9.2.2 Hormones and Dendritic Architecture

### Ovarian Steroids

A continual fluctuation in the numbers of dendritic spines on the pyramidal cells of the CA1 region has been reported in adult female rats and monkeys. This fluctuation occurs over a period of hours to days and is controlled by the levels of circulating ovarian steroids (Woolley et al., 1990b, 1997; Shors et al., 2001a; Hao et al., 2003; Cooke and Woolley, 2005). When ovarian steroids are at a high level, the number of dendritic spines is high. When the hormones are low, the number of spines is low. These changes in the number of dendritic spines are paralleled by changes in the number of excitatory synapses in this region (Woolley and McEwen, 1992; Woolley et al., 1996). The extent to which these structural changes reflect functional changes remains a matter of debate (Woolley, 1998). For example, conflicting literature exists on the influence of estrogen on behaviors associated with the hippocampus. Some reports indicate that estrogen improves performance on hippocampus-dependent tasks (Daniel et al., 1997; Gibbs, 1999; Daniel and Dohanich, 2001; Li et al., 2004; Sandstrom and Williams, 2004); and in some of these studies, the time course of behavioral improvement corresponds to changes in dendritic spines. Other reports have failed to demonstrate improvements in hippocampus-dependent tasks with estrogen treatment or across the estrous cycle (Berry et al., 1997; Warren and Juraska, 1997; Chesler and Juraska, 2000). Thus, the relation between behavior and dendritic spine number in the hippocampus remains unclear.

It is worth noting, however, that continuous estrous cycles, a common hormonal profile for female laboratory rodents, are probably uncommon in rodents living in the wild. A more likely endocrine profile would include postpubertal pregnancy followed by bouts of lactation, single estrous cycles just after weaning, and subsequent pregnancy. Thus, the relevance of estrogen-associated changes in dendritic spines on hippocampal function may lie in events such as pregnancy and the postpartum period (see Woolley, 1998, 1999 for commentary).

### Adrenal Steroids

High levels of circulating glucocorticoids have been associated with atrophy of dendrites in the CA3 region. Chronic treatment with corticosterone, the main glucocorticoid in rodents, decreases the complexity and size of the apical dendritic tree of CA3 pyramidal neurons (Woolley et al., 1990a). Although it is possible that these changes are an impending sign of cell death, which has been reported with chronic elevated glucocorticoids (Sapolsky et al., 1985), it has been suggested that retraction of dendrites may play an adaptive role in protecting the hippocampus from excessive glutamate (Luine et al., 1994).

## 9.2.3 Experience and Dendritic Architecture

### Stress

Dendritic architecture in the hippocampus is also influenced by experience. Chronic stress has generally been shown to have negative effects on the structure of dendrites in the hippocampus. As observed with chronic glucocorticoid treatment, the dendritic tree of the CA3 pyramidal neurons in adult male rats and tree shrews decreases in size following repeated restraint stress (Watanabe et al., 1992; Magarinos et al., 1996; McEwen, 1999). These effects appear to be reversible in unstressed conditions. In addition, changes in the dendritic tree with stress and recovery parallel performance on tasks that require the hippocampus (Luine et al., 1994).

Acute stress has also been shown to alter the number of dendritic spines on CA1 pyramidal cells of adult rats, but this effect seems to be dependent on the sex of the animal and, in the case of females, the stage of estrous. Brief, intermittent tail shocks have been shown to increase the number of dendritic spines on pyramidal cells of males (Shors et al., 2001a). By contrast, female rats showed the opposite effect—a decrease in the number of dendritic spines on pyramidal cells when shocked during diestrus but not when shocked during estrus (Shors et al., 2001a). Although it remains unclear what the functional significance of these effects is, it is worth noting that opposite effects of stress on learning have been reported in males and females (Wood et al., 2001). These behavioral effects appear to parallel the changes in dendritic spines suggesting a functional relation.

### Environmental Complexity and Learning

Beginning with the early work of Rosenzweig and Diamond (Rosenzweig et al., 1962; reviewed in Will et al., 2004), a large body of literature has amassed regarding the effects of living in an enriched laboratory environment on brain structure. These studies have demonstrated repeatedly that, compared to laboratory control animals, animals living in enriched environments during either development or adulthood have larger brains along multiple measures. Most of this work has focused on the neocortex, but the effects are generally similar in the hippocampus. Studies have demonstrated that living in enriched environments increases the size of the dendritic tree (Juraska et al., 1985; Faherty et al., 2003), the number of dendritic spines (Moser et al., 1994), and the number of synapses (Altschuler, 1979; Briones et al., 2005) in the hippocampus compared to controls. Other studies have shown that rearing in an enriched environment is associated with improved performance on hippocampus-dependent learning tasks (Juraska et al., 1984; van Praag et al., 2000; Teather et al., 2002).

Enriched laboratory environments typically included a multitude of stimuli that increase stress, physical activity, and learning. Numerous studies have sought to identify the specific experiential cues that mediate the brain changes; but to

date, questions remain. Several studies appear to have ruled out stress as a chief mediator of the effects of the enriched environment on the hippocampus either by demonstrating comparable stress hormone levels between groups or differential effects on brain structure following specific stressors. Some studies have suggested that physical activity is a contributing factor to the changes in hippocampal structure associated with living in an enriched environment. For instance, Eadie et al. (2005) reported an increased density of dendritic spine density on dentate granule cells in rodents that had access to a running wheel (but see Faherty et al., 2003). This finding is similar to that reported for animals living in enriched environments (Faherty et al., 2003). The extent to which changes in hippocampal structure induced by living in a complex environment are the result of one particular cue versus a constellation of cues remains unknown. The contribution of learning and synaptic plasticity to changes in hippocampal structure has also been investigated.

Several studies have reported structural changes in the hippocampus as a result of learning, or long-term potentiation (LTP), a form of synaptic plasticity often associated with learning. These effects of learning and LTP range from changes in the shape of dendritic spines (reviewed by Yuste and Bonhoeffer, 2001), increases in spine number (Moser et al., 1994; Trommald et al., 1996; O'Malley et al., 2000; Leuner et al., 2003), and changes in the number and distribution of synapses along dendrites (Chang et al., 1991; Rusakov et al., 1997; Andersen and Soleng, 1998; Toni et al., 1999). These findings mirror some of the changes associated with living in enriched environments. However, the extent to which these changes contribute to learning remains unknown.

#### 9.2.4 Structural Plasticity Following Damage

Perhaps not surprisingly, given the large degree of structural change that can occur in the intact hippocampal formation even in the adult animal, this region also has a remarkable capacity for regeneration after injury. During the early 1970s, Raisman and Field (1973) reported evidence for extensive, predictable reorganization of synaptic connections in the septal nuclei following transection of the fimbria. This seminal study set the stage for work designed to explore related structures, and shortly thereafter similar results were observed for the deafferented hippocampus. Since then, the phenomenon of axonal sprouting has been examined extensively following transection of perforant path axons. After this manipulation, nondamaged axons sprout and occupy the now devoid target spaces in a layer-specific manner (Lynch et al., 1976; Scheff et al., 1977; Deller and Frotscher, 1997; Frotscher et al., 1997). This remarkable phenomenon has had a large impact on neuroscience as it provided definitive evidence that regeneration in the adult brain was possible—a phenomenon suggested by the work of Ramon y Cajal and other early neuroanatomists (Stahnisch and Nitsch, 2002). The therapeutic implications of this work are clear: If the mechanisms underlying sprouting

could be discovered, it might be possible to harness them in the service of brain repair. The phenomenon is not specific to just one set of axons in the hippocampus: Uninjured axons that sprout when hippocampal afferents are severed include commissural and crossed entorhinal afferents (Deller and Frotscher, 1997), cholinergic septo-hippocampal fibers (Forster et al., 1997), serotonergic axons (Zhou et al., 1995), and noradrenergic fibers (Peterson, 1994). Other axons however, including perforant path fibers, do not appear to sprout.

In some studies, structural regeneration has been associated with functional recovery. Time-dependent changes in open field activity after unilateral entorhinal lesions are correlated with the growth of the crossed pathway from the contralateral entorhinal region (Steward et al., 1977). Whereas animals with unilateral entorhinal lesions are sometimes unable to perform hippocampus-dependent tasks shortly after the damage has occurred, recovery of function has been noted following regeneration of sprouted axons (Leonard et al., 1995). This is particularly intriguing given the fact that it is often a different population of cells whose axons repopulate the absent target sites after the lesion. However, it is not absolutely clear that axonal regeneration is the cause of functional recovery, even if it takes place over the same time period. For example, studies by Ramirez and Stein (1984) indicated that sectioning the dorsal psalterium (through which the growing entorhinal fibers of the crossed pathway ordinarily travel) does not alter the time course of functional recovery seen after unilateral entorhinal lesions. Other mechanisms have been associated with functional recovery after axotomy, including hyperactivity of the remaining axons (Gage et al., 1983a) and the supersensitivity of postsynaptic neurotransmitter receptors (Patel et al., 1996). In some cases, these additional mechanisms appear to subside once axonal ingrowth is complete (Gage et al., 1983b).

Other examples of structural plasticity in the hippocampal formation have been observed in studies using animal models of disease states such as epilepsy and stroke. In these cases, many cells in the hippocampal formation die. With time following seizure or stroke, there is considerable structural reorganization in the form of axon sprouting, which could be viewed as regenerative (Sloviter, 1999). Studies examining human brains of epileptic individuals and those with Alzheimer's disease have detected evidence of structural reorganization (Cotman et al., 1990; Nadler, 2003). The extent to which these compensatory structural changes slow functional deterioration remains unknown. In addition, it is possible that experience can enhance or potentially exacerbate damage-induced reorganization (Icanco and Greenough, 2000).

The brain is protected from mechanical injury by the skull and from chemical injury by the blood-brain barrier. Thus, it is not obvious that the regenerative capacity inherent to the hippocampus evolved to correct brain damage, particularly that which occurs in old age. However, axonal sprouting and synaptogenesis may be developmental phenomena that are reinstated in the presence of certain environmental cues (e.g.,

the formation of a large number of target sites following cell death). Alternatively, or in addition, axonal sprouting and synaptogenesis may be occurring under normal circumstances at a low level, and the magnitude of their occurrence increases with damage-associated cues. Given the large amount of evidence suggesting that the hippocampus is structurally plastic under normal conditions, the latter possibility seems especially likely.

### 9.2.5 Transplantation

The remarkable plasticity of the hippocampus has also been demonstrated through experiments designed to induce regrowth of the damaged hippocampus via transplantation. Studies have shown that the hippocampus of adult rats incorporates fetal tissue from various brain regions (Bjorklund and Stenevi, 1984; Bjorklund and Gage, 1985). These studies have demonstrated much greater growth and survival of transplanted tissue when the host hippocampus has been damaged either directly or via axotomy or fimbria-fornix destruction (Low et al., 1982; Gage and Bjorklund, 1986). Grafting of subcortical noradrenergic or cholinergic fetal tissue into the denervated adult hippocampus results in ingrowth of the transplanted tissue into the unoccupied target areas (Nilsson et al., 1988), restoration of neurotransmitter levels (Bjorklund et al., 1990; Kalen et al., 1991), emergence of relatively normal electrophysiological responses (Buzsaki et al., 1987), and at least partial recovery of function (Low et al., 1982). However, there appears to be an advantage of homotypic tissue in terms of restoring a denervated area; cholinergic fetal transplants are more likely to restore the structural, biochemical, and behavioral deficits associated with selective cholinergic lesions than nonspecific lesions affecting numerous afferent types (Leanza et al., 1998). These studies suggest possible approaches for treatment of human conditions associated with diminished hippocampal function. However, there are serious limitations to this approach. Apart from the concern of immune rejection (Lawrence et al., 1990), the grafted tissue is rarely incorporated completely, and its survival and continued efficacy are not guaranteed. These limitations, coupled with the recognition that certain parts of the brain support neurogenesis even during adulthood, have led to the development of transplant strategies using fetal stem cells.

Transplantation of expanded neural stem cells into the damaged hippocampus has revealed successful incorporation of new neurons into the CA fields. These studies have shown that new neurons can arise from progenitors, migrate to their appropriate locations where they form long distance axons, make appropriate connections, and exhibit normal electrophysiological responses (Englund et al., 2002). Studies suggest that the hippocampus, particularly the dentate gyrus, is conducive to the acceptance of neural stem cell transplants because the environment of this brain region supports neurogenesis under normal conditions (Fricker et al., 1999). The field of transplantation research has elucidated the capacity of the hippocampus to reorganize structurally when provided

with an exogenous source of afferents or progenitor cells. Future studies using information gleaned from investigations of naturally occurring adult neurogenesis may facilitate the successful replacement of damaged neurons and complete recovery of function. This approach, however, may be useful only under certain conditions where the primary neuropathological hallmark is cell death, such as occurs with stroke. Other conditions, such as Alzheimer's disease, which result in the accumulation of abnormal proteins and the formation of senile plaques and neurofibrillary tangles, may be less amenable to transplantation.

## 9.3 Adult Neurogenesis

The first evidence for adult neurogenesis in the intact mammalian brain was published more than 40 years ago by Joseph Altman and colleagues (Altman, 1962, 1963, 1969; Altman and Das, 1965a,b). Over the ensuing decades, the findings were corroborated (Kaplan and Hinds, 1977; Kaplan, 1981; Kaplan and Bell, 1984; but see Rakic 1985), but only during the last decade has the phenomenon received intensive scrutiny and investigation by the neuroscience community (Boxes 9–1 and 9–2). The dentate gyrus is one of two brain regions in which adult neurogenesis has been widely recognized (Box 9–2), and the basic steps in the process of forming new neurons in this area are well understood.

In the dentate gyrus, new cells originate from progenitor or precursor cells located in the dentate gyrus itself. These cells have the capacity to proliferate and are more restricted in their progeny than stem cells. The progenitor cells have some characteristics of astroglia (Seri et al., 2001) and are primarily concentrated in the subgranular zone, the region between the granule cell layer and the hilus. The subgranular zone is not a distinct layer but, rather, a sporadic collection of progenitor cell clusters lining the deep aspect of the granule cell layer. Cells in this region divide, presumably asymmetrically, to produce some daughter cells that retain the ability to divide and other cells that become either neurons or glia. The new cells migrate the short distance to the granule cell layer and differentiate into neurons (Fig. 9–1).

Adult neurogenesis has been observed in the hippocampus of virtually every mammalian species examined, including mice, voles, rats, cats, rabbits, guinea pigs, tree shrews, marmosets, macaques, and humans (Altman and Das, 1965a,b; Gould et al., 1997, 1998, 1999b; Kaplan and Hinds, 1977; Eriksson et al., 1998; Galea and McEwen, 1999; Kornack and Rakic, 1999). There is some debate about the relative significance of this phenomenon across vertebrate species, and the argument has been made that an inverse relation exists between the amount of adult neurogenesis and cognitive complexity (Rakic, 1985a,b). However, the robustness of adult neurogenesis in the brains of adult avians (Nottebohm, 2002), creatures with extensive cognitive capabilities, argues against this interpretation. Although it is difficult to assess the relative

**Box 9-1****Why Was Structural Change in the Adult Hippocampal Formation Not Detected Earlier?**

Given the magnitude of new neuron addition to the dentate gyrus, the fact that early neuroanatomists did not report evidence for structural change in this intensively studied brain region is puzzling. If ~9000 new cells are added to the dentate gyrus every day and a significant proportion of these cells extend axons, elaborate dendrites, and undergo synaptogenesis, evidence of massive structural change should have been noted. There are probably several reasons for this major oversight.

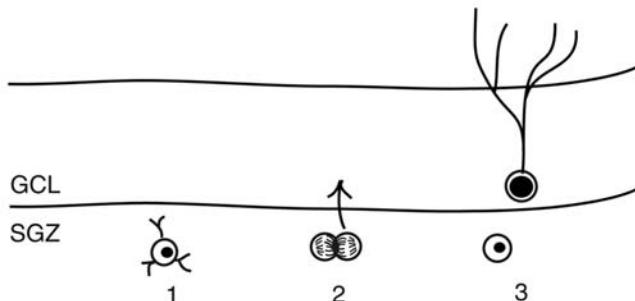

First, there is stability during the turnover. Neuron number in the dentate gyrus appears to be tightly regulated. In addition to massive cell production, neurite extension, and synaptogenesis, there is massive cell death, neurite retraction, and synapse elimination. Traditional histological methods would generally have failed to reveal these dynamic processes because they do not result in changes in the size or shape of the brain region or in the number of cells, dendritic elements, or synapses.

Second, because the prevailing view has been that structural change is a developmental, not adult, phenomenon, evidence for an adult change may have been interpreted otherwise. One possible example of this may be seen with descriptions of mossy fiber terminals in the CA3 region. Detailed neuroanatomical descriptions of the specialized synapses of mossy fibers on CA3 pyramidal cells, called “thorny excrescences,” have described numerous morphological types of these terminals. Previously, these various types of terminal were presented as evidence that mossy fiber synapses were unusually complex. Given our current understanding of neurogenesis in the region, it seems reasonable to consider the possibility that these various types of synapse reflect different maturational stages of connections formed by newly generated granule cells. Structural variability in the adult hippocampus may reflect the dynamic changes occurring.

**Box 9-2****Adult Neurogenesis in “Non-neurogenic” Brain Regions?**

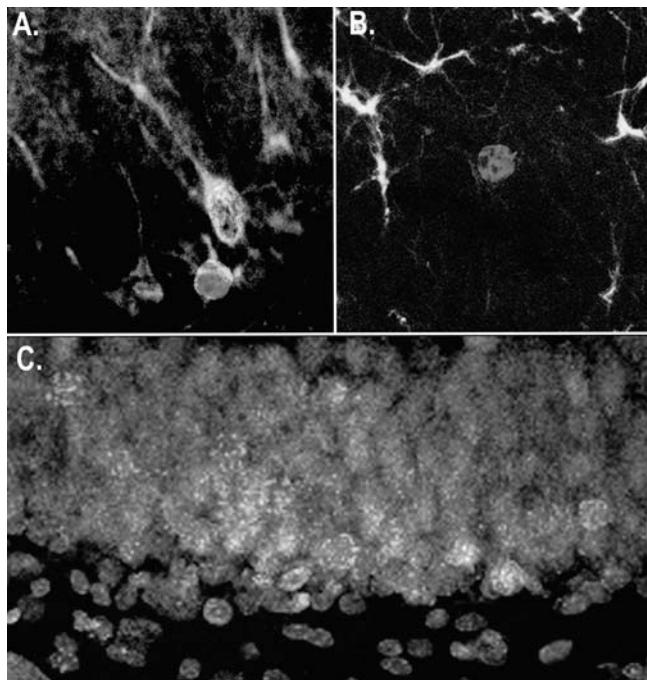

Around the time of the initial reports of adult neurogenesis in the dentate gyrus and olfactory bulb (Altman, 1962, 1969; Altman and Das, 1965a,b), Altman reported similar evidence for new neurons in the neocortex of adult rats and cats (Altman, 1962, 1963). This article was corroborated by a later study claiming new cells with ultrastructural characteristics of neurons in the neocortex of adult rats (Kaplan, 1981). This work was met with skepticism, as were the findings in the dentate gyrus and olfactory bulb (Rakic, 1985a,b; Kaplan, 2001). With the application of a different set of techniques (see Box 9-3), adult neurogenesis was rediscovered in the dentate gyrus and olfactory bulb during the 1990s and is now a relatively well established phenomenon. Both of these regions have been termed “neurogenic” in that they are widely believed to support adult neurogenesis. However, the case for the neocortex, as well as other brain regions, remains unresolved. Several studies have reported positive evidence in the form of BrdU-labeled cells with neuronal staining characteristics in the neocortex (Gould et al., 1999c, 2001; Bernier et al., 2002; Dayer et al., 2005), striatum (Bedard et al., 2002; Dayer et al., 2005), substantia nigra (Zhao et al., 2003), amygdala (Bernier et al., 2002; Fowler et al., 2005), and hypothalamus (Rankin et al., 2003; Fowler et al., 2005; Xu et al., 2005). Numerous other studies employing the same general methodologies reported no evidence for adult neurogenesis in these regions or evidence only for adult neurogenesis following damage (Magavi et al., 2000; Benraiss et al., 2001; Kornack and Rakic, 2001; Koketsu et al., 2003; Kodama et al., 2004; Yoshimi et al., 2005). The reasons for these discrepancies remain unclear, although they may be related to the fact that in the positive reports the relative number of new neurons reported in each of these regions is much lower than that reported in the olfactory bulb and dentate gyrus (see Gould et al., 2001 for a quantitative comparison of double-labeled cells between dentate gyrus and neocortex). If the phenomenon exists but at a much lower rate, it is possible that slight technical differences could make the difference between detecting and failing to detect a small number of new neurons. Alternatively, it is possible that the reports of adult neurogenesis outside the hippocampus and olfactory bulb are examples of false positives—new cells incorrectly identified as neurons or developmentally generated neurons incorrectly identified as new (Rakic, 2002). Future experimentation and the use of more definitive techniques should resolve these issues.

**Figure 9-1.** Adult neurogenesis in the dentate gyrus. 1. Precursor cells, expressing the characteristics of astrocytes, reside in the subgranular zone (SGZ). 2. Precursor cells divide asymmetrically at a rate that is modifiable by neural activity and experience. 3. Following division, one cell remains in the SGZ and retains the capacity to proliferate, and the other cell enters the granule cell layer (GCL) of the dentate gyrus. Most of the newly born cells that enter the granule cell layer acquire neuronal characteristics.

numbers of new neurons across species given that different methodologies are often utilized and there may be species differences in the efficacy of certain techniques, it seems clear that rodents exhibit a substantial amount of adult neurogenesis in the dentate gyrus.

In the rat dentate gyrus, the evidence that new cells differentiate into neurons is strong. New cells have been shown to receive synaptic input (Kaplan and Hinds, 1977; Markakis and

**Figure 9–2.** Most cells generated in the dentate gyrus of adults express neuronal characteristics. *A*. Photomicrograph of a BrdU-positive cell (red) in the adult rat dentate gyrus, expressing TUJ-1 (green), a marker of immature and mature neurons. *B*. Photomicrograph of a BrdU-positive cell (red) in the adult rat dentate gyrus, not expressing the astrocytic protein GFAP (green). *C*. Photomicrograph of a segment of dentate gyrus granule cell layer, triple-labeled with Hoechst, a DNA dye (blue), BrdU (red), and NeuN (green). Many but not all BrdU-positive cells express NeuN, a marker of mature neurons.

Gage, 1999), extend axons into the CA3 region (Stanfield and Trice, 1988; Hastings and Gould, 1999; Markakis and Gage, 1999), and express several biochemical markers of granule neurons, including NeuN, NSE, calbindin, MAP-2, and Tuj1 (Kuhn et al., 1996; Gould et al., 2001) (Fig. 9–2, see color insert; Box 9–3). Adult-generated cells in the mouse dentate gyrus have been shown to generate action potentials and exhibit other electrophysiological characteristics associated with granule cells (van Praag et al., 2002). Some newly generated cells in the dentate gyrus of adult rats may have the functional properties of inhibitory neurons (Liu et al., 2003). Although these findings suggest that two subpopulations of new neurons exist in this brain region (one with excitatory properties and the other with inhibitory properties), an alternative possibility is that new neurons temporarily exhibit characteristics of inhibitory neurons as part of a natural process of maturation.

### 9.3.1 Turnover of Dentate Gyrus Granule Cells

Several thousand new neurons are generated in the hippocampus every day in the young adult rat (Cameron and McKay, 2001) (Box 9–4). Although this number declines with age during adulthood, the phenomenon of adult neurogenesis appears to remain robust until animals become aged (Kuhn et al., 1996; Cameron and McKay, 1999). The addition of such a

large number of new neurons during adulthood raises the issue of whether the hippocampal formation continues to grow throughout life. It is now known that, alongside neurogenesis, there is substantial death of granule cells, especially of newborn neurons in adult rodents and primates under control conditions (Gould et al., 2001; Dayer et al., 2003). This cell death may offset the continual addition of new cells, resulting in a near-static total population of neurons (Box 9–1). The presence of pyknotic or degenerating cells in the dentate gyrus supports this view.

Several questions arise in connection with adult neurogenesis. First, do the new cells replace neurons that were born during development, or might they selectively replace those born during adulthood? Evidence suggests that both of these possibilities may be the case. Cells generated during the first postnatal week of life as well as those generated during adulthood decrease in number with time following mitosis (Dayer et al., 2003). However, most of the dying cells appear to be those that have been produced during adulthood. Pyknotic cells in the dentate gyrus are located primarily in the subgranular zone or deep in the granule cell layer, regions that contain progenitor cells and immature neurons. In addition, BrdU- and  $^3\text{H}$ -thymidine-labeling studies in adults suggest that the originally labeled population expands owing to mitosis and then drops off in number. Coincident with the decrease in labeled cell number is the appearance of BrdU-labeled pyknotic cells (Gould et al., 2001). However, in the intact brain, environmental factors have been shown to influence the survival of adult-generated granule cells. This raises the issue of whether information on the turnover of newly produced granule cells is confounded by the abnormal conditions under which laboratory control animals exist. Thus, the natural lifespan of adult-generated neurons in the dentate gyrus remains unknown.

### 9.3.2 Hormones and Adult Neurogenesis

A separate set of questions concerning neurogenesis has to do with its regulation. One potential regulatory mechanism is endocrine, as the hippocampal formation is known to be richly endowed with hormone receptors. Many cell types in the hippocampal formation contain hormone receptors and, as discussed above, this area responds to experimental hormone manipulations during adulthood with dramatic structural changes (McEwen, 1999). Several studies have shown that the production of new neurons in the dentate gyrus is sensitive to the levels of circulating steroid hormones. This regulation can be in a negative direction, with the net effect being a decrease in the number of immature granule neurons, or in a positive direction, with the net effect being an increase in the number of new neurons.

#### Negative Regulation: Glucocorticoids

Several studies have indicated that glucocorticoids inhibit the production of new neurons by decreasing the proliferation of granule cell precursors. During development and adulthood,

**Box 9–3****Methods for Visualizing New Neurons**

To show that a new neuron has been produced in the adult brain, cell division and differentiation of the progeny into neurons must be demonstrated. The traditional method for demonstrating mitosis in the brain is  $^3\text{H}$ -thymidine autoradiography. For *in vivo* studies, this technique requires injecting  $^3\text{H}$ -thymidine into live animals (usually intraperitoneally) and then examining the brains at various survival times after injection.  $^3\text{H}$ -thymidine is taken up by cells that are undergoing DNA synthesis in preparation for division.  $^3\text{H}$ -thymidine can be used as a marker of proliferating cells (at short survival times) and their daughter cells (at longer survival times).  $^3\text{H}$ -thymidine is a powerful method, but it has drawbacks, including lack of compatibility with stereological methods for cell counting and inability to determine with certainty whether new cells are co-labeled with cell type-specific markers.

A newer method, labeling with the thymidine analogue bromodeoxyuridine (BrdU), has been used more recently to investigate adult neurogenesis. BrdU is also incorporated into cells during S phase and can be used to label proliferating cells or their progeny. BrdU can be visualized using immunohistochemistry and has the advantage of being amenable to stereological estimates of the total number of new cells and the unequivocal demonstration that new cells are co-labeled with cell type-specific markers.

Evidence that new cells have differentiated into neurons can be achieved by combining  $^3\text{H}$ -thymidine or BrdU with the following.

1. Electron microscopy:  $^3\text{H}$ -thymidine autoradiography has been combined with electron microscopy to demonstrate synapses on cell bodies and dendrites of new cells in the dentate gyrus (Kaplan and Bell, 1984). BrdU labeling is less compatible with electron microscopic methods due to the harsh pretreatments necessary for staining.
2. Retrograde tracing:  $^3\text{H}$ -thymidine autoradiography and BrdU labeling have been combined with retrograde tracer injections to show that new cells in the dentate gyrus extend axons into the CA3 region (Stanfield and Trice, 1988; Hastings and Gould, 1999; Markakis and Gage, 1999). This method is particularly useful when combined with BrdU because confocal microscopy can be used to verify double labeling in orthogonal planes.
3. Immunohistochemistry for neuronal markers:  $^3\text{H}$ -thymidine autoradiography and BrdU labeling have been combined with immunolabeling for cell type-specific markers. These studies have shown that most cells made in the dentate gyrus of adult animals express neuronal markers (Kuhn et al., 1996; Cameron and McKay, 2001; Gould et al., 2001). This method is particularly useful when combined with BrdU because confocal microscopy can be used to assess double labeling throughout the extent of the cell.
4. Electrophysiology: There is evidence that new cells have the electrophysiological characteristics of neurons. This has been gained by identifying new cells with BrdU staining after electrophysiological characterization (Liu et al., 2003), by labeling new cells with GFP-tagged retrovirus (van Praag et al., 2002), and by recording from cells that are likely to be adult-generated on the basis of their location in the granule cell layer and staining for markers of immature neurons (Wang et al., 2000; Snyder et al., 2001). All of these approaches have revealed that new cells produced in the dentate gyrus during adulthood have the electrophysiological properties of neurons (see also Schmidt-Hieber et al., 2004 for the electrophysiological signature of newly born cells).

treating rat pups with corticosterone decreases the production of new granule cells (Gould et al., 1991; Cameron and Gould, 1994; Ambrogini et al., 2002). During adulthood, removal of circulating adrenal steroids by adrenalectomy increases the proliferation of granule cell precursors and ultimately the production of new neurons (Gould et al., 1992; Cameron and Gould, 1994). This phenomenon also occurs in aged animals in which granule cell production has diminished. Removal of adrenal steroids restores young adult levels of cell proliferation in the dentate gyrus of old rats (Cameron and McKay, 1999; Montaron et al., 2005).

The levels of circulating glucocorticoids change at various times of development and with experience, presenting the possibility that glucocorticoid inhibition of cell proliferation

may reflect naturally occurring processes relevant to hippocampal function. A good example may be observed in the dentate gyrus of the meadow vole. Meadow voles are seasonal breeders, and the breeding season is associated with higher levels of circulating glucocorticoids in females; cell proliferation is suppressed at this time (Galea and McEwen, 1999).

**Positive Regulation: Estrogen**

The ovarian steroid estradiol has a positive effect on the production of new cells in the dentate gyrus of adult rats (Tanapat et al., 1999, 2005; Banasr et al., 2001; Ormerod et al., 2003). Removal of estrogen by ovariectomy decreases the pro-

**Box 9–4****Methodological Issues Related to the BrdU Technique**

The introduction of BrdU labeling has significantly advanced our understanding of adult neurogenesis. However, it has become clear that our understanding of this technique was based on erroneous assumptions derived from earlier developmental studies and thus, the phenomenon of neurogenesis continues to be underestimated and, perhaps, misinterpreted. Cameron and McKay (2001) have shown that the modal dose of BrdU for studies of adult neurogenesis (50 mg/kg) labels fewer than 50% of the total cells in S phase. In contrast, when used during development, this dose appears to label all cells in S phase. Although BrdU is a small molecule, differences in metabolism or blood-brain barrier (BBB) permeability prevent the adult animal from incorporating it at the same rate as the developing animal. Higher doses of BrdU (up to 600 mg/kg) label more proliferating cells, do not label nonspecifically, and are not toxic to the cells or animals. Using higher doses of BrdU, it appears that approximately 9000 new cells are generated every day in the dentate gyrus of the young adult rat. Divisions of the progenitor cells are presumed to be asymmetrical. Thus, ~4500 new cells are produced daily; and approximately 80% of these cells (~3600) exhibit characteristics of immature neurons. Over the course of 1 month (30 days), the number of immature neurons generated would be ~108,000. Estimates of the number of granule cells in the adult rat range from 1.5 million to 2.0 million. Given these numbers, a conservative estimate of the percentage of immature neurons produced in a month of a young adult rat's life is about 5%.

These findings have two important implications. First, the number of new neurons produced during adulthood is substantially higher than was originally predicted. Second, studies using nonsaturating doses of BrdU to investigate the effects of experimental manipulations on neurogenesis may be detecting changes in BrdU availability (e.g., due to alterations in blood flow or changes in the BBB) in contrast to changes in the actual number of new cells (Gould and Gross, 2002).

liferation of new cells, and replacement of estradiol to ovariectomized animals restores the rate of cell proliferation. Moreover, a natural fluctuation in the proliferation of granule cell precursors is evident across the estrous cycle; cell proliferation is highest during proestrus, the time of maximal estrogen levels. The stimulation of cell proliferation by estrogen results in a sex difference that favors females in the production of immature neurons. However, estrogen-related increases in the production of new cells are transient: By a few weeks after BrdU injection, no difference in the number of new cells can be detected. As with estrogen-related differences in spine density, similar differences in new neuron production may be confounded by the manner in which laboratory animals are housed. Estrogen may further increase the production of new neurons by enhancing their survival (Ormerod et al., 2004).

**9.3.3. Experience and Adult Neurogenesis**

A second major regulatory factor governing neurogenesis is experience. Environmental experience takes many forms: sensory and motor experience, changing cognitive demands, and stress.

**Negative Regulation: Stress**

The catabolic actions of stress and stress hormones have long been recognized. A major component of the “fight or flight” reaction is the mobilization of energy stores to facilitate reaction to imminent danger (Selye, 1976). This response inhibits costly processes (e.g., growth) that are only important for the future. It should come as no surprise, then, that stress inhibits the production of new granule cells during development and in adulthood (Gould and Tanapat, 1999). This phenomenon has been demonstrated in three mammalian species using a range of stressors. Exposure of postnatal and adult rats to the odors of natural predators, electric shock, or restraint decreases the rate of cell proliferation in the dentate gyrus (Tanapat et al., 2001; Malberg and Duman, 2003; Pham et al., 2003; Westenbroek et al., 2004). Similar studies have been carried out in adult marmosets and adult and aged tree shrews and marmosets using stress paradigms of resident-intruder (Gould et al., 1998) and social subordination (Gould et al., 1997; Czeh et al., 2001; Simon et al., 2005). In all cases, stress has been shown to decrease the proliferation of granule cell precursors and ultimately the production of immature neurons in the dentate gyrus. This effect appears to be region-specific in that changes in the number of BrdU-labeled cells were not observed in the subventricular zone (another site of neurogenesis) following stress.

Interestingly, prenatal stress has a persistent impact on the later production of granule cells. In both rodents and monkeys, prenatal stress results in persistent dampening of the proliferation of granule cell precursors during adulthood (in rats: Lemaire et al., 2000) and the late juvenile period (in monkeys: Coe et al., 2003). Furthermore, the postnatal stress of maternal separation results in persistent suppression of cell proliferation and immature neuron production in adult rats (Mirescu et al., 2004). Adult rats subjected to maternal separation early in life not only exhibit impaired neurogenesis but they also exhibit no changes in adult neurogenesis when exposed to stress during adulthood. As indicated earlier, exposure to predator odor decreases adult neurogenesis in control animals (this effect is absent in maternally separated animals). Prenatal and early postnatal stress are associated with persistent changes in the hypothalamic-pituitary-adrenal (HPA) axis, including the development of an inefficient shut-down mechanism for glucocorticoids. These findings present the possibility that new cell production is persistently inhibited in animals exposed to early life stressors because these animals either experience higher than normal levels of glucocorticoids or are hypersensitive to normal levels of these hormones. Indeed, lowering glucocorticoid levels below control values by

adrenalectomy and low-dose corticosterone replacement has been shown to restore the levels of cell production in the dentate gyrus of maternally separated animals to control values (Mirescu et al., 2004). This is likely due to the fact that maternal separation results in lowered levels of corticosteroid-binding globulin, which modulates the amount of free corticosterone that enters the brain.

Collectively, these findings support the view that the production of immature neurons in the dentate gyrus varies depending on exposure to stressful experiences. In fact, the pool of immature neurons in the dentate gyrus may be an important substrate by which stress exerts long-lasting effects on hippocampal function. However, to understand the potential impact of stress on hippocampal structure and function, it may be necessary to examine these issues in animals living in more natural environments. Animals living in laboratory-controlled conditions appear to lose a larger proportion of adult-generated cells than those living in more complex environments (Kempermann et al., 1998; Nilsson et al., 1999; Tanapat et al., 2001). Thus far, the effects of chronic stress while living in naturalistic, relatively complex environments have not been explored.

#### **Positive Regulation: Environmental Complexity, Learning, and Physical Activity**

The first evidence that environmental complexity influences new hippocampal neurons in the adult was published by Barnea and Nottebohm (1994). This study showed that black-capped chickadees living in the wild maintained a higher number of new hippocampal neurons than those living in captivity. Work done on rodents also indicates a greater amount of cell proliferation and neurogenesis in the hippocampus of animals living in the wild compared to those living in the laboratory (Amrein et al., 2004a,b).

Adult neurogenesis as well as the entire volume of the hippocampal formation also changes over the seasons in some vertebrates. For example, the volume of the avian hippocampal formation fluctuates across the seasons in seed-caching birds such as the black-capped chickadee (Clayton, 1995, 1998; Smulders et al., 2000) and may be related to behaviors specific to these animals (see Chapter 13). Indeed, the lack of a change in the volume of this structure in birds that do not store food seasonally supports this view (Lee et al., 2001). This volumetric difference seems to be attributable to changes in the number of hippocampal neurons, with peak numbers occurring in the fall. Although sex differences in hippocampal volume have been reported in some species of food-storing mammals, such as gray squirrels, no seasonal changes have yet been observed (Lavenex et al., 2000). It may be that the phenomenon does not occur in mammals, or that naturally living species that occupy ecological niches with large changes in seasonal temperature and food availability need to be studied more closely.

Similar findings linking adult neurogenesis to experience were reported in the mouse and rat using an “enriched

environment” paradigm; juvenile, young adult, and old rodents living in enriched environments maintained more new granule cells than those living in standard, deprived laboratory cages (Kempermann et al., 1997, 1998, 2002; Nilsson et al., 1999; Brown et al., 2003). These studies may indicate that standard control animals, be they birds living in aviaries or rodents living in laboratory cages, are living in an extremely deprived state (Box 9–5). Given the elaborate social and cognitive abilities of primates, it is likely that monkeys living in standard laboratory cages are experiencing an even more deprived set of experiences than less complex vertebrates.

There are many variables that differ between living in the wild and living in captivity or, in captivity, between living in an enriched environment and living in a standard laboratory cage. Among them are stress, social interaction, physical activity, and learning. In addition to reporting that birds living in complex environments have more new hippocampal neurons, a seasonal difference in new neuron number correlates with a seasonal difference in seed caching and retrieval. Because these behaviors are likely to include spatial navigation, a function attributed to the hippocampal formation (see Chapter 13), a causative link between learning and new neurons has been proposed. It has been shown that the number of new hippocampal neurons in the avian hippocampus can be increased by engaging birds in learning tasks that involve this

#### **Box 9–5 Environmental Enrichment Versus Environmental Deprivation**

Numerous studies have investigated structural changes in the hippocampal formation associated with rearing or living in “enriched environments.” These studies have found several differences in the cortex, hippocampus, and other brain regions of animals living in the more complex environment compared to what is observed in animals living in standard laboratory cages (Rosenzweig et al., 1962; Icanco and Greenough, 2000; van Praag et al., 2000). In the case of rodents, the enriched environment typically consists of a larger living space, more conspecifics, toys, tunnels, exercise equipment, and often a more varied diet than the controls. Living in this type of environment enhances performance on certain hippocampus-dependent learning tasks and increases the hippocampal volume, number of dendrites of hippocampal neurons, number of glial cells, and number of new granule cells compared to controls. The most commonly applied interpretation of these findings is that hippocampal structure and function are responsive to environmental complexity. A converse interpretation is that they are deprivation effects; that is, the brain and behavior of control animals in the standard cages are abnormal because of the absence of normal stimulation. This puzzle could be solved by providing evidence for differences in animals living in super-complex versus complex environments.

brain region (Patel et al., 1997; Clayton, 1998). Studies have shown a similar phenomenon in rodents; learning tasks thought to depend on the integrity of the hippocampal formation enhance the number of new granule cells (Gould et al., 1999a; Ambrogini et al., 2000; Lemaire et al., 2000; Dobrossy et al., 2003; Leuner et al., 2004; Hairston et al., 2005; Olariu et al., 2005), whereas other types of learning may not have such an effect. For example, trace but not delay eyeblink conditioning increases the number of new granule cells in the dentate gyrus (Gould et al., 1999a; Leuner et al., 2004). This increase in the number of new neurons persists until at least 2 months after mitosis (Leuner et al., 2004) suggesting that the trophic effects of learning on new cells are not fleeting. Early training on tasks that require the hippocampal formation also enhances the number of new neurons, provided that learning has occurred; a significant correlation exists between the number of BrdU-labeled cells in the dentate gyrus and the percentage of conditioned responses in animals that have not yet fully acquired the conditioning task (Leuner et al., 2004). However, some studies have failed to find a significant increase in the number of new neurons following hippocampus-dependent learning (van Praag et al., 1999b; Snyder et al., 2005; Van der Borght et al., 2005), whereas others have reported decreased numbers of newly generated cells with learning (Dobrossy et al., 2003; Olariu et al., 2005; Pham et al., 2005). The reasons for these discrepancies remain unresolved; possible factors include variations in learning paradigms, different time courses between labeling new cells and training, and species and sex differences (reviewed by Abrous et al., 2005).

Because the hippocampus-dependent versions of the watermaze and eyeblink conditioning take more trials to acquire than the hippocampus-independent versions of these same tasks, it is possible that new cells respond especially to tasks that are more difficult. Although no study has yet matched the task difficulty of hippocampus-dependent and hippocampus-independent learning paradigms and examined new cell numbers, it is potentially instructive that place learning in the standard reference memory version of the watermaze is considerably easier (in terms of number of trials required to reach the criterion) than delay eyeblink conditioning. Thus, a simple relation to task difficulty—where this is operationally defined in terms of time or extent of training required for learning—does not seem to prevail.

Unlike the unsettled case for a link between learning and neurogenesis, there is now unambiguous evidence that physical activity increases cell proliferation and ultimately the production of new neurons in the dentate gyrus of adult rodents. Numerous studies have demonstrated that voluntary activity in a running wheel increases adult neurogenesis in rats and mice (van Praag et al., 1999ab; Fabel et al., 2003; Rhodes et al., 2003; Farmer et al., 2004; Holmes et al., 2004; Naylor et al., 2004; Persson et al., 2004; Bjornebekk et al., 2005). Even forced exercise, via running on a treadmill, has been shown to induce this effect (Trejo et al., 2001; Kim et al., 2004). This robust phenomenon is particularly surprising in light of the

fact that running causes activation of the HPA axis (Droste et al., 2003).

Although voluntary running might be considered a “positive stressor” (Selye, 1976), forced running is likely to have a more aversive component. Yet, both types of experience ultimately enhance adult neurogenesis. A few studies have demonstrated that high levels of running inhibit adult neurogenesis, but these negative effects appear to be specific to certain strains of animals (Naylor et al., 2004). The ability of this stimulus to override the negative actions of glucocorticoids is intriguing, and future experimentation is necessary to elucidate the mechanisms that enable running-induced neurogenesis despite activation of the HPA axis. It should be noted that there is an obvious hedonic component to running in rodents. Rodents are highly motivated to run and do so without additional incentives. In addition, rodents accustomed to running exhibit physiological and behavioral symptoms of withdrawal when access to a running wheel is denied. The extent to which these findings can be generalized to other animals that do not have an internal drive to run remains to be determined.

Some work suggests that the increase in neurogenesis associated with running leads to enhanced LTP as well as improved performance on hippocampus-dependent learning tasks (van Praag et al., 1999b). Although this evidence suggests a positive correlation between adult neurogenesis and learning, it is important to emphasize that running also alters other neural parameters in the hippocampus (Eadie et al., 2005). Thus, like the case for stress and enriched environments, changes in adult neurogenesis may contribute to altered hippocampal function, but they may not be the only cellular mediators of these effects.

### Individual Differences in Adult Neurogenesis

Individual differences in the acquisition of learning tasks abound, even among animals of the same strain housed under the same conditions. Differences in the rate of acquisition of the trace eyeblink conditioned response are correlated positively with the number of new neurons in the dentate gyrus (Leuner et al., 2004).

Individual differences also exist in reaction to novelty. Rats that are highly reactive to novelty exhibit lower levels of cell proliferation, and therefore of neurogenesis or survival, in the dentate gyrus than their less reactive counterparts (Lemaire et al., 1999). Moreover, individual differences in aggressive behavior exist and appear to correlate with the rate of adult neurogenesis. When adult rodents are group-housed in a relatively large, complex enclosure, a dominance hierarchy forms. Dominant animals, characterized by the amount of offensive or aggressive behavior displayed, have substantially more new neurons than subordinate animals. Once the dominance hierarchy is formed, the difference in the number of new neurons persists regardless of whether animals continue to live in the complex environment (Kozorovitskiy and Gould, 2004). These results again raise the issue of whether the natural expression of structural plasticity in a given species is

thwarted under artificial laboratory conditions. Differences in cell proliferation in the hippocampus of mountain chickadees depending on their dominance status have also been reported. Subordinate chickadees make fewer new cells in the hippocampus than dominant chickadees (Pravosudov and Omanska, 2005), again suggesting that individual experiences may increase variability on this measure.

#### 9.3.4 Neurogenesis Following Damage

Another question raised by the phenomenon of neurogenesis is whether the ongoing processes of cell death and cell proliferation in the dentate gyrus are causally linked. There are several grounds to suspect that they are. First, endocrine manipulations that alter survival of granule cells also affect the production of new cells in a direction that tends to keep the total number of cells constant. For example, removal of circulating adrenal steroids by adrenalectomy results in massive death of granule cells (Sloviter et al., 1989; Gould et al., 1990) as well as enhanced proliferation of granule cell precursors (Gould et al., 1992; Cameron and Gould, 1994). Second, a specific lesion of the granule cell layer, by mechanical or excitotoxic means, results in a compensatory increase in the proliferation of granule cell precursors and ultimately the production of new neurons (Gould and Tanapat, 1997). Third, experimental conditions associated with granule cell death, such as ischemia and seizures, result in increased granule cell neurogenesis (Parent et al., 1997; Scott et al., 2000; Jim

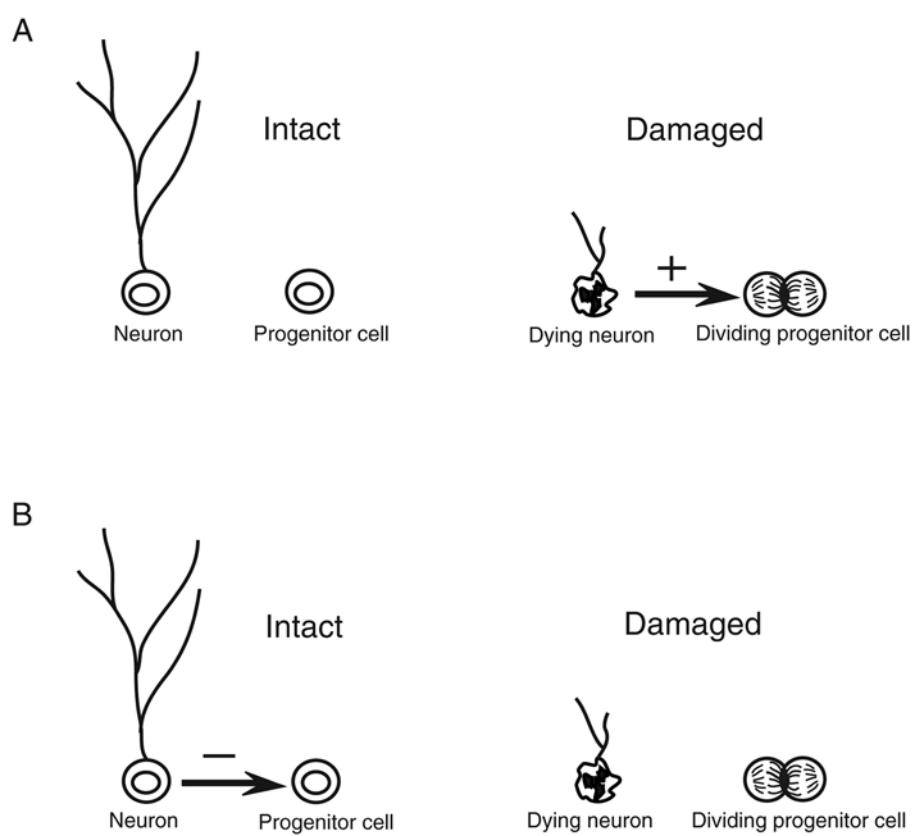

et al., 2001; Kee et al., 2001; Kokaia and Lindvall, 2003; Scharfman, 2004). Damage-induced neurogenesis can also be observed in the CA fields of the hippocampal formation; ischemic damage induces the production of new hippocampal pyramidal cells, cells not normally thought to undergo adult neurogenesis (Rietze et al., 2000; Nakatomi et al., 2002). The extent to which damage-induced neurogenesis contributes to functional recovery remains unknown (Scharfman, 2004), but some evidence suggests that neurogenesis is upregulated in neurodegenerative conditions such as Alzheimer's disease (Jim et al., 2004) and Parkinson's disease (Yoshimi et al., 2005). One report suggested that there is a functional relation between regenerative adult neurogenesis and recovery insofar as blocking cell proliferation with irradiation prevents the formation of new synapses after ischemia (Wang et al., 2005).

Damage-induced neurogenesis may occur via at least two, not mutually exclusive, mechanisms.

1. Dying neurons send signals to progenitors to divide at a faster rate.
2. Death of mature neurons releases progenitor cells from inhibition by eliminating a neurogenesis-inhibitory signal.

Both of these mechanisms have been identified in other systems (Hastings and Gould, 2003) (Fig. 9–3), but the relevance of these results to the adult hippocampal formation remains unknown.

**Figure 9–3.** Cell proliferation is enhanced with neuronal damage: alternative mechanisms. A. In the intact adult brain, differentiated neurons do not affect the rate of cell proliferation; however, dying neurons can release molecules that stimulate nearby precursors to divide. B. In the intact adult brain, differentiated neurons release molecules that suppress cell proliferation. Neuronal death removes this inhibition, permitting a higher rate of cell proliferation after damage.

### 9.3.5 Unusual Features of Adult-Generated Neurons

All cells are not created equal. Not only are there the well known differences between different cell types, there are also developmental differences between individual cells of a common cell type. The granule cell layer consists of neurons ranging in age from hours to years. Although many thousands of new neurons are added to the dentate gyrus every day, this is a relatively small proportion of the large number of mature granule neurons produced during development and that survive through to adulthood (the total number of granule neurons is approximately one to two million in the adult rat). For the newly born cells to have an impact on adult hippocampal function, they must have unique functional properties that empower them in the face of the numerical superiority of mature granule cells. Growing evidence suggests that the newly born cells may be functionally stronger.

#### Structural Characteristics of Adult-Generated Neurons

Adult-generated neurons are likely to have structural characteristics that differ from developmentally generated neurons. These structural differences may enable a relatively small number of immature neurons to exert a disproportionate effect on hippocampal physiology. For example, adult-generated granule cells are capable of undergoing rapid structural change, as evidenced by the fact that they have axons in the distal CA3 within 4 to 10 days after mitosis (Hastings and Gould, 1999). This suggests a great capacity to form new connections under the appropriate environmental conditions. Retrograde tracer studies have also suggested differences in the axon terminal fields of granule neurons produced at different developmental time points. Some granule cells produced during development have axons that diverge longitudinally in the CA3 region, whereas no such adult-generated granule cells have been observed (Hastings et al., 2002). Detailed information about the sequence of synaptogenesis onto newly generated granule cells in the dentate gyrus is not yet available. However, because adult-generated granule cells are produced in the deep part of the granule cell layer, their dendritic trees do not extend as far into the molecular layer as those generated during development. This presents the possibility that adult-generated granule cells, because of their location in the layer, receive a different proportion of synaptic inputs from various sources. Clearly, more research is needed to determine the extent to which cells produced at different time points form different types of circuits in the hippocampal formation.

#### Functional Characteristics of Adult-Generated Neurons

Immature neurons have electrophysiological characteristics which differ from those of mature neurons. For example, developing neurons have been shown to exhibit giant depo-

larizing potentials and respond to  $\gamma$ -aminobutyric acid (GABA) with depolarization instead of hyperpolarization. These data from hippocampal slices taken at different stages of development raise the possibility that adult-generated cells are transiently developmental in nature, at least for a short time after their generation. Indeed, it has been reported that immature granule cells in the dentate gyrus of the adult rat have more robust LTP than mature granule cells (Wang et al., 2000; Schmidt-Hieber et al., 2004). Moreover, this enhanced LTP cannot be inhibited by GABA agonists, unlike LTP elicited from mature granule cells (Snyder et al., 2001; Schmidt-Hieber et al., 2004). These findings support the view that a relatively small population of immature granule cells could exert a substantial functional influence over the hippocampal formation. However, research into this issue remains in its infancy; and much work is needed to determine the functional characteristics of new neurons in the dentate gyrus.

### 9.4 Possible Functions of New Neurons

The daily production of thousands of new granule cells and their incorporation into the existing circuitry are costly in terms of energy expenditure. It is likely that these new cells are not produced merely to replace older cells that die because a substantial amount of cell death occurring in this region involves the adult-generated population. The most intuitive explanation for the continual influx of new cells is that it provides an important mechanism for some aspect of the function of the dentate gyrus that cannot be obtained with a structure comprising mature neurons exclusively.

#### 9.4.1 A Possible Role in Learning?

The existence of a large pool of immature neurons in a brain region that is important for certain types of learning and memory raises the possibility that these new cells participate in these functions. Although most theories of learning do not involve new neurons, many ideas about hippocampal function are compatible with such a possibility. Chapter 13 discusses the wide range of current theories of hippocampal function. One theory is that the hippocampal formation acts to associate discontiguous events (i.e., stimuli that are separated by space or time) (Wallenstein et al., 1998). A continual influx of new neurons accompanied by rapid synapse formation could play a role in connecting stimuli separated spatially or temporally. A widely held view is that the hippocampal formation plays a temporary role in storing new memories. This theory is consistent with data showing that recent, but not remote, memories for certain information are eliminated by lesioning the hippocampal formation (Kim et al., 1995; Zola and Squire, 2001). A rapidly changing population of adult-generated neurons with unique functional properties may serve as a substrate for this temporary role of the hippocampal formation in information storage. Neurons produced during adulthood

might play a role in memory processing for a short time after their generation. The new cells might degenerate or undergo changes in connectivity, gene expression, or both around the time the hippocampal formation no longer plays a role in the storage of that particular memory. A temporary role for adult-generated granule neurons in learning has been suggested in canaries, in which seasonal changes in song correlate with the transient recruitment of more new neurons into the relevant circuitry (Barnea and Nottebohm, 1996; Nottebohm, 2002). However, a problem with taking this view of hippocampal memory is that it requires a cellular rather than a distributed synaptic view of memory storage. Neural network models of memory formation (see Chapter 14) support the distributed perspective. In addition, a temporary role for new neurons in learning implies that the new cells would persist only for as long as the hippocampus remains necessary for retention of that information. The observation that learning enhances the number of new neurons for at least 2 months (Leuner et al., 2004)—well beyond the time when the rodent hippocampal formation is necessary for the maintenance of those memories—argues against a clear role for new neurons in the temporary aspects of information storage.

Thus, although several theories of hippocampal learning are consistent with a possible role for new neurons, there are many details to be worked out. Do any data exist to support such a possibility? There is now some evidence for a positive correlation between the number of new hippocampal neurons and learning. For example, many factors and conditions that increase the number of new granule neurons have been shown to be associated with improved performance on hippocampus-dependent tasks, although the causal relation remains unproven (Gould et al., 1999a). Examples of factors that enhance both the number of new neurons and hippocampus-dependent learning are estrogen treatment and living in an enriched environment. Similarly, situations that decrease the number of new hippocampal neurons, such as glucocorticoids and stress, are associated with impaired performance on these tasks.

However, some recent studies have found either no relation between learning and the number of new neurons or, in fact, an inverse relation. With regard to the first case, aging is associated with a decline in new cell production in the hippocampus, and yet this decrease does not appear to be always associated with impaired performance on hippocampus-dependent tasks (Merrill et al., 2003). With regard to the second case, chronic stress has been shown to inhibit neurogenesis persistently in tree shrews; yet, this experience is associated with improved, not impaired, performance on a specific spatial navigation learning task (Bartolomucci et al., 2002). Do these negative findings indicate that new neurons are not involved in learning? Perhaps, but they may indicate that modulation of the rate at which new neurons accumulate affects hippocampal function only under certain conditions. Because stress, aging, and environmental complexity influence multiple brain measures in addition to neurogenesis, it is possible that changes in the new neuron number relate to learn-

ing only when imposed upon a particular neural background and under certain learning circumstances. For example, a decline in the new neuron number may fail to correlate with learning impairment because other age-associated changes dominate hippocampal function, such as diminished numbers of synapses (Morrison and Hof, 2002). When examining data related to the issue of adult neurogenesis and learning, it is important to note that new cells are likely to require some time for integration into the existing circuitry. Dendrites must be grown and functional synaptic connections formed on them; axons must grow and find their targets. Thus, acute changes in cell proliferation are not likely to influence hippocampal function until a certain amount of time has passed. Chronic changes in cell proliferation are those most likely to have functional consequences because their effects may be additive. This point is well illustrated by considering the acute and chronic effects of stress. Acute stress and chronic stress diminish the proliferation of granule cell precursors in the dentate gyrus. However, acute stress has been shown (with certain paradigms) to enhance learning, whereas chronic stress typically impairs learning (McEwen, 1999; Shors, 2001).

A direct link between new neurons and learning remains controversial. Thus far, two approaches have been used to deplete new cells: antimitotic agents and irradiation. Focal irradiation has been shown to decrease the number of new neurons almost completely, whereas treatment with the antimitotic agent methylazoxymethanol acetate (MAM) for 2 weeks has been shown to diminish the pool of new neurons by about 80% (Shors et al., 2000b, 2002; Bruel-Jungerman et al., 2005). The first obvious question is whether the depletion of new neurons produced during adulthood would be sufficient to influence hippocampal function. Cameron and McKay (2001) have shown that approximately 9000 new cells are produced every day in the rat dentate gyrus. If we assume that cell division in this population is asymmetrical, a maximum of 4500 new cells would be available to differentiate into neurons. Of this population, about 80% express markers of immature neurons (3600). Assuming a 30-day month, with approximately 108,000 immature neurons generated during this time, complete depletion would eliminate about 100,800 immature neurons (> 5% of the total number of granule cells, which is about 1.5–2.0 million). Although this is not a proportionately large number, if, as indicated above, the granule cells produced during adulthood are functionally different—less likely to be inhibited by GABA and more likely to display synaptic plasticity—they could be especially influential. Despite the fact that involvement of new neurons in learning is plausible, the available evidence supporting this view is incomplete and mixed.

Treatment with the antimitotic agent MAM has been shown to impair performance on trace eyeblink conditioning (Shors et al., 2001b). Delay eyeblink conditioning, the hippocampus-independent version of the same task, is unaffected by MAM treatment. Replenishment of immature neurons after cessation of MAM treatment results in the recovery of hippocampal function as indexed by normal trace eyeblink

conditioning. Additional studies have shown that focal irradiation (which stops cell proliferation and hence neurogenesis) of the hippocampal formation of adult rodents impairs performance of a place recognition task in a T maze but not of an object recognition task (Madsen et al., 2003); it also impairs performance in a spatial version of the Barnes maze (Raber et al., 2004). In addition, a role for new neurons in enhanced learning associated with living in an enriched environment has been reported, using MAM to decrease the production of neurons (Bruel-Jungerman et al., 2005). These results are surprising given that studies of behavioral changes following lesions of the hippocampus rarely uncover a learning impairment unless a large percentage of the total hippocampal formation is destroyed (Moser et al., 1995). This again raises the issue of whether the increased efficacy of adult-generated neurons compared to their developmentally generated counterparts imparts a relatively small number of new neurons with substantial power to influence hippocampal function.

It is important to note that contradictory data exist. One study revealed that other forms of hippocampus-dependent learning tasks are insensitive to manipulations that decrease the number of new neurons. For example, spatial learning in a watermaze is not impaired by MAM treatment or irradiation (Shors et al., 2002; Snyder et al., 2005). Moreover, a simple form of contextual fear conditioning (a learning paradigm that involves the hippocampal formation) (Fanselow, 2000) is unaffected by MAM treatment (Shors et al., 2002). Because both spatial learning and context fear conditioning are both much more rapidly acquired than trace eyeblink conditioning, the possibility that new cells are important only for training on difficult tasks arises, as previously indicated. This suggests that either new dentate granule cells participate in only certain types of hippocampus-dependent learning (e.g., those that involve associating stimuli separated in time) or that some action of the drug other than its effects on neuron production is impairing trace eyeblink learning. However, the results from irradiation studies suggest that spatial memory, if not learning, is affected by depletion of new neurons. Prevention of neurogenesis results in an inability to retain spatial information pertaining to watermaze learning, whereas learning itself remains unaffected (Snyder et al., 2005).

All methods utilized thus far to block adult neurogenesis in the dentate gyrus are likely to have some nonspecific effects. MAM is a nonspecific antimitotic agent (sometimes used for chemotherapy). Impairment of hippocampus-dependent learning could be the result of the generalized toxic effects of the drug. The efficacy of MAM appears to vary across studies, with some investigators reporting larger depletions in new neuron number than others (compare Shors et al., 2000 and Bruel-Jungerman et al., 2005 with Dupret et al., 2005). In addition, variability in the degree to which the drug is reported to be toxic at doses sufficient to block neurogenesis exists (compare Shors et al., 2000 and Bruel-Jungerman et al., 2005 with Dupret et al., 2005). The reasons for these differences remain unknown but may be related to the overall

health of the animals at the start of the study and the degree to which they experience stress during treatment. However, there is general agreement across groups that at high doses MAM is generally toxic. Nonspecific effects of treatment are also a feature of irradiation. Although the possibility that spurious changes, in contrast to specific effects on adult neurogenesis, contribute to the learning deficits with MAM treatment cannot be completely ruled out, there is some evidence to suggest this is not the case. The same regimen of MAM treatment that produces learning impairment does not cause weight loss, liver damage, or structural changes to the brain (including the hippocampus and cerebellum) (Shors et al., 2000; Bruel-Jungerman et al., 2005). In addition, MAM treatment does not prevent the hippocampus from having some normal electrophysiological responses, including induction of LTP in the CA1 region.

Collectively, these findings suggest that new neurons may play a role in certain types of learning but not others. Definitive information awaits the development of better methods for controlling neuronal proliferation and survival in the absence of nonspecific effects that are functionally deleterious. Transgenic mice designed to knock out new neurons during specific times of adulthood would be useful tools for investigating the possible role of new neurons in learning. If these animals exhibit normal learning and memory on a multitude of tasks, the function of new neurons will remain a completely open question. One possibility is that the new neurons participate in learning but only in a redundant fashion. That is, the new neurons may be necessary for learning only when other aspects of hippocampal function are compromised (e.g., following irradiation or treatment with an antimitotic agent).

#### **9.4.2 A Possible Role in Endocrine Regulation?**

In addition to its widely recognized role as a brain region involved in learning and memory, the hippocampal formation plays a less publicized role in the regulation of endocrine function. As indicated earlier, the hippocampal formation is known to have a relatively high concentration of steroid hormone receptors, in particular adrenal steroid receptors (McEwen, 1999). The hippocampal formation has been linked functionally to regulation of the HPA axis. In particular, it is purported to play a role in limiting the levels of circulating glucocorticoids following stress. For example, lesions of the hippocampal formation prevent the efficient shut-off of the HPA axis and the return of glucocorticoid levels to their basal state (Herman et al., 1995).

Research into the effects of early stressors on the development of the HPA axis and adult neurogenesis has revealed potential links between adult-generated neurons and hippocampal neuroendocrine function. That is, prenatal and postnatal stress have been shown to result in persistent changes in the HPA axis in the form of inefficient shut-off of the stress response during adulthood. Early stressors have additionally been shown to diminish cell proliferation in an

acute manner and to dampen permanently the production of new neurons even during adulthood (Lemaire et al., 2000; Coe et al., 2003). These findings raise the as yet untested possibility that adult-generated neurons play an important role in regulating the HPA axis. Studies designed to examine the effects of specific depletion of adult-generated neurons on the shut-off of the stress response might reveal evidence that would add support to this view.

Observations of individuals suffering from psychiatric conditions, such as depression and posttraumatic stress disorder, have revealed signs of HPA axis dysregulation and diminished hippocampal volume in magnetic resonance imaging (MRI) studies (Vythilingam et al., 2002). Although the mechanisms that underlie diminished hippocampal volume in these conditions are unknown, it is possible that persistently decreased neurogenesis plays a role. Interestingly, the psychiatric conditions are also associated with impaired learning, but the mechanisms that underlie these cognitive changes remain unknown.

#### **9.4.3 A Possible Role in the Etiology and Treatment of Depression?**

A growing body of evidence points to a role for new granule neurons in the etiology of depression. This idea grew out of three findings: (1) hippocampal volume is smaller in depressed patients; (2) stress, which predisposes individuals to develop depression, inhibits hippocampal neurogenesis; and (3) antidepressants enhance hippocampal neurogenesis. These observations have led to the suggestion that some of the symptoms associated with depression may result from a persistent decrease in new neuron formation. This idea has been tested more directly in a study examining the effects of focal irradiation on the behavioral effects of antidepressants in mice (Santarelli et al., 2003). Prevention of an antidepressant-induced increase in adult neurogenesis blocks the ability of this therapy to alter behavioral signs of anxiety. These findings suggest that the efficacy of antidepressants may depend on their ability to restore neurogenesis to normal levels. To establish these links more conclusively, evidence that the hippocampus does indeed participate in the symptomatology of depression would be necessary. Furthermore, confirmation that diminished hippocampal volume—which has not been reported in all studies of depressed patients and is extremely small even when it has been established (about a 5% reduction)—is the result of reduced neurogenesis seems critical.

#### **ACKNOWLEDGMENTS**

Special thanks go to the editors for constructive criticism on several drafts of the manuscript. Also, my thanks go to past and present members of my laboratory for their hard work and dedication, especially Yevgenia Kozorovitskiy for help with the chapter and providing figures. Finally, thanks to the NIH and NARSAD for funding some of the research described this chapter.

## Synaptic Plasticity in the Hippocampus

### 10.1 Overview

Of all the properties of hippocampal synapses, perhaps the most beguiling and consequential, and certainly the most enthusiastically studied, is their ability to respond to specific patterns of activation with long-lasting increases or decreases in synaptic efficacy. Although it is now clear that synaptic plasticity is a property of many, perhaps most, excitatory synapses in the brain, much of what is known about long-term potentiation (LTP) and long-term depression (LTD) has been worked out in the structure where they were discovered. When it comes to synaptic plasticity, the hippocampus is the *fons et origo*, the onlie begetter, the home team.

The chapter opens with a brief historical account of the first two decades of research into LTP and LTD. During this period, from 1966 to the mid-1980s, the major characteristics of LTP, including its persistence, input specificity, and associativity, were established, the critical role of the *N*-methyl-D-aspartate (NMDA) receptor in the induction of LTP identified, and the first steps taken to link LTP to hippocampus-dependent learning. At the end of this period, it was clear that at most hippocampal synapses the conditions required for the induction of LTP are identical to the conditions required for the activation of the NMDA receptor, and that the cellular event that triggers the induction of LTP is the influx of  $\text{Ca}^{2+}$  through the activated NMDA receptor. We then, in Section 10.2, begin our survey of synaptic plasticity in the hippocampus with a discussion of the various short-term forms of plasticity that hippocampal synapses share with most if not all synapses: paired-pulse facilitation and depression and post-tetanic potentiation. We devote the next two sections, 10.3 and 10.4, to the mechanisms supporting the induction and expression of NMDA receptor-dependent LTP, the form of LTP displayed by, for example, perforant path-granule cell synapses and by commissural and Schaffer collateral synapses on CA1 pyramidal cells. Section 10.3 covers the properties of LTP, the proto-

cols that produce it, and the role of the NMDA receptor. Other aspects of NMDA receptor-dependent synaptic plasticity in the hippocampus are introduced, including EPSP-spike (E-S) potentiation, synaptic scaling, and metaplasticity. In the next section, 10.4, we turn to the mechanisms that support the expression of LTP. In contrast to the consensus that exists concerning the NMDA receptor-dependent events that mediate the induction of LTP, the mechanisms underlying its expression—that is, the pre- or postsynaptic changes that directly result in an increase in synaptic efficacy—are more complex and less well understood. Attention has mostly focused on postsynaptic changes involving the phosphorylation or insertion of AMPA receptor subunits. We assess the evidence that presynaptic changes also contribute to the increase in synaptic efficacy during the first few hours after induction. The study of morphological changes goes back to the very early days of LTP research, and it has often been proposed that a growth in the number or size of synapses is a correlate of LTP. Modern optical techniques allow spine growth to be imaged in real time, and there is evidence that this may occur in LTP. Additional mechanisms, involving gene transcription and protein synthesis, are required to sustain LTP for longer periods, giving rise to the distinction between early LTP (E-LTP) and protein synthesis-dependent late LTP (L-LTP). Late LTP, like early LTP, is input-specific, which raises the question of how somatically generated transcripts and proteins are targeted specifically to recently activated inputs, a discussion that leads to the idea of synaptic tagging.

Around the time that the NMDA receptor was being hailed for the elegant molecular explanation it offered for input specificity and associativity, examples of activity-dependent plasticity that did not require the NMDA receptor were being uncovered. In particular, the mossy fiber projection from granule cells to CA3 pyramidal cells supports a very different form of LTP that is not blocked by NMDA receptor antagonists. Both the induction and expression of mossy fiber LTP appear to be predominantly presynaptic. The discussion of

mossy fiber LTP receives its own section, 10.5, and is followed, in 10.6, by a survey of neuromodulatory systems that affect LTP, such as the cholinergic input, catecholamines, and neurotrophins. In section 10.7 we explore the world of long-term depression, and the “depotentiation” of LTP. Although more difficult to obtain than LTP, and more difficult in adult than juvenile animals, a substantial literature, both *in vitro* and *in vivo*, supports the idea that LTD has both NMDA receptor-dependent and NMDA receptor-independent forms. Synaptic plasticity is not confined to excitatory connections between principal neurons; in Section 10.8 we examine the evidence for LTP and LTD at excitatory synapses onto interneurons and inhibitory synapses made by interneurons. Next, in section 10.9, we turn to synaptic plasticity in development, and in the aging animal, and discuss how LTP and LTD are affected in animal models of cognitive decline.

Finally, what's it all for? Why do hippocampal synapses display these striking forms of plasticity, and does the intact animal exploit them to acquire and store memories? In Section 10.10 we survey and assess the evidence relating to this central question. The readers will probably not be surprised to learn that we are able to provide only partial answers.

### 10.1.1 LTP: The First Two Decades

The term “synaptic plasticity” was introduced by the Polish psychologist Jerzy Konorski to describe the persistent, activity-driven changes in synaptic efficacy that he assumed, in common with most neuroscientists since Santiago Ramon y Cajal, to be the basis of information storage in the brain (Konorski, 1948). A formal hypothesis embodying this idea was advanced by the Canadian psychologist Donald Hebb in 1949. According to Hebb's celebrated postulate (Hebb, 1949),

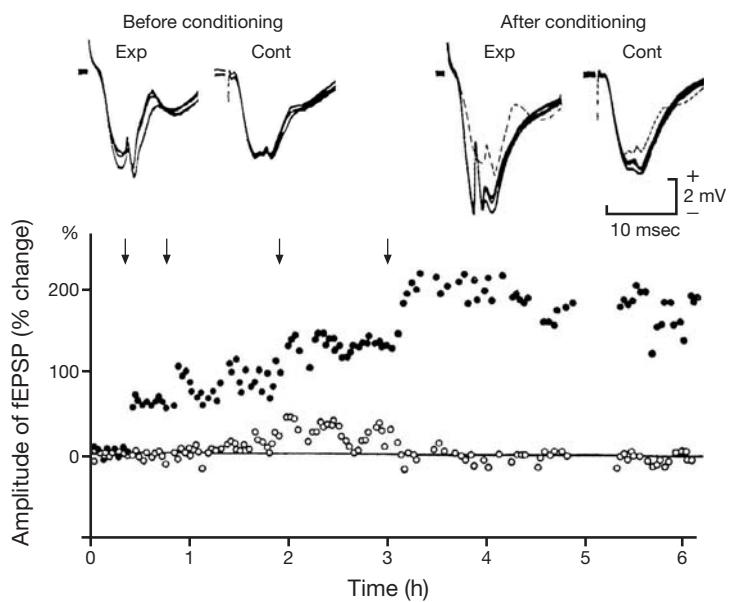

When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased.

Nearly 25 years were to pass before the first description of a Hebb-like synapse in the mammalian brain. In 1973, Tim Bliss and Terje Lømo reported that long-lasting changes in synaptic efficacy at perforant path-granule cell synapses in the hippocampus could be induced by brief tetanic stimulation (Bliss and Lømo, 1973). The discovery of what has come to be known as “long-term potentiation” (or LTP) emerged from experiments that Per Andersen and Lømo, then a PhD student, were conducting at the University of Oslo during the mid-1960s on the phenomenon of frequency potentiation in excitatory hippocampal pathways. Working with anesthetized rabbits, Andersen had earlier observed that field potentials evoked by stimulation at frequencies of 1 Hz or less were stable, whereas the response to successive stimuli grew steadily larger when the stimulus frequency was stepped up to 5 to 10 Hz (Andersen, 1960). While exploring this phenomenon in the dentate gyrus, Lømo noticed that after episodes of high-

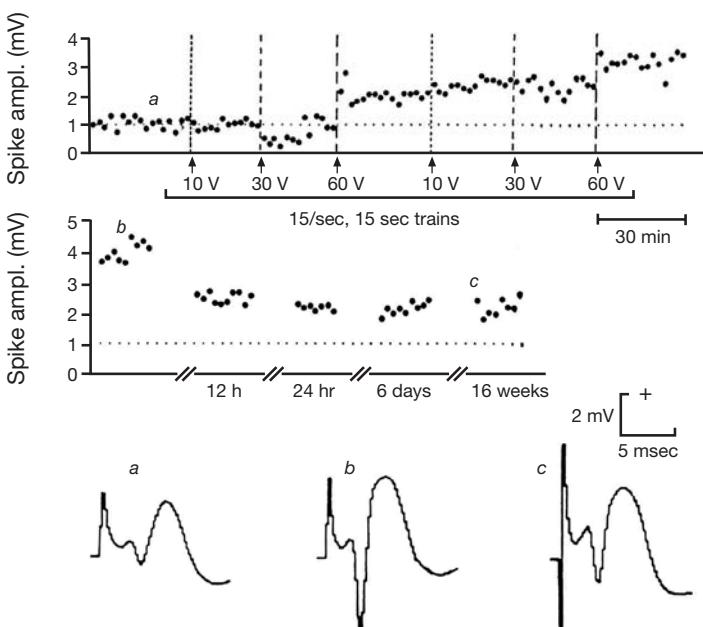

frequency stimulation of the perforant path lasting a few seconds the responses evoked by subsequent stimuli could remain enhanced for many tens of minutes. He reported his observations at the 1966 meeting of the Scandinavian Physiological Society in Åbo, Finland (Lømo, 1966). In 1968, Lømo and Bliss, a postdoctoral fellow from the National Institute for Medical Research in London with an interest in the neural basis of learning, embarked on a systematic investigation of what they at first called long-lasting potentiation (later renamed long-term potentiation by Graham Goddard) (Douglas and Goddard, 1975), a name that stuck no doubt because its acronym, LTP, tripped more lightly off the tongue than LLP. Bliss and Lømo delivered test stimuli at intervals of 2 to 3 seconds to the perforant path on each side of the brain and recorded the evoked response from either the granule cell layer of the dentate gyrus or the synaptic terminal region in the molecular layer. Tetanic stimulation of 100 Hz for 3 to 4 seconds or, more usually, 15 Hz for 10 to 20 seconds was given to the perforant path on one side, the other acting as a nontetanized control. An example of the potentiation they observed following repeated episodes of tetanic stimulation is shown in Figure 10-1A. In many cases, potentiation of the field EPSP (fEPSP) was accompanied by an increase in the amplitude and a decrease in the latency of the population spike (see traces in Fig. 10-1A) (for an introduction to field potentials and their interpretation, see Chapter 2, Box 2-1). The potentiation was apparent within 30 to 60 seconds of the tetanus and could be followed, with little decrement, for several hours.

A more extensive account by Bliss and Lømo of the background to their experiments can be found at <http://www.ergito.com/main-lcd.jsp:bcs=EXP.13.8>; other recollections of the early days of LTP by Andersen, Bliss, Lømo, Graham Collingridge, Gary Lynch, Bruce McNaughton, and Richard Morris are gathered in *LTP: Enhancing Neuroscience for 30 Years* (Oxford: Oxford University Press; 2004. Reprinted from Bliss et al., 2003).

Subsequently, Bliss and Tony Gardner-Medwin (1973) found that tetanus-induced potentiation could persist for many days in the unanesthetized rabbit with chronically implanted electrodes (Fig. 10-1B). Potentiation was not seen with low-intensity tetanization but required a stimulation strength that exceeded a threshold approximately equal to that required to activate a population spike. Analysis of input-output curves suggested that only the synaptic inputs that had actually been tetanized were potentiated, a phenomenon called “input specificity” (Bliss et al., 1973). Direct proof was delivered some years later following the introduction of the hippocampal slice preparation, which made it easier to activate two separate pathways converging on the same population of cells. LTP of the fEPSP was induced in the tetanized pathway, whereas the response evoked in the second, untetanized pathway remained at baseline levels (Andersen et al. 1977). In some cases, LTP of the population spike occurred without a corresponding change in the fEPSP (Bliss and Lømo, 1973). This result implies the existence of a second component of LTP,

**A**

**Figure 10-1.** Tetanic stimulation induces long-lasting potentiation in the dentate gyrus of the intact rabbit. **A.** Brief tetanic stimulation (arrows) of the perforant path induces a rapid, persistent increase in the amplitude of the field EPSP. Further episodes of tetanic stimulation (15 Hz for 15 seconds) produce more potentiation until eventually, as illustrated in Figure 10-2A, the response saturates. The sample responses above reveal that the amplitude of the population spike is also potentiated and its latency reduced. (Source: Bliss and Lømo, 1973.) **B.** Potentiation of the population spike lasting for many weeks in a freely moving rabbit with chronically implanted electrodes given high-frequency trains of increasing stimulus intensity. Note the lack of effect of weak trains. The upper and lower part of the figure are continuous. Following the second train at 60 V, the response was monitored for 45 minutes and the animal then returned to its home cage. Twelve hours later, potentiation had declined to about half its maximum value and remained at that level for the following 16 weeks. The traces at the bottom of the panel were obtained at times indicated by a–c in the spike amplitude plots. (Source: Bliss and Gardner-Medwin, 1973.)

**B**

reflecting an increase in the coupling between the synaptic response and the population spike. The effect was subsequently given the name EPSP-spike (E-S) potentiation (Andersen et al., 1980).

Other important early contributions to the study of LTP in the intact animal came from the laboratory of Graham Goddard in Halifax, Nova Scotia. These studies established that briefer, more physiologically plausible tetani (7 stimuli at 400 Hz) could produce LTP in the perforant path of the anesthetized rat (Douglas and Goddard, 1975) and formalized the notion of *cooperativity* between afferent fibers to explain the existence of an intensity threshold for LTP induction

(McNaughton et al., 1978). Goddard and his colleagues, principally Rob Douglas, Carol Barnes, and Bruce McNaughton, were also the first to find a way to block the induction of LTP—by delivering a coincident high-frequency train to the commissural input to the dentate gyrus (Douglas et al., 1982). Because commissural stimulation suppressed the firing of granule cells, this last result suggested that the “locus of control” for induction was postsynaptic. From Goddard’s laboratory too came the first description of the property of *associativity*, whereby a weak input could be potentiated if its activation coincided with a tetanus to another input (McNaughton et al., 1978). Around the same time, associativ-

ity was also documented in the weak pathway made by contralateral perforant path fibers to the molecular layer of the dentate gyrus (Levy and Steward, 1979).

The experiments described so far were all carried out on intact animals. Introduction of the living brain slice as a physiological preparation by Henry McIlwain during the 1960s (see Chapter 2) stimulated the development of the transverse hippocampal slice preparation in the Oslo laboratory (Skrede and Westgaard, 1971). This preparation allows ready access to all pathways of the dentate gyrus and hippocampus, provides mechanical stability for intracellular recording, and makes possible rapid pharmacological manipulation of the extracellular environment (see Chapter 5). Not surprisingly, it has achieved enormous popularity with investigators of synaptic function. Using this preparation, LTP was revealed at two other hippocampal pathways: the mossy fiber projection to CA3 pyramidal cells and the interleaved commissural and Schaffer collateral fibers from CA3 to CA1 pyramidal cells (Schwartzkroin and Wester, 1975). We refer to these fibers as the Schaffer-commissural projection. As we have seen, the transverse slice also allowed the *input specificity* of LTP to be demonstrated in a more direct way than had been possible in the dentate gyrus *in vivo* (Andersen et al., 1977; Lynch et al., 1977).

In contrast to *in vivo* preparations where the dentate gyrus offers the most stable recording conditions, the region most commonly studied *in vitro* has been area CA1. This is partly because LTP in the dentate gyrus *in vitro* is difficult to obtain without reducing tonic inhibition by perfusing a GABA<sub>A</sub> receptor antagonist (Wigström and Gustafsson, 1983) and perhaps partly because of a feeling of unease engendered by the fact that in the slice preparation the perforant path fibers are unattached to their parent cell bodies. It is well to remember that the hippocampal slice is a heavily reduced preparation. Although it makes possible a range of physiological and pharmacological experiments that would not otherwise be feasible, a full understanding of the mechanisms and significance of hippocampal synaptic plasticity cannot be reached by *in vitro* studies alone.

Experimental analysis of the properties and mechanisms of LTP has concentrated on the Hebbian form of synaptic plasticity exhibited by the perforant path projection to granule cells of the dentate gyrus and by Schaffer-commissural afferents to area CA1. It is this “classical” form of LTP that we discuss in most detail. Tetanic stimulation of both these pathways results in a rapid, persistent increase in synaptic responses, whether recorded intracellularly or extracellularly. LTP can be followed for many hours in both the slice preparation and the anesthetized animal and for days, weeks, or months in animals with implanted electrodes. LTP generally decays to baseline over a period of several days in rats with electrodes chronically implanted in the dentate gyrus, though potentiation lasting more than a year has been reported (Abraham, 2003).

Two important clues to the mechanisms underlying the induction of LTP were discovered in 1983. The first clue was provided by Graham Collingridge and colleagues, who

showed that D-2-amino-5-phosphonopentanoic acid (D-AP5), a highly specific antagonist of the NMDA subtype of glutamate receptor that had been developed by Jeff Watkins and coworkers (Davies et al., 1981), blocks the induction of LTP in area CA1 while having little or no effect on synaptic responses recorded at low rates of stimulation (Collingridge et al., 1983). Then Gary Lynch and his collaborators reported that injection of a calcium chelator, ethyleneglycol-bis-( $\beta$ -aminoethylether)-N,N,N',N'-tetraacetic acid (EGTA), into CA1 pyramidal cells blocks the induction of LTP (Lynch et al., 1983). This experiment confirmed the critical importance of the postsynaptic cell in the induction process and established an essential role for calcium.

As discussed in Chapter 6, excitatory synapses express up to four types of postsynaptic glutamate receptor:  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), kainate, NMDA, and metabotropic glutamate (mGlu) receptors. The excitatory postsynaptic currents (EPSCs) evoked at low rates of stimulation are largely mediated by activation of AMPA receptors (Davies and Collingridge, 1989). NMDA receptors contribute only a small component of these EPSCs but are critical for synaptic plasticity. Two unexpected properties of the NMDA receptor were identified during the 1980s. First, the NMDA channel is unusual for a ligand-conducted ionophore in that its conductance is both ligand- and voltage-dependent. At near-resting membrane potentials, the channel is blocked by Mg<sup>2+</sup>, and substantial depolarization is required to drive Mg<sup>2+</sup> from the channel (Ault et al., 1980; Mayer et al., 1984; Nowak et al., 1984). Thus, activation of the NMDA channel requires the temporal coincidence of activity in presynaptic terminals to release transmitter plus adequate depolarization of the postsynaptic membrane. The properties of cooperativity, input specificity, and associativity follow directly from the dual ligand and voltage dependence of the NMDA receptor. As a result of these properties, the NMDA receptor can be thought of as a molecular coincidence detector, endowing pyramidal and granule cells with the capacity to detect coincident activity at multiple excitatory inputs. Second, the ionophore of the activated NMDA receptor is permeable to Ca<sup>2+</sup> ions (MacDermott et al., 1986; Jahr and Stevens, 1987; Ascher and Nowak, 1988). This led to the idea that the trigger for the cellular processes leading to LTP is the entry of Ca<sup>2+</sup> ions through the ionophore associated with the NMDA receptor and the subsequent activation of Ca<sup>2+</sup>-dependent enzymes in the dendritic spine.

Thus, by the second half of the 1980s studies had matured to the point where a simple, compelling molecular explanation could be given for three defining properties of LTP: cooperativity, input specificity, and associativity. The hypothesis that the necessary and sufficient conditions for inducing LTP are just those required to activate the NMDA receptor received further support in 1986. Holger Wigström, Bengt Gustafsson, and others showed that even low-frequency stimuli could induce LTP in single CA1 pyramidal cells if each stimulus was given in conjunction with a strong depolarizing pulse (Wigström et al., 1986). This dramatic result showed that the

induction of LTP did not absolutely depend on the strong, high-frequency trains that had been largely used up until then and the artificial nature of which had called into question the physiological relevance of LTP; on the contrary, weak low-frequency stimulation was equally effective provided the target cell was sufficiently depolarized by neighboring activity. The realization of the Hebbian nature of the induction of LTP took root at the same time as Richard Morris and his colleagues were demonstrating that animals without the capacity for hippocampal LTP owing to blockade of the NMDA receptor were severely impaired in the acquisition and retention of spatial learning in the watermaze (Morris et al., 1986). The mid-1980s was thus a time when LTP seemed well on the way to gaining acceptance as a physiological mechanism underlying the cognitive faculties of learning and memory and mark an appropriate point at which to bring this brief historical survey to a conclusion.

## 10.2 Transient Activity-dependent Plasticity in Hippocampal Synapses

### 10.2.1 Short-term Activity-dependent Changes in Synaptic Efficacy in the Hippocampal Formation

Synaptic transmission at the level of the single synapse is an inherently stochastic process (see Box 10–1; see also Chapter 6, Box 6–1) that can be modulated by prior activity in the presynaptic or postsynaptic neuron and by a wide variety of neuromodulators acting both pre- and postsynaptically. Some of the activity-dependent changes in synaptic efficacy that occur in the hippocampal formation, such as facilitation and depression, augmentation, and (post-tetanic) potentiation, are relatively short-lasting. It is with these short-lived types of plasticity that we begin our discussion (reviewed by Zucker and Regehr, 2002) (see Chapter 6–2).

### 10.2.2 Single Stimuli in Hippocampal Pathways Produce Two Transient Aftereffects: Facilitation and Depression

The aftereffects on synaptic transmission of a single stimulus can be tested by delivering a second stimulus at a variable time after the first. When pairs of stimuli are delivered to the perforant path, the amplitude of the second response recorded in the molecular layer of the dentate gyrus *in vivo* is typically facilitated at interstimulus intervals of less than 200 to 300 ms and depressed at longer intervals of up to a few seconds (McNaughton, 1980, 1982). Similar effects are seen at Schaffer-commissural synapses in area CA1 (Andersen, 1960). Paired-pulse facilitation and depression were first studied in the neuromuscular junction and appear to be a common feature of all chemically transmitting synapses (Magleby, 1979; Nicholls et al., 2001).

### Facilitation

Facilitation can be attributed to the transient increase in the concentration of intraterminal calcium produced by an invading action potential. The concentration declines to basal values over a few hundred milliseconds, but the calcium influx at the time of the second stimulus adds to the residual calcium from the first, resulting in an enhanced calcium concentration and hence to an increase in the probability of release (Wu and Saggau, 1994). The magnitude of facilitation is inversely related to the initial probability of release. Analysis of elementary (quantal) synaptic events suggests that facilitation is largely due to presynaptic mechanisms (Zucker and Regehr, 2002). Note, however, that a postsynaptic component of facilitation has been described in both cortical pyramidal cells (Rozov and Burnashev, 1999) and CA1 pyramidal neurons (Bagal et al., 2005). A widely used test for discriminating presynaptic from postsynaptic mechanisms in LTP was introduced by McNaughton (1982), based on the fact that the higher the probability of release, the less scope there is for presynaptically mediated facilitation, and so the smaller is the observed degree of paired-pulse facilitation. A reduction in paired-pulse facilitation following the expression of LTP is therefore often taken as evidence for an increase in the probability of release. Initial studies found that whereas paired-pulse facilitation was decreased in post-tetanic potentiation (PTP), there was no change in LTP, implying that the expression mechanism was more likely to be postsynaptic (see Fig. 10–10A). As with most tests for the locus of expression of LTP, the paired-pulse facilitation test is suggestive but not conclusive: For example, no change in facilitation would be observed if LTP resulted from recruitment of a population of silent boutons (that is, boutons with zero probability of release before the induction of LTP) that, following induction, assumed a distribution of release probabilities similar to that of the population activated before induction. (See below and Box 10–1 for a discussion of this and other tests to determine the locus of expression of LTP.)

### Depression

Transient depression of synaptic efficacy also occurs to the second of a pair of stimuli. To a large extent, this can be explained by a process of vesicle depletion, although receptor desensitization may also make a contribution. Evidence that transmitter depletion contributes to depression comes from the observation that in situations where transmitter release is artificially reduced, as when extracellular calcium concentration is lowered, depression is attenuated. This allows the full time course of facilitation to be revealed. Transmitter released by an action potential can also dampen the response produced by a subsequent stimulus via negative feedback involving activation of presynaptic glutamate receptors. In a similar manner, presynaptic GABA<sub>B</sub> autoreceptors on inhibitory terminals are thought to be responsible for the reduced inhibition that underlies the effectiveness of primed burst stimulation in

**Box 10-1****Pitfalls of Paired-Pulse Facilitation and Quantal Analysis as Techniques for Studying the Locus of Change in Synaptic Plasticity****PAIRED-PULSE FACILITATION**

Paired-pulse facilitation (PPF) is due to an activity-dependent presynaptic modulation of transmitter release (Zucker and Regehr, 2002). It reflects the fact that at many synapses, such as those made by Schaffer commissural axons, an invading action potential has a greater chance of evoking exocytosis of neurotransmitter when it arrives within a few tens of milliseconds of a preceding action potential. When studying PPF, two stimuli are delivered with an interval of, say, 50 ms, and the amplitude of the first and second synaptic responses are compared. The amplitude of the second response relative to the first (facilitation ratio) is then a reflection of the increase in the probability of transmitter release ( $Pr$ ). Facilitation is a function of the mean  $Pr$  of the synapses under study. Clearly if  $Pr$  is at or close to 1, there is little or no scope for facilitation. The standard argument, first advanced in the context of LTP by McNaughton (1982), is that modulation of synaptic efficacy due to a change in  $Pr$  is reflected in a converse change in facilitation; that is, an increase in  $Pr$  results in a decrease in facilitation and vice versa. During the first few minutes after a tetanus, the rapidly declining phases of PTP and short-term potentiation (STP) are mirrored by a decrease in facilitation; this is as expected for PTP, which is presynaptically mediated (see Section 10.2.3) and suggests that the early kinase-independent phenomenon of STP is also presynaptic. Thereafter, during LTP, facilitation is at baseline levels, arguing against a presynaptic change in LTP (see Fig. 10–11A). However, the evidence provided by a PPF analysis is suggestive rather than conclusive, and a change in PPF is not a wholly reliable guide to a presynaptic locus. To take a hypothetical example, suppose PPF increases after the induction of LTD. The conventional interpretation would be that this reflects a reduction in  $Pr$ . However, there are plausible postsynaptic changes that could give rise to an increase in PPF. Thus, if LTD involves the internalization of receptors, and the probability of internalization is dependent on the binding of transmitter, receptors at those synapses with the highest  $Pr$  would be internalized first. In this model, the mean  $Pr$  of the remaining active synapses would steadily fall, and PPF would increase as a result of a purely postsynaptic change. Evidence for this model is found in mGluR-dependent LTD (see Section 10.7.5)

**QUANTAL ANALYSIS**

When the quantal variable  $n$ , the number of release sites, is large (e.g., when stimulating many Schaffer-commissural fibers) the stochastic nature of neurotransmitter release is seen as trial-by-trial fluctuations in the amplitude of the evoked synaptic response. A measure of this variability is the coefficient of variance ( $CV = SD/\text{mean}$ ), which is sensitive to changes in  $Pr$  and  $n$  but also, in some circumstances, to postsynaptic factors (Auger and Marty, 2000). For example, if during LTP  $Pr$  tends toward 1 (i.e., fewer failures), there is less variability due to trial-by-trial fluctuations in neurotransmitter release, and  $CV$  decreases. In the case of minimal stimulation, where one or at most a few axons are stimulated, there may be random failures of response due to the failure of the invading action potential to cause exocytosis of transmitter. A decrease in failures is classically equated with an increase in  $Pr$  and vice versa.

When a package of neurotransmitter is released, it evokes a postsynaptic response, the size of which is referred to as the quantal amplitude ( $q$ ). The magnitude of this response varies from trial to trial as a result of the stochastic nature of postsynaptic channel opening and fluctuations in the amount of L-glutamate released. When a single release site is activated ( $n = 1$ ), the variability in the magnitude of successful responses is due solely to this intra-site quantal variance. When multiple sites are activated ( $n > 1$ ) there is an additional variance due to the between-site variation in quantal size. This inter-site variability could be large, reflecting, for example, differences in receptor number and electrotonic distance from the recording site.

The study of the relative contributions of  $n$ ,  $Pr$ , and  $q$  to changes in synaptic efficacy is the subject of quantal analysis. Typically, quantal analysis involves collecting many responses to plot an amplitude frequency histogram. The mean amplitude of an evoked synaptic response is simply  $n.Pr.q$ . The spacing between peaks in the histogram provides an estimate of  $q$ . A change in  $q$  alters the interpeak spacing without altering the amplitudes of the peaks, whereas a change in  $n$  or  $Pr$  modifies the amplitudes of the peaks but not the spacing between them.

Although these approaches are powerful in theory, they are often difficult to interpret in practice. There are many reasons for this situation, which can be considered in two main categories. The first major problem is the difficulty of making accurate measurements. This requires high quality voltage-clamp recordings, so events are measured (as far as possible) at

(Continued)

the same membrane voltage. It also requires the elimination of as many confounding variables (e.g., voltage-dependent conductances that may be imperfectly clamped, and synaptic inhibition) as is practical. Assuming that this has been achieved, a remaining major problem is that unitary EPSCs in hippocampal neurons are very small. As a result, it is difficult to distinguish all of the EPSCs above the background noise. Consequently, estimates of the frequency and amplitude distributions of miniature EPSCs can be inaccurate, and small evoked EPSCs may be misclassified as failures. The technically demanding technique of dendritic recording close to the site of synaptic activation improves the signal-to-noise ratio; using this approach it has been shown that EPSCs at Schaffer commissural synapses can be generated by fewer than five AMPA receptors (Isaac et al., 1998). These very small responses would probably be undetectable with standard somatic recording techniques and so would be misclassified as failures. A second problem is that quantal variance (both inter- and intra-site) is often large, making it difficult to construct clean histograms for quantal analysis.

The second class of problem is how to interpret the parameters that are altered during LTP or LTD. The classical interpretation is that changes in  $n$  or  $Pr$  are due to presynaptic changes, and changes in  $q$  are due to postsynaptic changes. However, even at the neuromuscular junction where quantal analysis was invented and the application used to most powerful effect, it was recognized that these parameters could be interpreted in different ways. For example, an increase in  $q$  could be due to more neurotransmitter contained in a synaptic vesicle. In hippocampal neurons, LTP is often associated with a decrease in the failure rate (Malinow and Tsien, 1990). This was initially interpreted in the classical tradition as an increase in  $Pr$ . However, the failure rate is determined by the product of  $Pr$  and  $n$ , the number of competent synaptic sites. It was subsequently postulated (Kullmann, 1994) and then demonstrated (Isaac et al., 1995; Liao et al., 1995) that a decrease in failures may be due to the unsilencing of silent synapses (see Fig. 10–21A). The idea is that a stimulated afferent fiber may fail to generate a response either because  $Pr = 0$  or because there are no postsynaptic receptors to which transmitter can bind. By awakening these synapses, LTP adds new synaptic sites ( $n$ ) to the equation. There has been much debate as to whether the increase in  $n$  is presynaptic (more functional release sites) or postsynaptic (more synapses with functional receptors), as discussed in Section 10.4; but either way, this alters radically the interpretation of changes in failure rates. The unsilencing of silent synapses during LTP and, conversely, the silencing of synapses during LTD is now a widely documented phenomenon (see Sections 10.4 and 10.7) and needs to be taken into account during any interpretation of analyses of the quantal parameters of LTP. For example, alterations in the frequency of spontaneous mini-EPSCs could reflect changes in  $Pr$  and/or  $n$ , where changes in  $n$  reflect pre- or postsynaptic unsilencing of silent synapses.

Alterations in  $n$ , whether pre- or postsynaptic, can also explain changes in PPF, as in the hypothetical example given above in which a postsynaptic change gives rise to a change in PPF. Conversely, presynaptic changes could occur without a change in PPF (e.g., if LTP were achieved by unsilencing of a population of new release sites with a similar distribution of  $Pr$  to existing sites). Therefore changes in each of the basic electrophysiological parameters of neurotransmission ( $n$ ,  $Pr$ ,  $q$ , PPF) can have more than one, radically different interpretation.

inducing LTP (Davies et al., 1991) (see Section 10.3.1 and Fig. 10–6).

Facilitation and depression necessarily interact. The conditions for facilitation are set in place by the arrival of an action potential at the presynaptic terminal and are independent of whether transmitter release occurs. The same is not true for depression, which is a consequence of transmitter release. Thus, if a pair of action potentials invades the terminal within a few tens of milliseconds, the response to the second action potential is determined by both facilitation and inhibition if the first action potential resulted in transmitter release but is influenced by facilitation alone if the first action potential fails to release transmitter. On the other hand, where release probability is relatively high, thus limiting the scope for facilitation, depression may predominate at all intervals; this appears to be

the case in vitro at synapses of the medial but, interestingly, not the lateral perforant path (McNaughton, 1980; Allen et al., 2000). Another consequence of the interplay between facilitation and depression is the difficulty of predicting how the induction of LTP affects a cell's response to bursts of stimuli. The increased response to single test stimuli conventionally used to monitor synaptic efficacy in LTP experiments is not necessarily a useful predictor of the response that a postsynaptic cell might make to a burst of afferent impulses. For example, an increase in the probability of release as the result of the induction of LTP might, because of paired-pulse depression, lead to a reduction in the probability of release to the second or following stimuli in the burst (Lisman, 1997). However, although Markram and Tsodyks (1996) reported effects of this kind at potentiated synapses in visual cortex,

Selig et al. (1999) did not find a similar redistribution of synaptic efficacy when bursts of stimuli were delivered to potentiated hippocampal synapses; instead, the response to each stimulus of the burst was potentiated.

Paired-pulse facilitation and depression of the population spike can give useful information about feedforward and feedback inhibitory circuits in the hippocampus. If the first of a pair of stimuli is strong enough to evoke a sizable population spike, a brief period of intense GABA<sub>A</sub>-mediated feedback inhibition lasting 10 to 20 ms is generated, during which time a second stimulus of equal or lesser intensity does not evoke a population spike; this gives way to a much longer period of spike facilitation that can be explained by suppression of feed-forward inhibition mediated by presynaptic GABA<sub>B</sub> autoreceptors; this effect peaks at an interstimulus interval of 100 to 200 ms and can last for 1000 ms or longer (Davies et al., 1991).

### **10.2.3 Post-tetanic Potentiation Is the Sum of Two Exponential Components: Augmentation and Potentiation**

Repetitive stimulation of peripheral and central synapses brings into play another transient facilitatory process called post-tetanic potentiation (PTP). At perforant path synapses, a weak high-frequency train leads to a substantial elevation of test responses immediately after the train, which declines back to baseline within a few minutes (Fig. 10–2A). With longer stimulus trains, PTP is superimposed on a background of LTP, and this complicates the analysis of the time course of both phenomena. When suitable controls are conducted, PTP is seen to be the sum of two exponential processes known as *augmentation* and *potentiation* that in the medial perforant path have time constants of 7 s and 2 to 3 minutes, respectively (McNaughton, 1982). The concentration of Ca<sup>2+</sup> in terminal boutons rises during PTP, suggesting that, like facilitation, it is a presynaptic process (Wu and Saggau, 1994; Tang and Zucker, 1997).

## **10.3 NMDA Receptor-dependent Long-term Potentiation: Properties and Determinants**

We begin by discussing the varieties of stimulus protocol that lead to the induction of NMDA receptor-dependent LTP and then explore more fully its properties and characteristics.

### **10.3.1 Long-term Potentiation: Tetanic Stimulation Induces a Persistent Increase in Synaptic Efficacy**

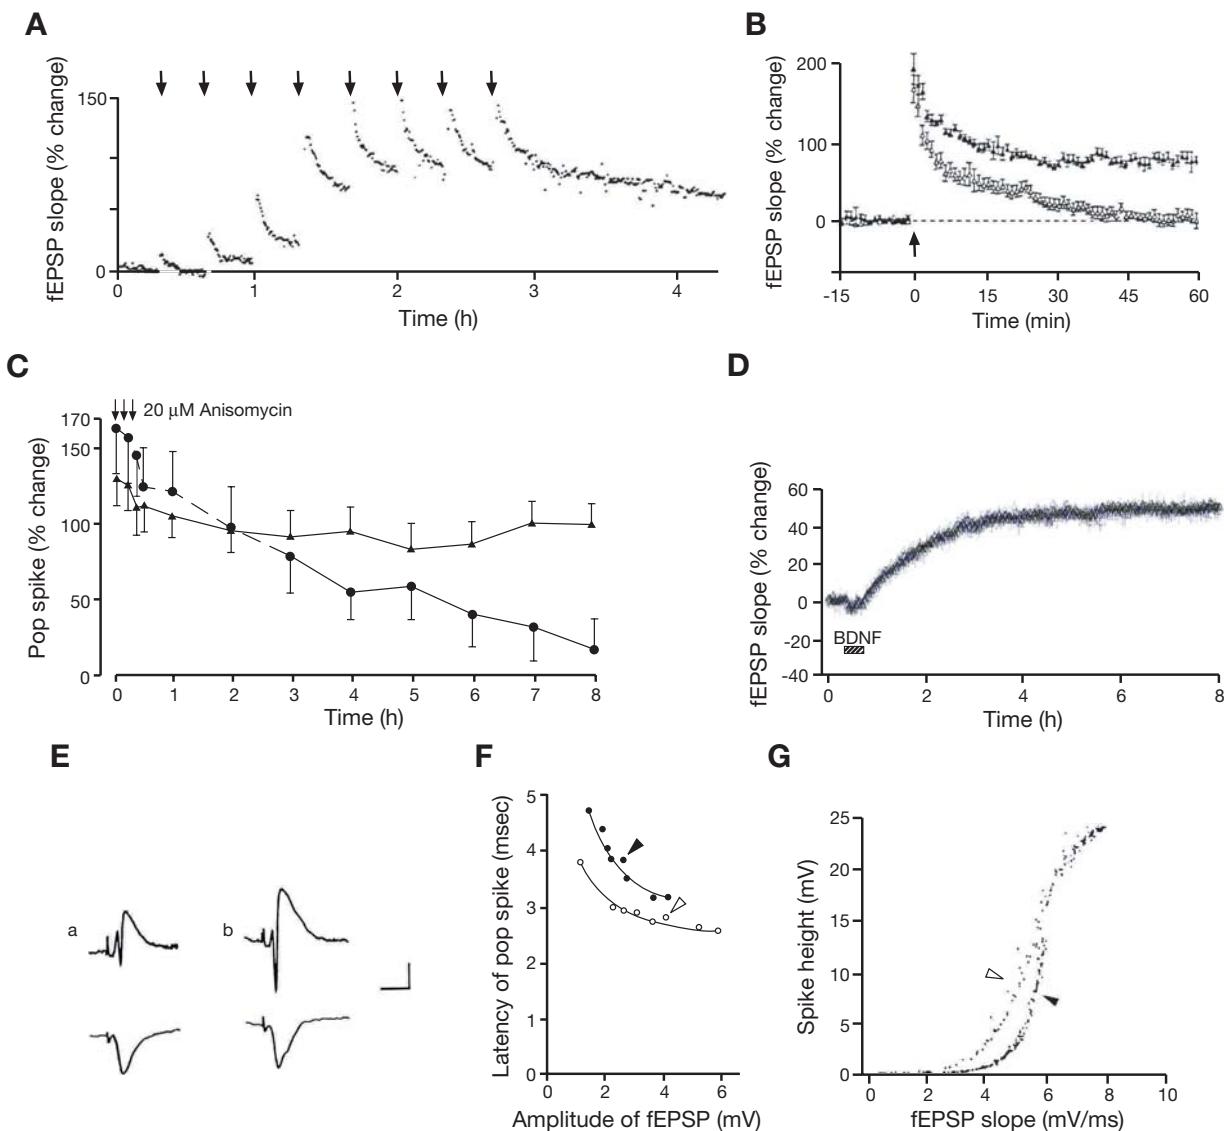

Whether conducted *in vivo* or *in vitro*, a typical experiment on LTP takes the following form. The animal or brain slice is prepared, electrodes are located at the appropriate sites for stimulating and recording, and observations are made to ensure that electrophysiological responses are stable, via a

computer-based system that calculates various measures of field potentials, EPSPs or EPSCs, as appropriate (Bortolotto et al., 2002). Once this preliminary work is complete, the experiment proper progresses through three phases. In the first phase baseline responses are elicited using low-frequency test pulses (e.g., at 30-second intervals) for a period sufficient to ensure stability (the duration of which depends on the type of experiment to be performed but typically is in the range of 10–60 minutes). Sometimes an input-output curve is obtained in which the strength of the stimulation is systematically varied to provide information on the relation between the fiber volley (reflecting the number of fibers activated), the synaptic component of the evoked response (the fEPSP), and the population spike (reflecting the number of cells discharged). The second phase is brief but critical: It is the point at which the stimulated pathway is tetanized or, in the case of most intracellular recordings, the moment when afferent stimulation is paired with postsynaptic depolarization. Common tetanization protocols include one or more trains of pulses at 100 Hz for 1 second per train or patterns consisting of shorter trains arranged in a pattern that contains a theta frequency component (see below). The third phase involves a return to low-frequency stimulation at the same frequency and intensity as was used to measure the baseline; data for further input-output curves may be collected at intervals after tetanization.

In a typical LTP experiment, the response is dramatically amplified following the tetanus. The initial slope of the EPSP rises more steeply, the onset latency of the population spike (if present) is reduced, and its amplitude is often enhanced several-fold. So startling is the transformation that Bliss and Marina Lynch (1988) were moved to confess “no matter how often one has witnessed the phenomenon, it is impossible not to retain a sense of amazement that such modest stimulation can produce so immediate, so profound and so persistent an effect.” The basic phenomenon of LTP is easily elicited and gratifyingly immediate.

It is a common convention to refer to synaptic potentiation as LTP if the potentiated response is maintained without appreciable downward drift for longer than 30 to 60 minutes. This covers only the early phase of LTP, however, and allows the experimenter to say nothing about later phases. In field potential studies, three phases of potentiation can be defined on the basis of susceptibility to drugs. As discussed in more detail below, LTP decays to baseline over a period of 3 to 5 hours when induction takes place in the presence of inhibitors of gene transcription or protein synthesis. Frey and coworkers assigned the name “late LTP” (L-LTP) to the persistent, protein synthesis-dependent phase of LTP; the protein synthesis-independent phase was termed “early LTP” (E-LTP) (Frey et al., 1993). A third, earlier phase that survives protein kinase inhibitors and decays to baseline usually within 30–60 minutes is referred to as “short-term potentiation” (STP).

Originally observed in anesthetized rabbits, hippocampal LTP has since been described in numerous vertebrate species, including rats, guinea pigs, mice, and chicks (Margrie et al.,

**Figure 10-2.** Types of activity-dependent potentiation in the hippocampus. **A.** Post-tetanic potentiation (PTP), lasting for a few minutes, is always induced in the dentate gyrus of the intact animal, even when longer-lasting forms of potentiation are saturated by repeated tetanization. Tetani of increasing intensity were given; note that at the lowest intensity LTP is not induced though PTP is still present. (Source: Bliss et al., 1983.) **B.** Short-term potentiation (STP) in area CA1 in vitro. In the presence of a broad-spectrum protein kinase inhibitor, tetanus-induced potentiation returns to baseline within 30 to 60 minutes (open triangles). After initial PTP, LTP in control medium (filled triangles) persists without further decrement for 60 minutes. (Source: Malenka et al., 1989.) **C.** The protein synthesis inhibitor anisomycin curtails the duration of LTP. The amplitude of the population spike in area CA1 in vitro was monitored after tetanic stimulation in control medium (triangles) or in the presence of anisomycin (circles). **E-LTP**, defined as the component of LTP that is protein synthesis-independent, returns to baseline within 5 to 8 hours. Late LTP is the more persistent component that is blocked by protein synthesis inhibitors. (Source: Frey et al., 1988.) **D.** Transient exposure to brain-derived neurotrophic factor (BDNF) induces a slow-onset late LTP in the dentate gyrus of the anesthetized rat. (Source: Bramham and Messaoudi, 2005.) **E.** LTP of the

population spike without potentiation of the fEPSP. Field potentials recorded in the pyramidal cell layer (upper traces) and stratum radiatum (lower traces) of area CA1 before (left) and 25 minutes after the induction of LTP by an orthodromic/antidromic pairing protocol. Calibration: 10 ms, 2 mV. (Source: Jester et al., 1995.) **F.** The latency of the population spike plotted as a function of the amplitude of the EPSP before (solid circles) and 8 hours after (open circles) induction of LTP by tetanic stimulation of the perforant path (same experiment as in Figure 10-1A). The curve was plotted from responses evoked by a series of stimuli generated at different stimulus strengths. Note that an fEPSP of a given amplitude evokes a population spike with a shorter latency after the induction of LTP than before, demonstrating that LTP consists not only of an increase in the synaptic drive but enhancement of the coupling between synaptic input and cell firing. This latter component is called EPSP-spike (E-S) potentiation. (Source: Bliss and Lømo, 1973.) **G.** Another experiment in which E-S curves were generated before and after the induction of LTP. Here, the amplitude of the population spike is plotted against the EPSP. The curve shifts to the left, reflecting E-S potentiation. (Source: Bliss et al., 1983.) In F, G points indicated by filled and open arrow heads were obtained before and after induction of LTP respectively.

1998), macaque monkeys (Urban et al., 1996), and humans (Beck et al., 2000; reviewed by Cooke and Bliss, 2006).

Long-term potentiation has been subjected to more intense study in the hippocampal formation (particularly the dentate gyrus and CA1 and CA3 pyramidal subfields) than elsewhere in the brain. In addition to the synapses of the tri-synaptic loop (i.e., perforant path to granule cells; mossy fibers to CA3 cells; Schaffer collaterals to CA1 cells), LTP has been observed at associational connections between CA3 cells, the perforant path projections to area CA3 (Do et al., 2002) and area CA1 (Colbert and Levy, 1993), the projections from CA1 to the subiculum (O'Mara et al., 2000), in some but not all excitatory connections onto hippocampal interneurons (Lamsa et al., 2005) and even at synaptic connections made by hippocampal CA1 neurons on a class of macroglia-like cells (Ge et al., 2006). However, the fact that LTP has been observed in birds and reptiles lacking a laminated hippocampal formation raises the possibility that its discovery in the mammalian hippocampus was fortuitous. Although the laminated structure of the hippocampus makes it particularly convenient for the study of LTP, there is no reason to suppose that hippocampal synapses occupy a privileged position in the hierarchy of plasticity. LTP has been described in many other brain regions (Racine et al., 1983), including cerebellum (Crépel and Jaillard, 1991), amygdala (Chapman et al., 1990), sensory cortex (Artola and Singer, 1987), motor cortex (Sakamoto et al., 1987), prefrontal cortex (Laroche et al., 1990), and nucleus accumbens (Kombian and Malenka, 1994). Long-term changes in synaptic efficacy have also been found in sympathetic ganglia (Brown and McAfee, 1982) and in the nociceptive circuitry of the spinal cord (Ikeda et al., 2003).

#### A Wide Range of Stimulus Protocols Can Induce LTP

LTP can be induced by a broad range of stimulus parameters. As first noted by Bliss and Gardner-Medwin (1973) in their study of LTP in awake rabbits, the stimulus intensity during the tetanus must be sufficiently strong. In a systematic study of this effect, McNaughton et al. (1978) gradually increased the intensity of tetanization to reveal that LTP occurred only above what they termed the “cooperativity” threshold. PTP was observed at lower intensities with the response amplitude declining to baseline between successive tetanizations (see example in Fig. 10–2A). Their supposition was that some minimum number of afferent fibers had to be activated for LTP to occur and that thereafter the magnitude of LTP could increase until an asymptote was reached. However, it is now known that activation of some minimum number of fibers is neither a necessary nor a sufficient condition for inducing LTP. Although not indisputably established, it is likely that LTP can be induced by activating a single axon if a target cell of that axon is sufficiently depolarized. In the behaving animal, therefore, there may be circumstances in which individual synapses can be independently potentiated. Nevertheless, cooperativity serves as a reminder that a threshold for LTP, whether expressed in terms of the number of activated axons

or in terms of local dendritic depolarization, does exist and has important consequences for network behavior. First, network stability is less at risk from unrestricted increases in excitatory drive; second, the cooperativity threshold may act as filter, restricting access to long-term storage to those neural signals with a sufficiently high information content.

The magnitude and duration of LTP is also a function of tetanus intensity. If a tetanus that is suprathreshold for LTP is repeated, it may induce a further increment of LTP when repeated some time later (Bliss and Lømo, 1973), suggesting that at the level of the single synapse LTP may be incremental rather than all-or-none. Eventually, however, LTP becomes saturated, and tetanic stimulation produces no further effect. Clearly, the response to identical episodes of tetanic stimulation depends on the history of the network, and this has given rise to the concept of metaplasticity (see below). The maximal level of synaptic efficacy a given pathway can reach is not necessarily attained when LTP is apparently saturated. In the first place, PTP can transiently elevate the response above the existing level. Furthermore, if an interval of several hours is allowed to elapse after saturating tetanic stimulation, additional potentiation can be elicited with a further tetanus, even if there has been no decrement in the response during the intervening period (Frey et al., 1995).

The stimulus patterns used to elicit LTP have varied widely among laboratories, ranging from brief trains at 400 Hz (Douglas and Goddard, 1975) to single stimuli of high intensity repeated at 1 Hz in the presence of picrotoxin (Abraham et al., 1986). Probably the most commonly used protocol is a single train of 100 Hz for 1 second. Two other widely used protocols are primed-burst stimulation (PBS) and theta-burst stimulation (TBS), in which the common feature is an interval of 200 ms, either between a priming stimulus and a brief burst of stimuli in the case of PBS (Larson and Lynch, 1986), or between a succession of brief trains in TBS (Rose and Dunwiddie, 1986). It may not be coincidental that 200 ms is close to the periodicity of the theta rhythm (an endogenous hippocampal rhythm generated during movement—see Chapter 11). In most cases, it is probably true to say that the choice of protocol favored by a particular laboratory relies more on tradition than any clearly demonstrated superiority. In a parametric study of induction protocols in which theta-burst stimulation was compared with simple trains of high-frequency stimulation, Hernandez et al. (2005) concluded that the major factor controlling the magnitude of LTP is the number of stimuli in a train rather than the pattern of stimulation. High-frequency trains can be used to induce LTP in cell populations or single cells. In the latter case, two other protocols for inducing LTP are available: pairing, and spike timing. With the former, single stimuli repeated at low frequency are paired with depolarizing pulses that induce brisk firing of the recorded cell (Abraham et al., 1986; Kelso et al., 1986). With spike timing-dependent potentiation (STDP), the pairing is between the afferent stimulus and a brief depolarizing pulse that fires the target cell only once. The latter protocol allows the timing between pre- and postsynaptic firing to be con-

trolled with some precision and has led to the important observation that LTP occurs only when the presynaptic impulse precedes the firing of the target cell; when the opposite relation obtains, the result is LTD rather than LTP (Bi and Poo, 1998) (see Section 10.3.8).

The reason for the effectiveness of the prime-burst or theta-burst procedure has been clarified (Davies et al., 1991). The priming stimulus (or initial brief train) activates feedforward GABA interneurons, leading to GABA<sub>A</sub>- and GABA<sub>B</sub>-mediated hyperpolarization in the pyramidal cell but, importantly, also to activation of presynaptic GABA<sub>B</sub> autoreceptors. The latter produce a transient reduction in GABA release that is maximal at around 100 to 200 ms. Thus the second train produces much less GABA-mediated hyperpolarization with consequent enhancement of the voltage-dependent NMDA receptor-mediated current. Minimal patterns of stimulation of this kind are far more likely to occur naturally than the longer trains of tens or hundreds of stimuli (e.g., 100 Hz for 1 second) that are frequently used for reasons of convenience and custom. Hippocampal pyramidal neurons can and do fire in high-frequency bursts, although it remains to be established whether LTP is induced by naturally occurring patterns of activity in the freely moving animal (Buzsaki, 1987) (see Chapter 8, Section 8.4 for a further discussion of this point).

### 10.3.2 Time Course of LTP: Rapid Onset and Variable Duration

How quickly after a tetanus is LTP induced? The time course of the onset of LTP is difficult to measure because it is confounded by the extremely rapid onset of PTP. By studying PTP in isolation using trains subthreshold for LTP or in the presence of AP5, which blocks the induction of LTP without affecting PTP, and by making the assumption that LTP and PTP are independent processes, it is possible to dissect out the two processes (McNaughton, 1980; Gustafsson et al., 1989). In CA1 *in vitro*, LTP begins within 2 to 3 seconds of the tetanus, peaks within 30 seconds, and then declines for 10 to 20 minutes to a lower, more stable value. In the dentate gyrus, LTP takes longer (1–2 minutes) to reach its peak (Hanse and Gustafsson, 1992). Estimates are confounded, however, by the possibility that onset kinetics are modulated by the test stimulus given to sample synaptic responses.

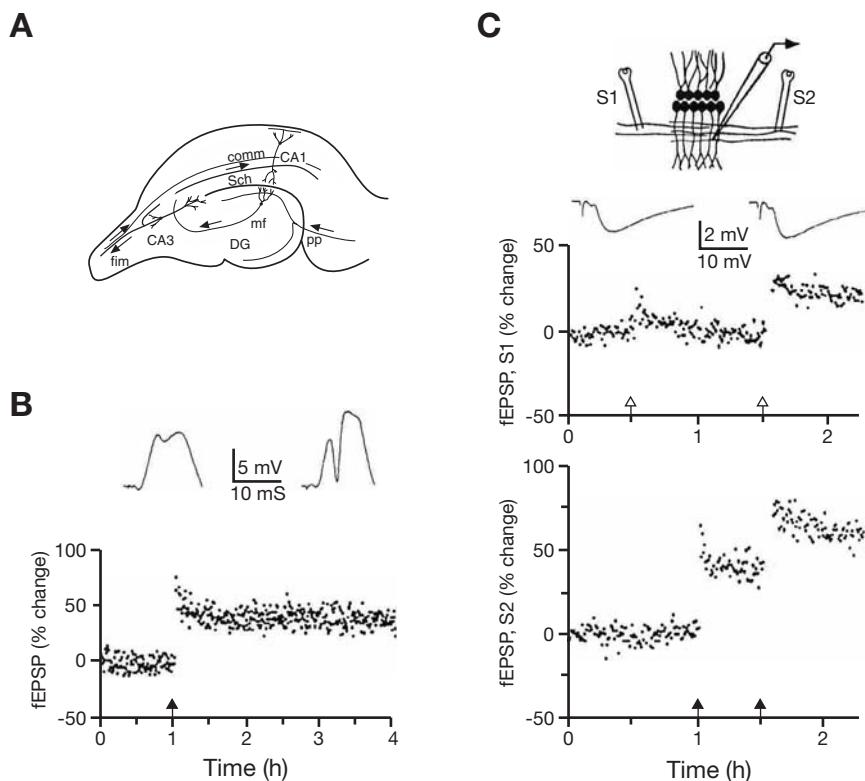

How long does LTP last? This is a question of obvious significance but one to which no simple answer can be given. A short answer is that LTP shows variable persistence. The duration of the effect depends on the parameters of the tetanus, the type of preparation, and the region of the hippocampus. In both hippocampal slices and anesthetized animals, the maximal duration of LTP is obviously limited to the lifetime of the preparation. In the intact animal, time constants as short as a few days (Racine et al., 1983) and as long as 73 days (Doyère and Laroche, 1992) to more than a year (Abraham, 2003) have been reported for the dentate gyrus. Fewer experiments have been carried out in area CA1 *in vivo*, but it

has been claimed that LTP in this region is sometimes nondecremental (Staubli and Lynch, 1987). Later, we discuss mechanisms responsible for modulating the persistence of LTP. Intriguingly, the decay of LTP may be an active process, as in the dentate gyrus LTP is prolonged if an NMDA receptor antagonist is given after induction (Villarreal et al., 2001).

Can all excitatory synapses onto principal cells in the hippocampus be potentiated? Not all attempts to induce LTP between pairs of cells using a pairing induction protocol or between a presumed single axon and a target cell have been successful. However, this may reflect an unhealthy or dialyzed cell or an inappropriate stimulus protocol for that synapse. Based on results of attempting to induce LTP by a pairing protocol using minimal stimulation to activate one or at most a few synapses in area CA1, Petersen et al. (1998) estimated that between 45% and 75% of excitatory synapses in area CA1 can be potentiated, a proportion low enough to raise suspicions that not all such synapses are potentiable. A similar conclusion was reached by Debanne et al. (1999), working with pairs of interconnected cells in organotypic hippocampal cultures. In their sample, 24% of unitary EPSPs (a term here used to cover the multiple connections that a CA3 cell in organotypic culture may make with a target CA3 or CA1 cell) could not be potentiated. Unpotentiable connections may represent synapses at which LTP has been saturated and that might therefore be more susceptible to LTD-inducing stimulation, but 63% of nonpotentiable connections in the experiments of Debanne et al. (1999) could not be depressed either. These studies suggest that there is a small proportion of excitatory synapses on hippocampal pyramidal cells, perhaps 10% to 20% of the total, that do not exhibit synaptic plasticity.

### 10.3.3 Three Distinct Temporal Components of Potentiation: STP, Early LTP, Late LTP

Broad-spectrum protein kinase inhibitors curtail the duration of potentiation to an hour or so (e.g., Lovinger et al., 1987; Malenka et al., 1989; Malinow et al., 1989 Matthies and Reymann, 1993; see also reviews by Soderling and Derkach, 2000; Lisman et al., 2002; Nguyen and Woo, 2003) (Fig. 10–2B and Section 10.4.3). In the presence of protein synthesis inhibitors such as emetine or anisomycin, or transcription inhibitors such as actinomycin, the potentiated response in area CA1 of hippocampal slices returns to baseline within 5 to 6 hours (Frey et al., 1988) (Fig. 10–2C). From these findings emerged the defining characteristics of early and late LTP (E-LTP and L-LTP) as protein kinase-dependent and protein synthesis-dependent, respectively. Note that this leaves a component of LTP, usually lasting less than an hour, referred to as short-term potentiation (STP). STP is NMDA receptor-dependent but depends neither on protein synthesis nor, in general, on protein kinase activity (Fig. 10–2B). Weak stimulus trains sometimes produce E-LTP without L-LTP, but no stimulus protocols have been identified that produce L-LTP without the preceding phase of E-LTP. However, as we shall

**Figure 10-3.** Induction properties of LTP: cooperativity, input specificity, and associativity. *A*, Diagram of a transverse section through hippocampus showing principal excitatory connections. *B*, LTP induced by a tetanus (250 Hz for 200 ms) to the perforant path in an anesthetized rat. Field responses recorded in the granule cell layer before and after the induction of LTP are shown above. *C*, Input specificity and associativity demonstrated using a two-pathway protocol in area CA1 in vitro. Stimulating electrodes S1 and S2 are placed in the stratum radiatum on either side of a recording electrode to excite two independent sets of axons. The

slope of the fEPSP evoked by test stimuli to S1 and S2 are plotted in the two panels below the diagram of the recording arrangement. The intensity of the tetanus delivered via S1 is set below the cooperativity threshold for LTP, so only PTP is elicited (upper panel). At 1 hour a strong tetanus is given to S2, inducing robust LTP. Note that the response to S1 is unchanged: LTP is input-specific. However, when a weak tetanus to S1, which by itself is ineffective, is combined with a strong tetanus to S2, LTP is induced in both inputs. This is the property of associativity. (Source: Bliss and Collingridge, 1993.)

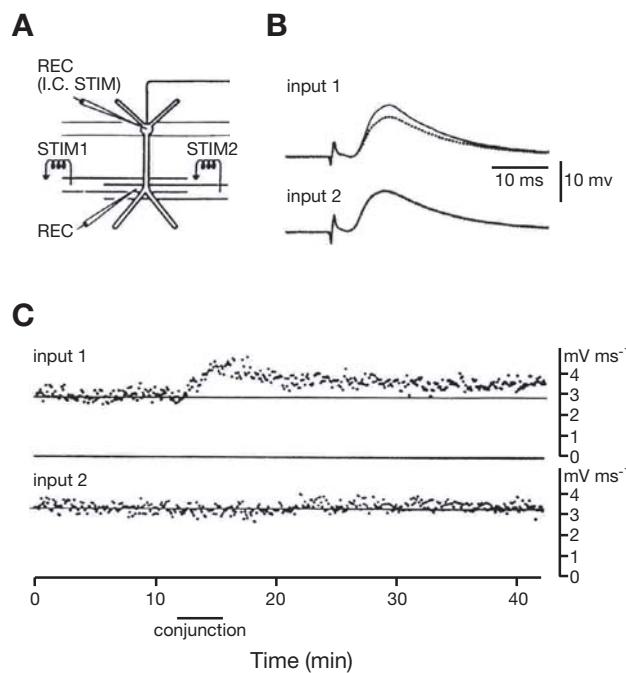

see in Section 10.4.9, late-onset, protein synthesis-dependent potentiation can be induced by applying activators of PKA to area CA1, or brain-derived neurotrophic factor (BDNF) to the dentate gyrus (Fig. 10-2D).

#### 10.3.4 Input-Specificity of LTP: Potentiation Occurs Only at Active Synapses

Compelling evidence for input specificity was first obtained in area CA1 of the hippocampal slice in experiments using two stimulating electrodes positioned to activate two sets of fibers converging on the same cell population (Andersen et al., 1977; Lynch et al., 1977). Tetanization of either pathway resulted in potentiation specific to that pathway. This outcome is true whether one stimulating pathway is in the stratum oriens and the other in the stratum radiatum, or both pathways are in the same stratum. The two-pathway design, which has made an important contribution to physiological studies of LTP, exploits the fact that most fibers travel at an angle to the plane

of the slice. Thus, stimulating electrodes positioned on either side of the target neuron (in single-cell studies) or of a population of neurons (in field recordings) activate a nonoverlapping set of axons projecting to the same target cell(s) (Fig. 10-4).

Input specificity at the relatively crude level of two-pathway experiments does not imply specificity at the level of single synapses. To demonstrate the latter, it will be necessary to monitor the activation of neighboring synapses. Optical methods offer the best chance of achieving this, but the relevant experiments have not yet been done. Even so, experiments can be conducted to investigate whether the expression of LTP is restricted to the synapses at which it is induced. Two ingenious electrophysiological studies, one by Haley et al. (1996) and the other by Engert and Bonhoeffer (1997), suggest that synapse specificity breaks down within a radius of a few tens of microns of a site of potentiation, regardless of whether synapses are on the same target cell or are active at the time of potentiation.

**Figure 10-4.** LTP as a Hebbian mechanism. The repeated pairing of single stimuli with depolarization of the membrane potential is sufficient to induce LTP. *A*, Experimental arrangement, with two independent afferent pathways and an intracellular electrode to record evoked EPSPs and through which current can be passed to depolarize the membrane potential. *B*, Examples of EPSPs before and after the induction of LTP in input 1. Note that there is no change in input 2. *C*, Plots of the response evoked by test stimuli delivered alternately at an interval of 3.5 seconds to S1 and S2. During the period indicated by the bar (“conjunction”), the stimulus to S1 was followed 7 ms later by a 400-ms depolarizing pulse that elicited a burst of cell firing. The pairing of single stimuli and depolarization induced an increase in the EPSP that reached a maximum within 20 to 30 pairings and persisted, with some initial decay, for the rest of the recording session. The response to the second pathway was unaffected. (Source: Wigström et al., 1986.)

### 10.3.5 Associativity: Induction of LTP Is Influenced by Activity at Other Synapses

Associativity, a defining property of LTP, was discovered by McNaughton et al. (1978), and independently by Levy and Steward (1979) who introduced the term in the context of LTP. In both cases, interactions between two afferent pathways in the dentate gyrus of the anesthetized rat were examined. McNaughton and his colleagues compared cooperativity in the medial and lateral perforant path projections to the ipsilateral dentate gyrus; they found that when weak tetani were given simultaneously to the medial and lateral branches of the perforant path, LTP was induced in both pathways, though each tetanus, when given separately, was below the cooperativity threshold. Levy and Steward investigated the properties of the crossed perforant path. The latter is a weak projection containing few axons that projects from the entorhinal cortex

to the molecular layer of the contralateral dentate gyrus. Tetanic stimulation of the weak crossed pathway was incapable of inducing LTP when given alone; but if given at the same time as a tetanus to the strong ipsilateral perforant pathway, LTP was induced in both ipsilateral and contralateral pathways (see Fig. 10-17A). This experiment demonstrated that activity at one input has the potential for promoting plasticity at another active input—in other words that LTP is associative. Levy and Steward argued that the associative property of LTP was a desirable feature of “memory elements in the hippocampal formation.” These two sets of experiments also made it clear that the distinction between cooperativity and associativity is essentially semantic. Cooperativity can be thought of as an associative interaction between the afferent fibers accessible to a single stimulating electrode. Associativity was subsequently observed at the intracellular level in the hippocampal slice using a two-pathway design (Barrionuevo and Brown, 1983).

These early experiments did not distinguish between associative interactions occurring presynaptically and postsynaptically. One possibility was that cooperativity and associativity reflected the requirement for sufficient depolarization of the target cells. As already noted, experiments demonstrating that inhibition of granule cells by commissural afferents could suppress the induction of LTP, suggested to Goddard and his colleagues that the postsynaptic cell provided the “locus of control” for LTP (Douglas et al., 1982). In 1986 Wigström, Gustafsson and their coworkers (Wigström et al., 1986), and independently two other groups (Kelso et al., 1986; Sastry et al., 1986), confirmed in spectacular fashion that LTP in area CA1 could be induced by the simple expedient of repeatedly pairing single stimuli to Schaffer-commissural fibers with a depolarizing pulse generating multiple spikes in the impaled cell (Fig. 10-4). The explanation for the efficacy of this procedure became clear when it was shown that it enabled NMDAR-mediated responses to be evoked by single stimuli (Collingridge et al., 1988). Pairing single stimuli with iontophoretic application of glutamate was similarly effective at inducing LTP (Hvalby et al., 1987). By varying the time between the stimulus and the onset of the depolarizing pulse, the time window for associative interaction could be studied. The maximum effect occurred when the stimulus was given at the beginning of the 100-ms depolarizing pulse; the degree of potentiation declined to zero when the interval between this single stimulus and the onset of the depolarizing pulse was longer than 100 ms and no potentiation occurred if the afferent stimulus was given after the depolarizing pulse (Gustafsson et al., 1987). Extracellular experiments in the dentate gyrus (Levy and Steward, 1983) and in area CA1 (Gustafsson and Wigström, 1986; Kelso et al., 1986), using a two-pathway protocol with one “weak” and one “strong” input also showed that associative potentiation of the weak pathway requires near-coincidence of weak and strong inputs, with potentiation occurring if the weak immediately precedes the strong input but not if the strong precedes the weak input.

The timing requirements for coincident pre- and postsynaptic activity that emerged from these early experiments are somewhat less constrained than those that have more recently been characterized in the context of spike timing-dependent plasticity (STDP) (see Section 10.3.8).

Because of its potential for strengthening co-active inputs, the property of associativity lies at the heart of the role that LTP is likely to play in memory functions of the hippocampus. Note that cooperativity, associativity, and input specificity can all be explained on the assumption that the induction of LTP at a given synapse requires presynaptic activity with coincident activation of the postsynaptic neuron. This is very close to the criterion that Hebb proposed for the enhancement of synaptic strength in hypothetical neural circuits mediating associative conditioning (Hebb, 1949). Consequently, hippocampal synapses displaying associative LTP are often referred to as “Hebb synapses.” In the next section we explore the Hebbian nature of LTP in more detail.

#### 10.3.6 Requirement for Tight Coincidence of Presynaptic and Postsynaptic Activity Implies a Hebbian Induction Rule

There is convincing evidence that the induction of LTP in the Schaffer-commissural projection in area CA1 is indeed Hebbian in nature. In the first place, the postsynaptic cell plays an obligatory role in induction, as first revealed in experiments showing that LTP could be blocked by injecting the calcium chelator EGTA into the postsynaptic cell (Lynch et al., 1983) (Fig. 10–5B) or by hyperpolarizing the postsynaptic neuron (Malinow and Miller, 1986). In later work, Malenka et al. (1992) used a caged form of the calcium chelator 1,2-bis(aminophenoxy)ethane-*N,N,N',N'*-tetraacetic acid (BAPTA), in which BAPTA is bound as an inactive but photolabile

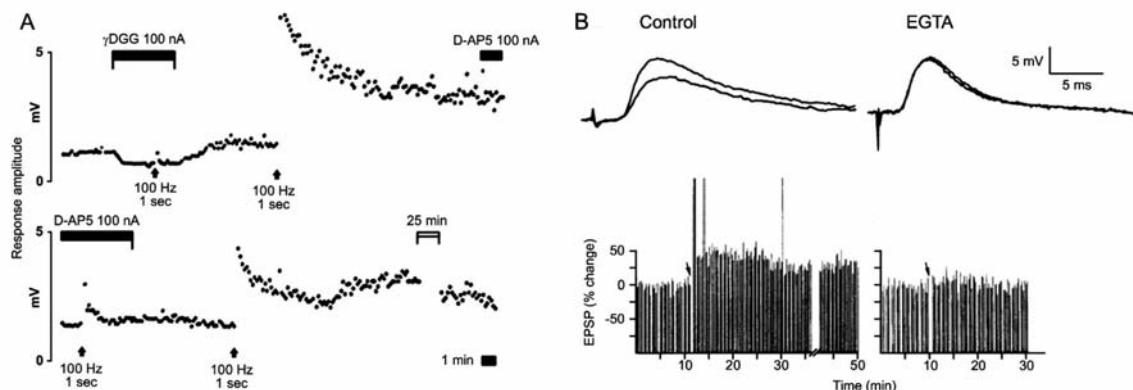

molecular complex, from which it can be rapidly released by a flash of ultraviolet light, to establish that the obligatory rise in calcium is confined to a window of less than 2.0 to 2.5 seconds following the tetanus. Second, as we have seen, LTP can be induced by the repeated conjunction of single (Wigström et al., 1986) or multiple (Kelso et al., 1986; Sastry et al., 1986) afferent volleys with strong depolarizing pulses applied through an intracellular electrode. In the latter experiments, the relatively long depolarizing pulses produced multiple spikes falling on either side of the single afferent stimulus. Later work by Magee and Johnston (1997), Bi and Poo (1998), and others established that LTP in the hippocampus, as in neocortex (Markram et al., 1997), can be induced by repeated pairing of an afferent stimulus with a single back-propagating action potential, provided the EPSP precedes the action potential by less than ~10 ms (STDP) (reviewed in Dan and Poo, 2004) (see Section 10.3.8).

#### Is Postsynaptic Spiking Necessary for LTP?

Hebb’s postulate implies that the postsynaptic cell must fire for changes in synaptic weight to occur. There are several types of plasticity where this is not the case (for example, as we shall see, mossy fiber LTP, heterosynaptic LTP and LTD, mGluR-dependent LTD), and firing may not be necessary for LTP even at the canonical Hebbian synapse, the Schaffer-commissural projection to hippocampal CA1 pyramidal cells. Many protocols for inducing LTP in this pathway do fire the postsynaptic cell (for example, STDP and some though not all forms of pairing), but with tetanic stimulation the target cell may fire only to the first stimulus of the train or not at all (for review see Linden, 1999). Moreover, pairing-induced LTP is not blocked by intracellular injection of lidocaine derivatives such as QX-314 that block spiking (Kelso et al., 1986; Gustafs-

**Figure 10–5.** The induction of LTP requires activation of NMDA receptors and postsynaptic  $\text{Ca}^{2+}$  signaling. A. A plot of synaptic response versus time to show that the broad spectrum glutamate receptor antagonist  $\gamma$ -D-glutamylglycine ( $\gamma$ DGG), applied to the synaptic region by microiontophoresis, depresses synaptic transmission and blocks induction of LTP. In contrast, D-2-amino-5-phosphonopentanoate (D-AP5) has no effect on pre-established LTP but blocks its induction. A single tetanus (100 Hz, 1 second) was delivered at the points indicated by arrows. The stimulus inten-

sity was reduced between the time-course plots shown in the upper and lower sections of the figure. (Source: Collingridge et al., 1983.) B. Intracellular recordings showing superimposed EPSPs before and after induction of LTP under control conditions (left) and the block of LTP induction when the intracellular electrode contained the  $\text{Ca}^{2+}$  buffer EGTA (right). Plots of the change in EPSP amplitude over time from a control and an EGTA-filled cell are also shown. A tetanus was delivered at the times indicated by small arrows. (Source: Lynch et al., 1983.)

son et al., 1987). According to Thomas et al. (1998), intracellular QX-314 prevents LTP induced by low-frequency theta trains but has no effect on the efficacy of high-frequency trains. Primed burst stimulation can readily induce LTP in area CA1 in vitro at stimulus strengths that are below threshold for spike firing (Davies et al., 1991). In some circumstances, even low-frequency trains can induce LTP without firing the postsynaptic cell (Krastenikov et al., 2004; but see Pike et al., 1999). LTP can also be induced by repetitive pulses of glutamate targeted by two-photon excitation of a caged precursor to a single spine, a protocol that does not fire the postsynaptic cell and is on the face of it entirely lacking in associative credentials (Matsuzaki et al., 2004). In contrast, STDP, which may or may not be the usual mechanism by which synaptic weights are modified *in vivo*, is defined by a requirement for postsynaptic spiking. Indeed, STDP is the very cynosure of Hebbian plasticity; not only does it require tight temporal contiguity of presynaptic and postsynaptic firing, but the back-propagating spike provides the associative signal that informs dendritic synapses that the postsynaptic cell has fired. However, even here, in Hebb's heartland, locally generated and spatially restricted spiking can, in distal dendrites, take the place of a back-propagating action potential (Golding et al., 2003). It seems safe to conclude that postsynaptic somatic action potentials are not an absolute requirement for LTP at Schaffer-commissural synapses, at least *in vitro*. Whether a strict Hebbian conjunction of pre- and postsynaptic spiking is the norm *in vivo* remains to be seen (Lisman and Spruston, 2005).

In summary, although it is experimentally possible to bypass the postsynaptic action potential, it may be that in a physiological context the only way that sufficient depolarization can be obtained is by postsynaptic firing, as postulated by Hebb. To the extent that it is the idea of sufficient depolarization, however produced, that is critical for NMDA receptor activation, the strict form of the Hebbian coincidence rule can be relaxed slightly without compromising its spirit: It is the coincidence, within a narrow time window of firing in the presynaptic cell with *sufficient depolarization* in the postsynaptic cell, that is the criterion for the induction of LTP. These considerations allow us to formulate a Hebbian induction rule for associative synaptic potentiation at excitatory synapses on CA1 pyramidal and dentate granule cells:

*A synapse will be potentiated if, and only if, it is active at a time when its dendritic spine is sufficiently depolarized.*

It is easy to see—and is an instructive exercise for the reader to confirm—that this rule accounts for the properties of cooperativity, input specificity, and associativity.

### 10.3.7 Molecular Basis for the Hebbian Induction Rule: Voltage Dependence of the NMDA Receptor Explains Cooperativity, Input Specificity, and Associativity

Perhaps the most remarkable advance to date in understanding the cellular mechanisms responsible for LTP has been

elucidation of the role of the NMDA receptor in its induction. The first indication of the importance of this subtype of glutamate receptor came in 1983, when it was found that a specific NMDA receptor antagonist, D(-)aminophosphopen-tanoic acid (D-AP5) (Davies et al., 1981), blocked induction of LTP in area CA1 of the hippocampal slice (Collingridge et al., 1983) (Fig. 10–5A). Because AP5 does not affect the response to single stimuli, the NMDA receptor is not involved in any obvious way in the mediation of synaptic transmission at low frequencies (see Chapter 6). Moreover, AP5 does not block LTP once it is induced, indicating that the effect of the drug is on the induction, rather than the expression, of LTP. The finding that blockade of the NMDA receptor suppresses the induction of LTP has been confirmed using other competitive NMDA antagonists (Harris et al., 1984), the use-dependent noncompetitive antagonist MK-801 (Coan et al., 1987) and the glycine site antagonist 7-chlorokynurenic acid (Bashir et al., 1990). Independent confirmation that the NMDA receptor is necessary for LTP has been provided by studies on genetically engineered mice. Particularly convincing evidence came from experiments in which the cre-lox technique was used to delete genes in a cell-type and region-specific way (see Section 10.10). Tsien et al. (1996), for example, created mice harboring a deletion of NMDAR1 (the obligatory subunit of the NMDA receptor) in area CA1 but not in the dentate gyrus. Slices from these animals showed no LTP in CA1 but normal LTP in the dentate gyrus. In site-directed mutagenesis experiments, Sprengel et al. (1998) created mice in which the intracellular carboxy terminus of the NMDA receptor was deleted. The inability of these mutants to display LTP despite unaltered  $\text{Ca}^{2+}$  current through the mutant receptor indicates that the NMDA receptor plays a further role in the genesis of LTP, downstream of its function as a  $\text{Ca}^{2+}$ -permeable ionophore.

An explanation of how NMDA receptors trigger the induction of LTP quickly followed the discovery of their critical role in the process. It was already known that NMDA receptor-mediated responses are potently blocked by  $\text{Mg}^{2+}$  in spinal cord neurons (Evans et al., 1977). In addition, MacDonald and Wojtowicz (1980) had discovered that, in contrast to all other known ligand-gated ion fluxes, NMDA receptor-mediated responses are strongly voltage-dependent. The key observation that made everything clear was the discovery in 1984 that the voltage dependence was caused by the  $\text{Mg}^{2+}$  block (Mayer et al., 1984; Nowak et al., 1984). At resting membrane potential, glutamate or other NMDA receptor ligands induce negligible inward current through the channel associated with the NMDA receptor. With increasing depolarization,  $\text{Mg}^{2+}$  ions are driven from the channel, and an inward current carried by  $\text{Na}^+$  and  $\text{Ca}^{2+}$  develops.

It was quickly realized that the dual ligand and voltage dependence of the NMDA receptor response offers an elegant molecular mechanism for both the induction of LTP (Collingridge, 1985) and the properties of associativity and input specificity (Wigström and Gustafsson, 1985). Two conditions must be met for an NMDA receptor-mediated response

to be generated: presynaptic activity to release glutamate and strong postsynaptic depolarization to relieve the  $Mg^{2+}$  block of the NMDA receptor channel. These are just the conditions that, as we saw in the previous section, are required for the induction of LTP. Because  $Ca^{2+}$  is required for the induction of LTP (Lynch et al., 1983), and because activated NMDA receptor channels, unlike most ionotropic AMPA receptor channels, are highly permeable to calcium (MacDermott et al., 1986; Jahr and Stevens, 1987, 1993), it seems reasonable to conclude that the trigger for the induction of LTP is the entry of calcium ions through the channel associated with the NMDA receptor.

Although activation of NMDA receptors is a necessary condition for the induction of a major component of LTP at Schaffer-commissural and perforant path synapses, it is not, or at least not always, a sufficient condition. NMDA alone can induce short-term potentiation Collingridge et al. (1983), but neither NMDA (Kauer et al., 1988) nor glutamate (Hvalby et al., 1987), when applied alone to hippocampal slices, readily induces long-lasting potentiation. This result does not sit easily with a purely postsynaptic model of the induction and expression of LTP but is consistent with models in which the expression of LTP is dependent, in part, on presynaptic mechanisms. Alternatively, other postsynaptic signaling pathways, such as mGluRs, may be necessary co-triggers. In addition, the way in which NMDA receptors are activated may be a critical factor, as more prolonged application of NMDA receptors tends to induce LTD or depotentiation, which could mask or obliterate any underlying potentiation. Photolysis of caged glutamate combined with depolarization does, however, produce long-lasting potentiation of the responses of single spines in organotypic culture to test pulses of uncaged glutamate (Bagal, et al., 2005). Thus, in this preparation, NMDA receptor activation is sufficient to induce a postsynaptic component of LTP.

#### **Role of NMDAR subtypes in LTP.**

There is evidence that specific NMDAR subtypes are involved in LTP. A role for NR2A-containing NMDARs was suggested in experiments in which the NR2A subunit was knocked out (Sakimura et al., 1995). These animals still exhibited LTP but its magnitude was reduced to approximately half of that seen in wildtypes. This may reflect developmental consequences of the knockout but subsequent pharmacological experiments have also suggested a role for different NR2 subtypes in LTP. For example, LTP was found to be more sensitive to NR2A/2B selective antagonists, whilst LTD was more sensitive to NR2C/D selective antagonists (Hrabetova et al., 2000). This differential sensitivity suggested a role for NR2A and/or NR2B receptors in LTP. Sorting out the relative roles of NR2A and NR2B-containing receptors has proved difficult and may be confounded by the existence of triheteromers that comprise both NR2A and NR2B subunits, in addition to the obligatory NR1 subunit. An NR2A selective antagonist, NVP-AAM077, inhibits LTP (Liu et al., 2004; Berberich et al., 2005). However, the selectivity of this compound versus the other

four subunits is rather narrow (Feng et al., 2004). NR2B antagonists are much more selective, but highly variable results have been reported ranging from complete block of LTP (Barria and Malinow, 2005) to no effect on LTP (Liu et al., 2004a). Further work is clearly required to establish the relative roles of the different NR2 subunits in LTP.

#### **10.3.8 Spike Timing-dependent Plasticity (STDP)**

Explicit in Hebb's postulate is the notion of causality: Presynaptic cell A must "repeatedly or persistently take part" in firing postsynaptic cell B. In a Hebb synapse, therefore, an increase in synaptic weight occurs only when the presynaptic cell fires shortly before the postsynaptic cell. If induction is mediated by the postsynaptic cell, this condition may be expressed as a requirement that the synaptically generated current should begin before, but overlap with, the firing of the postsynaptic cell. In practice, given the time course of excitatory EPSCs (and, in particular, of the NMDA receptor-mediated component of the EPSC), this interval may extend to a few tens of milliseconds. Early experiments on associative LTP using "weak" and "strong" inputs to the dentate gyrus suggested that LTP satisfies these requirements for temporal contiguity (Levy and Steward, 1983). The weak pathway was potentiated only if it was active within 20 ms of activation of the strong pathway. Moreover, if the order of activation was reversed, with the weak input stimulated up to 20 ms after the strong input, LTD was induced (Levy and Steward, 1983). As discussed above, other two-pathway studies using intracellular recording confirmed the importance of temporal contiguity in pre- and postsynaptic spiking for the induction of LTP (Gustafsson and Wigström, 1986; Kelso and Brown, 1986; reviewed in Bi and Poo, 2001).

In two of the conventional ways to induce LTP—tetanic stimulation and low frequency pairing of presynaptic stimuli with trains of postsynaptic spikes induced by a depolarizing pulse—the precise temporal relation between pre- and postsynaptic spiking is not straightforward. During a tetanus at 100 Hz, firing of the postsynaptic cell rapidly accommodates, and the number of coincident action potentials in pre- and postsynaptic cells is limited. During pairing, there is generally only one presynaptic spike and multiple firing of the postsynaptic cell. In 1994, Stuart and Sakmann demonstrated unequivocally that the action potential in cortical pyramidal cells propagates back into the dendritic tree (Stuart and Sakmann, 1994). This discovery identified an associative signal at the synapse that could link presynaptic and postsynaptic firing and initiated a period of intense study into the effects of varying the timing between presynaptic firing and the back-propagating action potential. The first synapses to be investigated were local excitatory connections between cortical pyramidal cells (Markram et al., 1997). Potentiation was achieved when the presynaptic spike preceded the postsynaptic spike, with maximal potentiation at near-zero intervals, and the degree of potentiation declining with longer intervals; at delays greater than 20 ms no effect was seen. When postsy-

naptic firing preceded presynaptic firing, the effect was reversed and LTD was induced; again the maximum effect was seen at the shortest post-pre intervals, declining to zero over 20 ms. STDP—the term was introduced by Song et al. (2000)—has also been extensively studied in the hippocampus (Bi and Poo, 1998; Debanne et al., 1998; reviewed by Bi and Poo, 2001 and Lisman and Spruston, 2005) (see Fig. 10–19C,D, below). In dissociated hippocampal cultures, the STDP function relating magnitude and direction of plasticity to the interval between the pair of pre- and postsynaptic spikes is antisymmetrical (Fig. 10–19D), as it is in cortical pyramidal cells. In acute slices, however, the function is more symmetrical, with two intervals of depression flanking the region of potentiation (Nishiyama et al., 2000) (see Section 10.7.3).

The STDP function predicts the polarity and magnitude of change to a single pair of action potentials, one in the presynaptic cell and the other in the postsynaptic cell. How does the computation scale up when trains of spikes are considered? In the simplest case, any two trains in the two connected cells can be considered as sets of pairs, with each of the  $n_1$  action potentials in one train paired with each of the  $n_2$  action potentials in the other train, forming a total of  $n_1 \times n_2$  pairs. The STDP function can be used to compute the effect on plasticity for each pair independently and the total effect calculated by summing the contribution to synaptic weight contributed by each pair. Providing the STDP function has a bias in favor of depression (i.e., the integral of the post-before-pre function exceeds that of the pre-before-post function), a stable network evolves in which inputs that are biased toward firing the postsynaptic cell are strengthened at the expense of those that are not (Song et al., 2000). However, experiments in the visual cortex suggest that spike pairs do not combine independently in this way, and that the first spike in a short train has a disproportionate effect on the outcome (Froemke and Dan, 2002). A model based on these findings proved more accurate than the independent model for predicting the polarity and magnitude of plasticity when naturally recorded spike trains were used as artificial stimuli for monosynaptically linked pairs of layer 2/3 neurons in cortical slices. However, it is not clear that either model can account for the fact that repeated pairing of single presynaptic spikes delivered during a depolarization-induced spike train in the postsynaptic cell invariably produces LTP.

Inhibitory synapses onto hippocampal pyramidal cells exhibit an atypical temporal window for STDP—whatever the order, provided the interneuron and target pyramidal cell fire within 20 ms of each other, the synapse is potentiated (see Section 10.8.2).

### 10.3.9 $\text{Ca}^{2+}$ Signaling in LTP

#### $\text{Ca}^{2+}$ Release from $\text{Ca}^{2+}$ Stores Contributes to Induction of LTP

A major source of  $\text{Ca}^{2+}$  in neurons is via release from intracellular stores. A role for  $\text{Ca}^{2+}$  stores in synaptic plasticity is

implicated by the finding that thapsigargin, which prevents the refilling of these stores, can block the induction but not the expression of LTP at CA1 synapses (Harvey and Collingridge, 1992).  $\text{Ca}^{2+}$  may be released from stores via the generation of inositol trisphosphate (IP3) and/or via  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release media by IP3 and/or ryanodine receptors, respectively. Evidence that  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release may be important was provided by the finding that dantrolene, an inhibitor of ryanodine receptors, blocks induction of LTP at these synapses (Obenauer et al., 1989). In support of this possibility, tetanic stimulation was shown to elicit a large NMDA receptor-dependent  $\text{Ca}^{2+}$  signal at synapses that was substantially inhibited by either thapsigargin or ryanodine (Alford et al., 1993). Collectively, these data suggest that  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release can greatly augment the  $\text{Ca}^{2+}$  signal that permeates NMDA receptors and may be involved in the induction of LTP. Such a signal may maintain the specificity of LTP, as NMDA receptor-triggered, store-derived  $\text{Ca}^{2+}$  signals can be observed within individual spines (Emptage et al., 1999). Conceivably, however, under certain circumstances sufficient  $\text{Ca}^{2+}$  may enter directly via NMDA receptors such that the boost from intracellular stores is not required. Also conceivably,  $\text{Ca}^{2+}$  release from intracellular stores may be induced by other mechanisms, for example via activation of voltage-gated  $\text{Ca}^{2+}$  channels, phospholipase C (PLC)-coupled receptors, or other  $\text{Ca}^{2+}$ -permeable ligand-gated channels. Any of these paths could, in theory, induce NMDAR-dependent LTP without activating the normal induction trigger, the NMDA receptor itself. There is evidence that  $\text{Ca}^{2+}$  permeation through presynaptic kainate receptors can trigger  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release to induce an NMDA receptor-independent form of LTP at mossy fiber synapses on CA3 pyramidal cells (Lauri et al., 2003), as discussed in Section 10.5.3. Again, the extent to which  $\text{Ca}^{2+}$  release from intracellular stores is exploited by the hippocampus during NMDA receptor-dependent LTP *in vivo* is not known.

#### $\text{Ca}^{2+}$ Entry via Voltage-gated $\text{Ca}^{2+}$ Channels Enables NMDA Receptor-independent LTP

Although it is accepted that  $\text{Ca}^{2+}$  entry directly through the NMDAR channel is the trigger for NMDAR-dependent LTP, this pathway is not necessarily the only source of elevated intracellular  $\text{Ca}^{2+}$ . In particular, depolarization during summed EPSPs leads to  $\text{Ca}^{2+}$  entry via voltage-gated  $\text{Ca}^{2+}$  channels (VGCCs). Because NMDA receptors provide much of the depolarization during a high-frequency synaptic response (Herron et al., 1986), this  $\text{Ca}^{2+}$  source is largely NMDAR-dependent (Alford et al., 1993). Determining the relative importance of the two NMDAR-dependent sources is not a trivial matter. In theory, the latter can be excluded in voltage-clamp experiments, but a perfect clamp of synapses located on dendritic spines is not achievable. Blocking VGCCs pharmacologically is also problematic as certain types are required for neurotransmitter release. An alternative strategy has been to activate VGCCs by intracellular depolarization, in the absence

of evoked synaptic transmission. This generally does not induce LTP unless phosphatases are also blocked (Wyllie and Nicoll, 1994). The logical conclusion is that it may be possible to induce LTP if sufficient  $\text{Ca}^{2+}$  enters via VGCCs because it can access the sites that normally are reached only by the  $\text{Ca}^{2+}$ -permeating NMDARs. It follows, therefore, that under most conditions VGCCs are not required for the induction of NMDAR-dependent LTP. On the other hand, stronger induction protocols would promote the activation of VGCCs. Because the depolarization spreads to other regions of the cell, this could lead to partial breakdown in input specificity. It might also result in  $\text{Ca}^{2+}$  entry at the cell soma, where it could act as a nuclear signal. At the extreme, depolarization provided by AMPA receptors alone could result in  $\text{Ca}^{2+}$  entry and LTP that appears to be NMDAR-independent but in fact engages the same mechanisms as NMDAR-dependent LTP downstream of the NMDAR. Consistent with this notion, there is evidence that higher frequencies during tetanization (e.g., 200 Hz) promote NMDAR-independent LTP in the Schaffer-commissural pathway (Grover and Teyler, 1990). However, in this case the downstream signaling pathways may be also different, pointing to the existence of a truly NMDAR-independent form of LTP at these synapses (Cavus and Teyler, 1996). This LTP develops relatively slowly, is of small amplitude but is long-lasting, and is triggered by entry of  $\text{Ca}^{2+}$  through L-type calcium channels (Grover and Teyler, 1990). The L-type channel isoform has now been identified as  $\text{Ca}_v1.2$ , and mutant mice with inactivation of this isoform do not display NMDA receptor-independent LTP (Moosmang et al., 2005). Significantly, they are also severely impaired in a spatial discrimination task, demonstrating that NMDA receptor-independent LTP contributes to the neural processing of hippocampus-dependent learning and memory.  $\text{Ca}^{2+}$ -dependent mechanisms contributing to protein synthesis in the late form of NMDAR-independent LTP are discussed in Section 10.4.9.

### **10.3.10 Metabotropic Glutamate Receptors Contribute to Induction of NMDA Receptor-dependent LTP**

Metabotropic glutamate receptors (mGluRs), by virtue of their coupling to G proteins, can affect various intracellular signaling pathways that might be involved in LTP. The first direct evidence that they may be activated during the induction of LTP followed the development of the first selective mGluR antagonist,  $\alpha$ -methyl-4-carboxyphenylglycine (MCPG) (Eaton et al., 1993). MCPG had no effect on basal synaptic transmission or the expression of LTP but completely inhibited the induction of LTP in a fully reversible manner (Bashir et al., 1993). Unlike NMDAR antagonists, however, MCPG had no effect on STP. In complementary studies it was found that the selective activation of mGluRs with (1S,3R)-1-aminocyclopentane-1,3-dicarboxylic acid [(1S,3R)-ACPD] could induce LTP without the STP phase (Bortolotto and Collingridge, 1993). This “slow-onset” potentiation was not

prevented by an NMDAR antagonist, but it occluded NMDAR-dependent tetanus-induced LTP, suggesting convergence with the mechanisms underlying the expression of classical LTP. ACPD-induced slow-onset potentiation was blocked by thapsigargin. This observation provides a potential route by which ACPD may access NMDAR-dependent LTP, the point of convergence being the intracellular  $\text{Ca}^{2+}$  stores.  $\text{Ca}^{2+}$  release from these stores is normally triggered by  $\text{Ca}^{2+}$  permeating via NMDA receptors; but under certain circumstances, stored  $\text{Ca}^{2+}$  may be released by activation of mGluRs in the absence of NMDAR activation. Group I mGluRs (mGluR1 and mGluR5) couple to phospholipase C, leading to the liberation of IP3, which acts on IP3 receptors to trigger  $\text{Ca}^{2+}$  release from intracellular stores (see Chapter 6, Section 6.3). Consistent with this hypothesis, (1S,3R)-ACPD activates and MCPG inhibits both mGluR1 and mGluR5. An unusual aspect of the action of (1S,3R)-ACPD in area CA1 is that it depends on intact connections from area CA3 (Bortolotto and Collingridge, 1995). A possible explanation is that (1S,3R)-ACPD excites CA3 pyramidal cells sufficiently to depolarize CA1 neurons, which in turn may lead to the sensitization of intracellular  $\text{Ca}^{2+}$  stores to the mGluR-triggered generation of IP3. Consistent with this hypothesis, modest depolarization of CA1 neurons greatly facilitates the  $\text{Ca}^{2+}$ -mobilizing response to group I mGluR agonists (Rae et al., 2000).

Several studies have attempted to replicate the original MCPG experiments, with variable results. One camp agreed that MCPG blocked induction of LTP (Riedel and Reyman, 1993; Sergueeva et al., 1993; Richter-Levin et al., 1994), whereas the second camp found no effect of this antagonist (Manzoni et al., 1994; Selig et al., 1995b; Thomas and O'Dell, 1995; Martin and Morris, 1997). The simplest conclusion to be drawn from these findings is that MCPG-sensitive mGluRs may be necessary for the induction of LTP under certain, but not all, experimental conditions. A possible resolution of the controversy emerged when it was discovered that the activation of mGluRs did not have to occur at the same time as the tetanus that activated NMDA receptors (Bortolotto et al., 1994). Thus, the induction of LTP in one pathway prevented MCPG from inhibiting the induction of more LTP in the same pathway. The initial conditioning tetanus did not have to induce LTP, as a tetanus delivered in the presence of an NMDAR antagonist still produced the conditioning. This led to the proposal that the activation of mGluRs sets a “molecular switch” that negates the need for subsequent activation of mGluRs for induction of LTP in that pathway. Once activated, the switch remains set for at least several hours unless it is turned off by a depotentiating stimulus. These observations suggest that the initial activation of mGluRs converts them to a constitutively active state, although how this switch is achieved is not known. The molecular switch is a form of metaplasticity, which may explain some of the controversy surrounding the effects of MCPG on the induction of NMDAR-dependent LTP. It is likely, however, that other experimental factors are also important (Thomas and O'Dell, 1995; reviewed by Anwyl, 1999).

With the development of various mGluR knockout mice and newer mGluR antagonists, with differing patterns of subtype selectivity, the role of mGluR subtypes in NMDAR-dependent LTP has been further investigated. However, no clear picture has yet emerged. At Schaffer-commissural synapses there are high levels of mGluR5 postsynaptically and mGluR7 presynaptically. Other subunits, including mGluR1, may be expressed at lower levels. The knockout of mGluR1 was reported either to inhibit (Aiba et al., 1994) or to have no effect (Conquet et al., 1994) on the induction of LTP. Surprisingly, although an initial study reported a small decrease in LTP in the mGlu5 knockout (Lu et al., 1997), no effect was found by the same group in a more detailed follow-up investigation (Jia et al., 1998). Interestingly, although LTP was normal in the mGlu7 knockout, there was a deficiency in STP (Bushell et al., 2002). This suggests that presynaptic mGluRs play a role in this initial presynaptic form of plasticity, although developmental consequences of the loss of mGlu7 cannot be discounted. Perhaps most perplexing was the finding that LY341495, a compound that can be used at high concentrations to block all known mGluRs (mGluR1-8), had no effect on LTP (Fitzjohn et al., 1998). The difference between the effects of MCPG and LY341495, which can be demonstrated in the same pathway, suggests that either MCPG is acting on some receptor other than mGlu1-8 or that the blanket inhibition of mGluRs has effects that are different from the selective inhibition of some subunits. Clearly, further work is required to clarify the roles of mGluRs in NMDAR-dependent LTP.

#### 10.3.11 Role of GABA Receptors in the Induction of NMDAR-dependent LTP

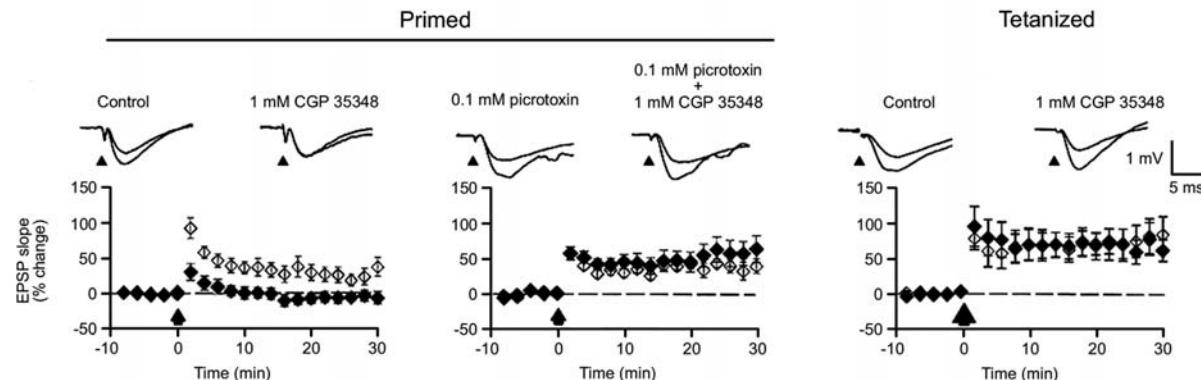

It has been known for many years that blockade of GABA inhibition can greatly facilitate the induction of NMDAR-dependent LTP (Wigström and Gustafsson, 1983). The mech-

anism for this effect is well established. Normally, when an EPSP is evoked by stimulation of an afferent pathway, such as the Schaffer commissural projection, it is curtailed by a biphasic inhibitory postsynaptic potential (IPSP) comprising a rapid GABA<sub>A</sub> receptor-mediated component and a slower GABA<sub>B</sub> receptor-mediated component. The hyperpolarizing effect of the IPSP intensifies the Mg<sup>2+</sup> block of NMDARs, and this greatly limits the extent to which NMDARs contribute to the synaptic response. This was first demonstrated by a simple pharmacological experiment. When GABA<sub>A</sub> receptors were blocked pharmacologically, an NMDAR-mediated synaptic response appeared during low-frequency stimulation in the presence of Mg<sup>2+</sup> (Herron et al., 1985; Dingledine et al., 1986). Indeed, it is probably no coincidence that the kinetics of the GABA<sub>A</sub> receptor-mediated IPSP is such that this component of the biphasic IPSP coincides with the greater part of the NMDAR-mediated conductance.

Blockade of GABA inhibition is not simply a pharmacological curiosity but a key feature of LTP induction. This is shown by the remarkable efficacy of "priming" induction protocols, discussed above, in which a single stimulus precedes a brief high-frequency burst by about 200 ms. A primed burst containing typically four shocks (i.e., five shocks in total) can induce LTP. The potency of the burst derives from the fact that the priming stimulus (or the preceding burst during "theta" patterns) causes a substantial reduction in the GABA receptor-mediated IPSP. The mechanism of this effect has been established (Davies et al., 1991) (Fig. 10-6). Some of the GABA that is released in response to the priming stimulus feeds back to activate GABA<sub>B</sub> autoreceptors, which results in inhibition of subsequent GABA release. Thus, the priming stimulus releases a normal level of GABA, but the stimuli during the burst release considerably less GABA, which facilitates the synaptic activation of NMDA receptors on pyramidal neurons. The kinetics of the GABA<sub>B</sub> autoreceptor mechanism determines the optimal timing for priming; it has a latency of

**Figure 10-6.** GABA<sub>B</sub> autoreceptors regulate the induction of LTP. LTP plots show that the GABA<sub>B</sub> antagonist CGP35348 (1 mM) blocks induction of LTP induced by primed-burst stimulation (1 priming stimulus followed 200 ms later by 4 shocks at 100 Hz) (left panel). However, the antagonist is ineffective if experiments are performed in the presence of a GABA<sub>A</sub> antagonist (middle panel) or if

a tetanus (100 Hz, 1 second) is used (right panel). The open symbols plot control experiments, and the filled symbols plot experiments performed in the presence of CGP35348. The primed-burst stimulus or tetanus was delivered at the times indicated by arrows. The traces were obtained during baseline and 30 minutes following the priming/tetanus. (Source: Davies et al., 1991.)

around 20 ms, a peak effect around 200 ms, and a duration of around 1 second (Davies et al., 1990). Thus, theta patterns of activity are tuned to the maximum depression of GABA inhibition by the autoreceptor mechanism. The importance of autoinhibition for the induction of LTP can be readily demonstrated. GABA<sub>B</sub> antagonists, applied at concentrations that prevent the GABA<sub>B</sub> autoreceptor from operating and thereby maintain GABA<sub>A</sub> receptor-mediated inhibition, completely prevent induction of LTP by priming stimulation. As one would predict for a mechanism that works by modulating GABA<sub>A</sub> receptor-mediated inhibition, GABA<sub>B</sub> antagonists do not block LTP induced in the presence of a GABA<sub>A</sub> receptor antagonist (Davies and Collingridge, 1993). They are also ineffective when tested against a conventional tetanus (e.g., 100 Hz for 1 second) as the GABA<sub>B</sub> autoreceptor mechanism operates for only a few stimuli. The system is finely tuned to suppress GABA inhibition during theta-type patterns of activity, which from a physiological perspective suggests that hippocampal synapses may be particularly susceptible to potentiation during exploration, locomotion, and other behavioral states that give rise to theta activity (see Chapter 11). The importance of the GABA<sub>B</sub> autoreceptor system is emphasized in the induction scheme for LTP illustrated in Figure 10–7.

Theoretically, many neurotransmitters and neuromodulators could interact with the LTP induction process via an effect on GABA inhibition. For example, it has been shown that endocannabinoids released from pyramidal neurons can depress GABA inhibition, which can result in the facilitation of LTP (see Section 10.3.12). In one series of experiments it was shown that LTP is associated with an endocannabinoid-mediated LTD of GABA inhibition in a narrow band surrounding the potentiated synapses (Chevaleyre and Castillo, 2004). The LTD of synaptic inhibition then promotes induction of LTP in this surround.

### **10.3.12 E-S Potentiation: A Component of LTP That Reflects Enhanced Coupling Between Synaptic Drive and Cell Firing**

#### **Characteristics of E-S Potentiation**

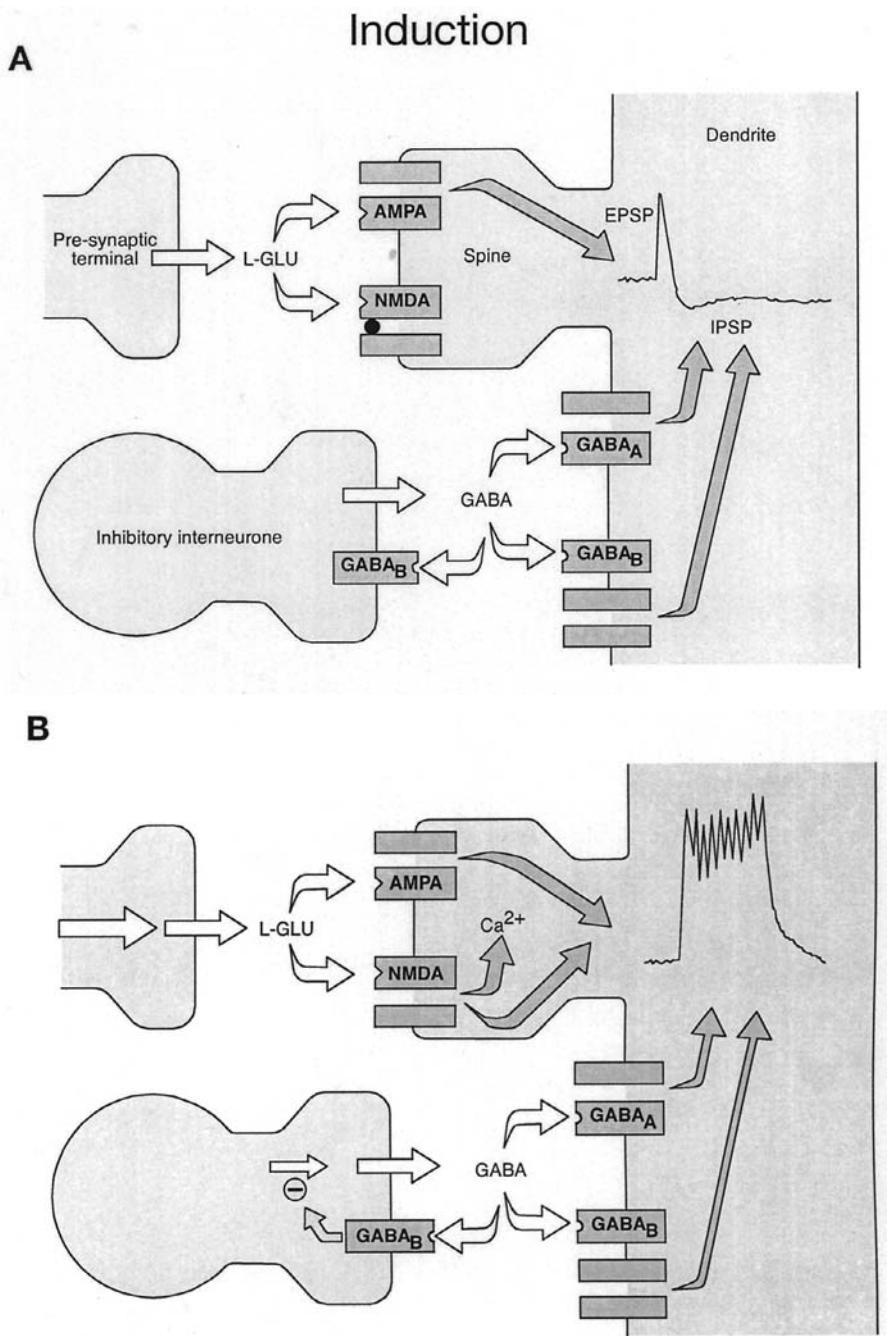

Conventional synaptic LTP is characterized by a persistent increase in synaptic current and a proportionate increase in the amplitude of the population spike or, in single unit recordings, in the probability of the cell firing an action potential in response to the test stimulus. In these cases, potentiation of the population spike, or an increase in the probability of cell firing, is no more than would be predicted from the increase in the EPSP. Often, though, the increase is much greater. In extreme cases, spike potentiation can occur in the absence of EPSP potentiation (Bliss and Lømo, 1973). This property of hippocampal synapses was given the name EPSP-spike or E-S potentiation by Andersen et al. (1980). In general, E-S potentiation appears as a leftward shift of the curve obtained by plotting the amplitude or latency of the popula-

tion spike, or the probability of unit discharge, against the slope of the synaptic component (Bliss et al., 1973) (Fig. 10–2E–G). Although E-S potentiation is usually observed in conjunction with synaptic LTP, pure E-S potentiation has been obtained in area CA1 *in vitro* by combining low-frequency afferent stimulation with high-frequency antidromic trains (Jester et al., 1995; Nakanishi et al., 2001). Like synaptic LTP, E-S potentiation in area CA1 is NMDAR-dependent (Jester et al., 1995; Lu et al., 2000a; Daoudal et al., 2002); and the observation that the NMDAR antagonist D-AP5 blocks both spike and EPSP potentiation implies that this is also the case in the dentate gyrus *in vivo* (Errington et al., 1987). However, E-S potentiation and synaptic LTP are differently affected by drugs that modulate the monoaminergic input to the hippocampus. Depletion of noradrenaline (norepinephrine) reduces synaptic LTP in the dentate gyrus but leaves LTP of the population spike unaffected (Bliss et al., 1983; Munro et al., 2001).

Several groups have reported that E-S potentiation is input-specific when induced by tetanic stimulation in area CA1 *in vitro* (Andersen et al., 1980; Daoudal et al., 2002; Marder and Buonomano, 2003). However, this conclusion has been disputed by Jester et al. (2003), who found that input specificity was violated in more than half of their experiments in CA1 *in vitro*; there is also evidence for a lack of input specificity in the dentate gyrus *in vivo* (Abraham et al., 1985). Further experiments are needed to resolve this question. The persistence of E-S potentiation has not been explored in the freely moving animal.

#### **Mechanisms of E-S Potentiation**

Inhibitors of GABA<sub>A</sub> receptors block a substantial component of E-S potentiation produced by tetanic stimulation (Abraham et al., 1987; Chavez-Noriega et al., 1989; Daoudal et al., 2002; Marder and Buonomano, 2003; Staff and Spruston, 2003), suggesting that it reflects an increase in excitability brought about by a relative reduction in feedforward inhibition. Support for this hypothesis has been provided by Lu et al. (2000a), who found that E-S potentiation in CA1 neurons is accompanied by a tetanus-induced LTD of feedforward IPSPs; both E-S potentiation and LTD of IPSPs were abolished by NMDA antagonists, or by injecting the phosphatase calcineurin into pyramidal cells. This last result implies that the site of induction of E-S potentiation is the inhibitory synapse on the principal cell, not the excitatory input to the GABAergic interneuron. Nevertheless, the latter site may contribute to persistent reduction in feedforward inhibition and hence to E-S potentiation because tetanic stimulation can induce LTD at these synapses (Laezza et al., 1999) (see Section 10.8.1). Because the expression of E-S potentiation manifests as an increase in postsynaptic cell firing for a given synaptic input, the results of Lu et al. (2000a) imply that expression of this form of LTP, like its induction, is postsynaptic. However, this is unlikely to be the whole story. E-S potentiation has been induced by a pairing protocol, in which plasticity in

**Figure 10–7.** Activation of NMDA receptors, modulated by other ionotropic amino acid receptors, triggers the induction of LTP in principal cells of area CA1 and dentate gyrus. *A.* Low-frequency stimulation of Schaffer commissural axons evokes an EPSP that is mediated by L-glutamate acting on AMPA receptors. The EPSP is followed by a biphasic IPSP, produced by glutamatergic excitation of feedforward GABAergic interneurons. The early part of the IPSP is due to activation of GABA<sub>A</sub> receptors, which are permeable to  $\text{Cl}^-$  ions; the slow component of the IPSP reflects activation of GABA<sub>B</sub> receptors, indirectly coupled to  $\text{K}^+$  channels. Because of its slow kinetics and the voltage-dependent block of its channel by  $\text{Mg}^{2+}$  ions, the NMDA receptor contributes little to the EPSP at low frequencies of stimulation. *B.* During high-frequency stimulation, the

activated spines become strongly depolarized with the result that the  $\text{Mg}^{2+}$  block of the NMDA receptor channel is relieved, allowing  $\text{Ca}^{2+}$  to permeate through the receptor. Factors that contribute to sustained depolarization, including temporal summation of EPSPs and the accumulation of  $\text{Cl}^-$  in the spine and  $\text{K}^+$  in the synaptic cleft, leading to depolarizing shifts in reversal potentials. Some protocols, in particular theta burst stimulation, depend for their efficacy on the suppression of inhibition mediated via GABA<sub>B</sub> autoreceptors on inhibitory terminals. The suppression of GABA release reaches a maximum around 200 ms after a priming stimulus, explaining the peculiar efficacy of priming and theta burst stimulation (see text). (Source: After Bliss and Collingridge (1993).)

inhibitory circuits presumably does not occur (Marder and Buonomano, 2004). There is also a component of E-S potentiation that is not GABA<sub>A</sub> receptor-dependent; in the well documented study by Daoudal et al. (2002), this component amounted to 40% of the overall effect.

A novel interpretation of the idea that E-S potentiation reflects a persistent reduction in inhibitory input has come from an analysis of mGluR-dependent LTD of inhibitory transmission between interneurons and pyramidal cells in area CA1, touched on above (Chevaleyre and Castillo, 2003). This unusual form of heterosynaptic inhibitory LTD is mediated by the activation of group 1 mGluRs on CA1 pyramidal cells by high-frequency stimulation of Schaffer-commissural fibers. There is a consequent retrograde release of the cannabinoid 2-AG (Wilson and Nicoll, 2001), leading to the activation of endogenous CB1 receptors on the terminals of inhibitory axons projecting to the same pyramidal cell and, by unknown mechanisms, to a suppression of the release of inhibitory transmitter. The persistent disinhibition leads to E-S potentiation. Chevaleyre and Castillo carried out their experiments in a medium that blocked ionotropic glutamate receptors. High-frequency stimulation in the presence of NMDAR antagonists should therefore lead to E-S potentiation without synaptic potentiation. However, both in area CA1 *in vitro* (Collingridge et al., 1983) and in the dentate gyrus *in vivo* (Errington et al., 1987), AP5 blocks potentiation of both the population spike and the fEPSP. It remains to be established whether the retrograde release of 2-AG provides an explanation for E-S potentiation in area CA1 *in vivo*.

The input specificity of E-S potentiation, whether established in the presence of a GABA<sub>A</sub> receptor antagonist (Daoudal et al., 2002) or in normal bathing medium (Marder and Buonomano, 2003), is something of a puzzle, as an increase in excitability, or the tendency to fire an action potential, is most readily explained in terms of the conductances controlling the threshold of cell firing at the axon hillock. Regardless of whether E-S potentiation is due to local disinhibition, we may ask how local changes in the region of those inputs whose activity results in E-S potentiation can give rise to increased probability of cell firing at those inputs and not at others. A possible mechanism is upregulation of postsynaptic conductances that allow local spiking, as modeled by Wathey et al. (1992). High-threshold calcium channels are potential candidates (Chetkovich et al., 1991; Wathey et al., 1992). In their analysis of GABA<sub>A</sub> receptor-independent E-S potentiation in hippocampal and cortical layer V pyramidal cells, Debanne and colleagues found evidence that the effect depended on the activation of group I mGluRs by the activated fibers, leading by an unknown pathway to suppression of a local K conductance (Daoudal et al., 2002; Sourdet et al., 2003). Induction of LTP in CA1 pyramidal cells results in persistent enhancement of local dendritic excitability, ascribed to modulation of the potassium current I<sub>A</sub> (Frick et al., 2004) or in cultured neurons to the nonspecific cation current I<sub>h</sub> (Wang et al., 2003). An increase in dendritic excitability may lead to local calcium spikes and generation of somatic action

potentials (Larkum et al., 1999) or favor the shift of the action potential initiation site toward the dendrites. An increase in dendritic excitability could preserve the input specificity of E-S potentiation via the generation of local Ca<sup>2+</sup> spikes, leading to somatic action potentials.

Bidirectional changes in the E-S relation have also been described (Daoudal et al., 2002; Wang et al., 2003). Like E-S potentiation, E-S depression is NMDAR-dependent and displays input specificity when monitored in the presence of picrotoxin (Daoudal et al., 2002).

### E-S Potentiation: Functional Considerations

The functional consequences of E-S potentiation and depression have not been explored in any depth, and will depend on several factors about which there is currently little information, including the persistence of the effect in the behaving animal and the degree to which input specificity is maintained. Reactivation of a specific network of cells in which E-S potentiation has been induced by a particular input pattern will be facilitated when that pattern is re-presented. Input specificity would add the useful feature that only the original input pattern would be subject to such amplification. Clearly, an increase (or decrease) in excitability will also enhance or depress the ability of the network to communicate with downstream targets.

### 10.3.13 Metaplasticity: The Magnitude and Direction of Activity-dependent Changes in Synaptic Weight Are Influenced by Prior Activity

The fact that LTP eventually reaches an asymptotic level after repeated episodes of high-frequency stimulation demonstrates that plasticity itself depends on the prior history of synaptic activity. The term “metaplasticity” was coined by Abraham and colleagues to describe this concept (Abraham and Bear, 1996; Abraham and Tate, 1997). The essential feature of metaplasticity is a persistent change in the plastic properties of the synapse brought about by prior synaptic or neuromodulatory activity that may or may not itself alter synaptic function. In the case of saturation, the prior activity (that is, preceding strong high-frequency trains) induces LTP. However, low-intensity (“priming”) trains, which themselves elicit no change in synaptic weight, can also inhibit the subsequent induction of LTP (Huang YY et al., 1992). This effect of priming trains can persist for 1 to 2 hours, is specific to the primed input, and is mediated by a mechanism that requires the activation of NMDA receptors. Similarly, low-frequency activation of NMDA receptors in Mg<sup>2+</sup>-free medium can prevent induction of LTP (Coan et al., 1989). These studies demonstrate the need for an optimal level of NMDAR activation for the induction of LTP; persistent low levels of activation may oppose induction of LTP via metaplasticity. Activation of mGluR receptors appears to facilitate the subsequent induction of LTP (Cohen and Abraham, 1996) and, as discussed above, can modify the subsequent requirement for mGluR activation for LTP induc-

tion (Bortolotto et al., 1994). There is evidence that early stimuli in the long low-frequency trains used to induce of LTD (see Section 10.7) perform a priming function; they do not themselves induce LTD but enable the later stimuli in the train to do so by an NMDAR-dependent mechanism (Mockett et al., 2002). An example of state dependence, which can be regarded as a form of metaplasticity, is provided by the observation that LTD cannot be induced in newly unsilenced synapses for the first 30 minutes after unsilencing (Montgomery and Madison, 2002) (see Section 10.7.6). Another, extreme case of metaplasticity is exhibited by synapses made by mossy fibers on interneurons in stratum lucidum of area CA3; at these synapses, depending on prior activity, tetanic stimulation of mossy fibers can produce either LTP or LTD (Pelkey et al., 2005) (see Section 10.8.1) for the mechanism underlying this striking instance of bidirectional plasticity. A striking case of metaplasticity is exhibited by synapses made by mossy fibers on interneurons in stratum lucidum of area CA3; at these synapses, depending on prior activity, tetanic stimulation of mossy fibers can produce either LTP or LTD (Pelkey et al., 2005) (see Section 10.8.1)

Some years before the first experimental studies of metaplasticity, the idea had been explored by Bienenstock, Cooper, and Munro in a theoretical analysis of developmental plasticity in the kitten visual system (Bienenstock et al., 1982; Bear et al., 1987). In the Bienenstock, Cooper, and Munro (BCM) model, the rate of change in synaptic weight,  $f$ , is a function of postsynaptic activity; it is negative for low rates of activity and positive for high rates of activity, corresponding to LTD and LTP respectively (see Box 10–2). The critical new feature of the BCM formulation is that the threshold for LTP,  $\theta$ , is not static but is itself a function of the average activity of the cell. For maintained high rates of activity, the threshold slides to the right, facilitating the subsequent induction of LTD, whereas for low rates of activity, the threshold moves to the left, encouraging the induction of LTP. An element of homeostasis is thereby introduced to the system, preventing runaway potentiation and allowing situations in which activity is low to regain synaptic strength when the input is restored. The BCM model accounts for several features of metaplasticity in the hippocampus. The facilitation of LTD (depotentiation) after induction of LTP is one example (to our knowledge, there are no data on the converse prediction that LTP should be easier to obtain after induction of LTD); saturation of LTP is another. Other aspects are not so easily explained by the BCM model, such as the fact that metaplastic effects commonly persist for only an hour or two, and the essentially homosynaptic nature of metaplasticity in the hippocampus. In the BCM theory,  $\theta$  is a global threshold applicable to all synapses and is a function only of postsynaptic activity, which itself reflects the integrated activity of all inputs to the cell. Yet metaplastic effects in the hippocampus are for the most part input-specific and do not seem to be much affected by heterosynaptic activity (Abraham and Tate, 1997).

The BCM rule is not the only synaptic learning rule with built-in homeostasis; other models are based on covariance

rules proposed by Stent (1973), Sejnowski (1977), Singer (1990), and Friedlander et al. (1993) among others. Thus, although we tend to regard plasticity as a mechanism for driving changes in synaptic function, these formal sets of rules, as well as the phenomenon of metaplasticity, remind us that plasticity can also be the engine of stability. If LTD is easier to induce after LTP (and vice versa) the strength of connections will tend to stabilize around a mean. Similar adjustments in cell excitability are discussed in Section 10.3.14.

The patterns of synaptic activity that lead to metaplasticity are in many cases comparable to those that induce LTP or LTD. In some forms of metaplasticity the NMDA receptor plays an essential role, presumably reflecting the plasticity of NMDA receptor-mediated responses themselves (see Section 10.4), whereas in others, such as that mediated by the molecular switch (Section 10.3.10), metabotropic glutamate receptors are involved. It is likely, then, that the cellular correlates of metaplasticity overlap with those of LTP and LTD, and the point has been made, with some justice, that biochemical correlates of metaplasticity may be mistaken for biochemical correlates of LTP or LTD (Abraham and Tate, 1997).

A possible candidate for the molecular basis of metaplasticity is the NMDA receptor. The 2B subunit of the NMDA receptor is phosphorylated in LTP, an effect that in the anesthetized animal peaks between 2 and 5 hours after induction (Rosenblum et al., 1996; Rostas et al., 1996). In freely-moving animals, LTP in the dentate gyrus is associated with an increase in NR1 and NR2B levels that are still present 48 hours after induction (Williams et al., 2003). Phosphorylation of NR2B in expression systems enhances NMDAR-mediated currents by increasing the open time of the channel. This has little effect on the largely AMPA receptor-mediated synaptic responses (and thus cannot be the mechanism for LTP itself), but it does have consequences for subsequent attempts to induce plasticity. On the face of it, phosphorylation of NR2B and the increased receptor subunit levels constitute a positive feedback system. However, based on the assumption that both LTD and LTP are triggered by increases in intracellular  $\text{Ca}^{2+}$ , with the threshold for LTD being lower than that for LTP, both types of plasticity are facilitated by the increase in NMDAR-mediated  $\text{Ca}^{2+}$  current. The entire BCM curve, including  $\theta$ , is shifted to the left; at low frequencies LTD is facilitated, and at intermediate and higher frequencies LTP is facilitated. Just this combination of effects is seen in the visual cortex following enhanced NMDAR function driven by sensory deprivation (Philpot et al., 2003). Another hint that changes in NMDA receptor function may underlie the expression of metaplasticity comes from the finding that low-intensity trains of the sort that impair the subsequent induction of LTP in area CA1 also induce LTD of the NMDAR-mediated component of the evoked response (Selig et al., 1995a).

Whatever the mechanisms by which changes in activity lead to metaplasticity, there is evidence that it may be affected by a variety of neuromodulators including corticosteroids, estrogen, catecholamines, acetylcholine, and serotonin. In general, these modulators lead to an increase in the threshold

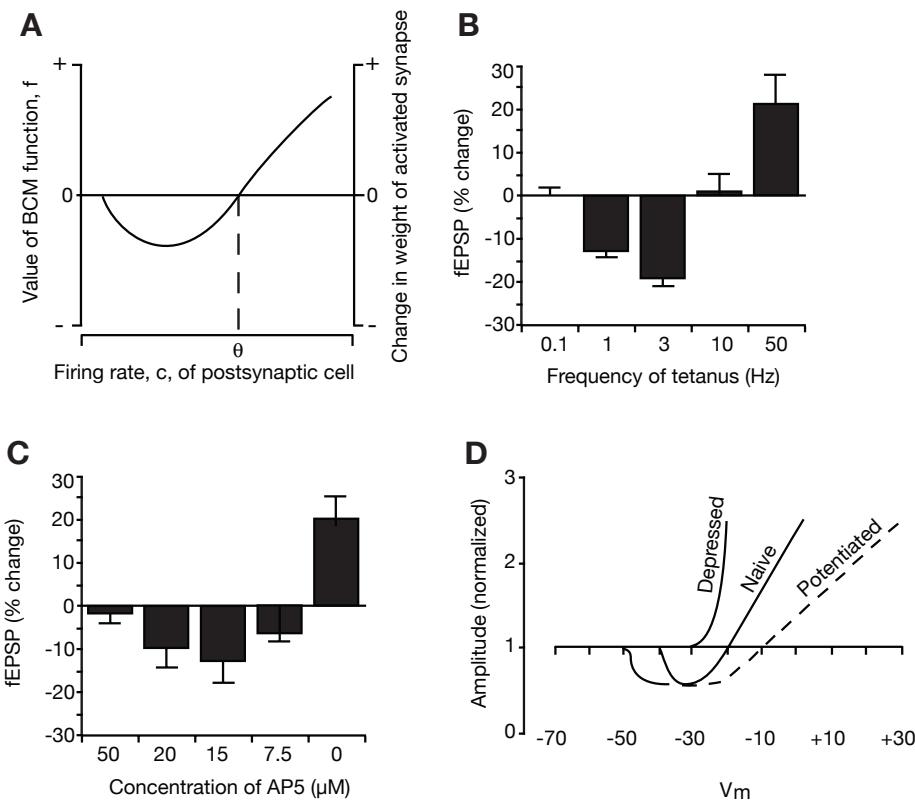

**Box 10-2****Synaptic Plasticity and the BCM Curve**

The BCM function was introduced by Bienenstock, Cooper, and Munro (Bienenstock et al., 1982) to provide a mathematical description of activity-dependent changes in synaptic weight in the developing visual system (see Bear, 1996, for its application to hippocampal plasticity). The BCM function,  $f$ , is a function of  $c$ , the firing rate of the postsynaptic cell; it changes sign at a value of  $c$  called the threshold,  $\theta$ ; this itself is a function of  $c$  and the variable  $\langle c \rangle$  (the mean rate of postsynaptic activity, measured over minutes or hours). Thus  $f$  is a function of both  $c$  and  $\langle c \rangle$ . In the BCM theory, the rate of change of synaptic efficacy,  $m_j$ , at the  $j$ th synapse on a cell, is given by the equation

$$dm_j/dt = f(c, \langle c \rangle) d_j$$

where  $d_j$  is the rate of activity at the  $j$ th synapse. Note that the value of the BCM function,  $f$ , is determined only by the state of the postsynaptic cell. Synaptic plasticity—the rate of change of synaptic weights—is a product of  $f$  and afferent activity,  $d_j$ .

The function  $f$  is shown graphically in Box Fig. 10-2A. Note that an active synapse will be potentiated if it is active when  $c > \theta$ . This is likely to happen only when the cell is driven at high frequency, as with tetanic stimulation (Box Fig. 10-2B) or its postsynaptic state is manipulated, as by application of AP5 (Box Fig. 10-2C) or by depolarization (Box Fig. 10-2D). If a synapse is activated alone at low frequency,  $c$  is less than  $\theta$ , and efficacy will be depressed. In general,  $\theta$  is a nonlinear function of  $\langle c \rangle$ ; see Bear et al. (1987) for a discussion of the case where  $\theta = \langle c \rangle$ . The magnitude of the change in synaptic weight is proportional to  $d_j$ , the rate of afferent activity; and there is no change when afferent activity is not driven ( $d_j = 0$ ). Note also that the BCM formulation bequeaths inherent stability to the network: When  $\langle c \rangle$  is high, the threshold shifts to the right, so synaptic weights tend to be reduced, and postsynaptic activity is correspondingly dampened; and when the mean afferent activity is low,  $\theta$  shifts to the left, synaptic weights increase, and activity is restored to the network. This prevents synaptic weights from increasing explosively when activity is high or decreasing to zero when activity is low.

(Continued)

The curve relating tetanus frequency to the magnitude and polarity of the change in synaptic efficacy is sometimes interpreted as if it is a direct illustration of the function,  $f$ , in the BCM theory. However, although the two sets of curves have a similar form, passing from negative values to positive values at a modifiable threshold, the changes in synaptic efficacy are a function of postsynaptic firing rate in BCM theory and of presynaptic activity along a restricted set of afferent fibers in experimental investigations of bidirectional plasticity. The two descriptions approach congruence if presynaptic activity in the stimulated afferent(s) is the main determinant of cell firing; this may be the case *in vitro* where spontaneous activity is low, but is not the case in general. Reversal from LTD to LTP can also be achieved in single cells by manipulating the membrane potential; in strongly depolarized cells, brief trains induce LTP, whereas the same trains given when the cell is weakly depolarized induce LTD (Cummings et al., 1996; Ngezahayo et al., 2000) (see Box Fig. 10–2D), confirming that the polarity of change is under the control of the postsynaptic cell. The reversal point for LTD/LTP ( $\theta$  in the BCM curve) is a function of past activity. For example, the prior induction of LTP *in vitro* shifts the reversal point (in terms of membrane depolarization) to the right, whereas the prior induction of LTD shifts it to the left (Ngezahayo et al., 2000) (see Box Fig. 10–2D). Similarly, prolonged prior antidromic or heterosynaptic activity in the dentate gyrus of the freely moving rat raises the threshold for LTP (Abraham et al., 2001). In each case, synaptic weights are changed in a direction that restores the output of the cell toward a non-zero mean.

**Box Fig. 10–1.** Bienenstock, Cooper, and Munro (BCM) curve and bidirectional synaptic plasticity. A. The BCM function  $f$  is negative for low firing rates of the postsynaptic cell, crosses zero at a threshold value ( $\theta$ ) and is positive thereafter. Because changes in synaptic weight at a given synapse are given in the BCM theory by  $f \cdot d$ , where  $d$  is the rate of afferent activity at that synapse, the curve for changes in synaptic weight has the same shape. (Source: After Bienenstock et al., 1982.) B. Bidirectional changes in synaptic weight can be achieved by manipulating the frequency of afferent stimulation. The total number of stimuli (900) was the same in each case. The result is consistent with the BCM theory, as changes in stimulus frequency affect the firing of the postsynaptic cell. (Source: Bear and Linden, 2001; after Dudek and Bear, 1992.) C. Pharmacological manipulation of the postsynaptic NMDA receptor with varying concentrations of AP5 elicit bidirectional plasticity. Afferent stimulation was the same in each case (600 stimuli at 20 Hz). In control medium, this protocol induced LTP. With weak to intermediate concentrations of AP5, sufficient to reduce the firing of the postsynaptic cell to afferent stimulation, LTD was induced. Finally, at a concentration of 50  $\mu\text{M}$ , changes in synaptic weight were blocked. (Source: Bear and Linden, 2001; after Cummings et al., 1996.) D. Bidirectional changes in synaptic weight produced by pairing afferent stimulation with depolarizing pulses to the postsynaptic cell. In each case, 100 afferent stimuli were given at 2 Hz. The polarity and magnitude of the change in synaptic efficacy was determined by the membrane potential to which the postsynaptic cell was clamped during pairing. In naive cells (not previously subjected to pairing), depolarization to  $-30$  mV resulted in LTD, whereas depolarization to  $-10$  mV or more led to LTP. Threshold ( $\theta$ ) was at  $-20$  mV. This experiment also revealed how prior activity can alter  $\theta$ . Once LTD had been induced,  $\theta$  shifted to the left; and pairing to  $-30$  mV, which in the naive cell had induced LTD, now resulted in no change. Conversely, if LTP was induced, it was subsequently possible to induce LTD at a more modest depolarizing potential, implying a rightward shift of  $\theta$  (dotted line, not experimentally confirmed). (Source: Ngezahayo et al., 2000.)

for LTP and a decrease in the threshold for LTD (reviewed by Abraham and Tate, 1997).

#### Transgenic Mice Can Exhibit Shifts in the BCM Curve

An example of a genetic modification leading to a striking shift in the frequency dependence of synaptic plasticity is the transgenic mouse carrying a mutated form of CaMKII engineered by Mayford et al. (1995). By changing a single residue

(threonine 286 to aspartate), the enzyme was rendered calcium-independent. The effect was to shift the curve relating the frequency of the conditioning train to the change in synaptic efficacy to the right in  $\alpha$ CaMKII(T286D) animals relative to wild-type littermates; thus, protocols that in wild-type mice produced LTP led to LTD in the transgenic animals. A similar shift to the left of the frequency or BCM curve for synaptic plasticity occurs in other mutants, including an NR2B overexpressing transgenic mouse (Tang et al., 1999) and a calcineu-

rin knockout (Zeng et al., 2001). In contrast, mice lacking the GluR2 subunit (Jia et al., 1996) or the postsynaptic density protein PSD95 (Migaud et al., 1998) showed a shift to the left of the frequency-response curve; thus, stimulus protocols that produced LTD in wild types induced LTP in the mutant animals. The shift in baseline  $\theta$  exhibited by these and other mutants suggests that there may be two mechanistically distinct forms of metaplasticity: (1) homosynaptic (input-specific) metaplasticity lasting not more than a few hours and attributable to post-translational changes in, for example, NMDA receptors; and (2) a more persistent, generalized form of metaplasticity that regulates baseline  $\theta$  and requires gene expression (Deisseroth et al., 1995; Abraham and Tate, 1997).

### 10.3.14 Synaptic Scaling and Long-term Changes in Intrinsic Excitability

A neural network in which Hebbian synapses provide the only mechanism for plasticity cannot sustain a state of dynamic stability in which the mean rate of activity remains constant, while the potential for modification of individual synapses is retained. In a Hebbian network, successful inputs are strengthened, becoming more successful, whereas unsuccessful inputs remain unsuccessful or are depressed; the network is ultimately driven to an invariant state where activity is controlled by a subset of maximally potentiated synapses. Several theoretical fixes to the problem of runaway excitation due to Hebbian positive feedback have been proposed. In the covariance rule proposed by Stent (1973), a synapse is potentiated when activity in the pre- and postsynaptic cells are in phase and depressed when they are out of phase. There is some experimental evidence for Stent's rule (Artola and Singer, 1993; Debanne et al., 1998). As we saw above, in the influential model proposed by Bielenstock et al. (1982) and extended and updated by Shouval et al. (2002), the magnitude and polarity of plastic changes are controlled by the overall activity of the network to maintain a constant mean firing rate (see also reviews by Abbott and Nelson, 2000 and Bi and Poo, 2001).

There is now considerable evidence that homeostatic mechanisms operate to maintain a constant mean level of firing in neural networks. Homeostasis is achieved by overall adjustments to synaptic weights, a process called "synaptic scaling." The phenomenon was first studied in cultured cortical networks. Addition of a GABA<sub>A</sub> antagonist to the culture medium produced an initial increase in spontaneous activity, but activity returned to control levels over the following 2 days (reviewed by Turrigiano and Nelson, 2004). In cultured hippocampal neurons, similarly, the GABA<sub>A</sub> antagonist picrotoxin produced a long-term reduction in surface AMPA receptors (Lissin et al., 1998). Homeostasis can also operate at the level of the single hippocampal pyramidal cell embedded in an active network of cultured hippocampal neurons. Overexpression of an inward-rectifier K channel resulted in an initial decrease in the firing rate of the transfected cell, but over time the firing rate was restored to control values by a homeostatic increase in synaptic drive (Burrone et al., 2002).

Finally, the increase in excitability of neurons in hippocampal cultures that is induced by prolonged blockade of activity appears to reflect an up regulation of synaptic AMPARs, driven by glial release of the cytokine tumor-necrosis factor- $\alpha$  (TNF- $\alpha$ ) (Stellwagen and Malenka, 2006).

Activity-dependent changes in intrinsic excitability have also been documented in hippocampal, cortical, and cerebellar neurons (for review see Zhang and Linden, 2003). An important insight was gained when two groups reported that persistent changes in local dendritic excitability accompany synaptic plasticity in CA1 pyramidal neurons. In one case, a theta-burst pairing protocol produced a long-lasting shift in the inactivation curve of the K<sup>+</sup> conductance I<sub>A</sub>, leading to local boosting of synaptic responses and back-propagating spikes (Frick et al., 2004). In the other study, spike timing-dependent plasticity was accompanied by persistent changes in the cationic current I<sub>h</sub> (Wang et al., 2003). These findings imply that the throughput of synaptic information to the soma is enhanced not just from the tetanized region but also from distal synapses on the same dendrite.

Another intriguing finding comes from the behavioral literature. About 50% of CA1 pyramidal cells examined in slices from rabbits trained in a trace conditioning task (eyeblink conditioning using a tone as the conditioned stimulus and an airpuff as the unconditioned stimulus) exhibited a reduction in spike frequency adaption and spike after-hyperpolarization (Moyer et al., 1996). (Although these changes in excitability last several days, they cannot encode the memory for the conditioned response, which can last months). A similar reduction in after-hyperpolarization is seen in rat CA1 neurons after spatial training in the watermaze (Oh et al., 2003). Activity-dependent changes in excitability, in contrast to the synaptic scaling produced by prolonged hypo- or hyperactivity, are in general nonhomeostatic because they act in the same direction as synaptic changes. Note also that changes in local dendritic excitability introduce a potential for metaplasticity, as they may affect subsequent STDP. Exploration of long-term changes in excitability is at an early stage, and relatively little is known about the conductances responsible or the second messenger systems that modulate them.

### Back-propagating Synaptic Plasticity and Long-range Cytoplasmic Signaling

Back-propagation of synaptic weight changes is the central feature of an efficient design for unsupervised learning in model neural networks (Rumelhart et al., 1986). There was, however, little evidence for back-propagation in biological nervous systems until the studies by Poo and his colleagues in hippocampal cultures (Fitzsimonds et al., 1997; Tao et al., 2000). LTP or LTD induced at a particular connection by spike pairing of presynaptic and postsynaptic neurons in the appropriate temporal conjunction—results in the spread of plasticity (of the same polarity) to other synapses onto the presynaptic neuron and to other synapses made by the presynaptic neuron. However, there is no spread to other connec-

tions made by or onto the postsynaptic neuron (Bi and Poo, 2001). Thus, LTP at a given synapse is propagated only to synapses made by or onto the presynaptic neuron. The presynaptic cell was voltage-clamped except when required to fire an action potential to induce the primary LTP; it is therefore likely that back-propagated changes are not activity-driven but involve some form of cytoplasmic long-range signaling. There are as yet no reports of back-propagating plasticity in hippocampal slices or in the hippocampus *in vivo*. However, in the developing retinotectal system of the tadpole, application of BDNF to the tectum (where axons of retinal ganglion cells terminate) results in potentiation of retinotectal synapses and a back-propagated increase in the number of glutamate receptors on dendrites of ganglion cells (Du and Poo, 2004).

## 10.4 NMDA Receptor-dependent LTP: Expression Mechanisms

### 10.4.1 From Induction to Expression of LTP

The various properties of LTP that we have summarized above arise from the complex interplay of biophysical and cell-biological mechanisms operating at the cellular and local circuit levels. In approaching this complexity, it is convenient to distinguish between the *induction* of LTP, which comprises the collection of short-lived events that trigger changes in synaptic weight but do not themselves affect it, and the *expression* of LTP, which includes all those mechanisms, whether presynaptic or postsynaptic, that directly enhance or, in the case of LTD, diminish synaptic efficacy. (Note that, in addition to expression, two other equivalent terms are found in the LTP literature: *persistence* and *maintenance*.) Thus, events associated with the activation of NMDA receptors, relief of the magnesium block, permeation of  $\text{Ca}^{2+}$  through the NMDA receptor, and activation of  $\text{Ca}^{2+}$ -dependent protein kinases can all be considered components of induction. Expression mechanisms include increases in the probability of transmitter release, phosphorylation of AMPA receptors and their insertion into the postsynaptic density.

### 10.4.2 STP Is a Transient Presynaptic Form of Plasticity

In an early experiment to probe for changes in postsynaptic sensitivity, it was observed that LTP was associated with a delayed increase in sensitivity to AMPAR agonists (Davies et al., 1989). This suggests that whereas E-LTP correlates in time with alterations in postsynaptic function, STP occurs without any such changes. The simplest interpretation of this result is that STP is presynaptic, a conclusion supported by a detailed paired-pulse facilitation analysis (Volianskis and Jensen, 2003). This study revealed a surprising property of STP: It decays in an activity-dependent manner. If afferent stimulation is discontinued after tetenization, STP appears at full

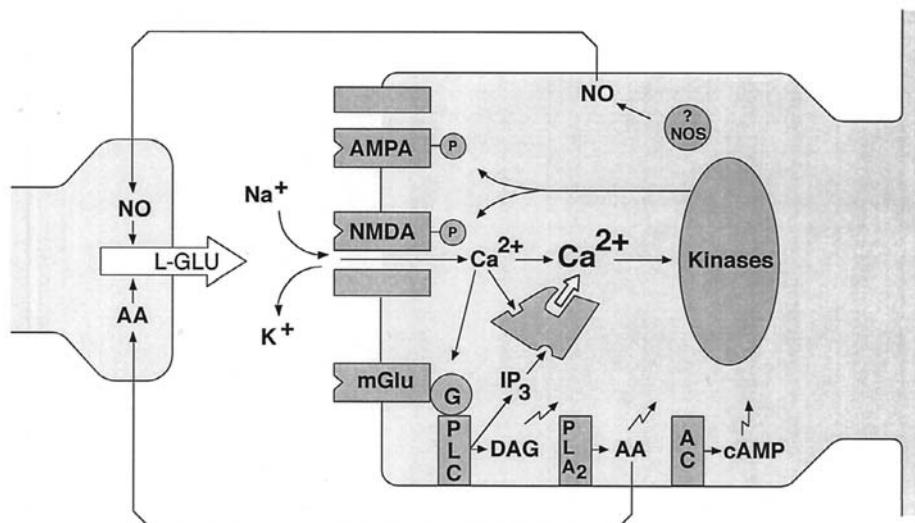

strength and decays with the same time course when afferent stimulation is resumed, even when the intervening period is as long as 6 hours. [As a result, it was proposed that STP may be more accurately referred to as a transient form of LTP (T-LTP); however, here we retain the more widely known term, STP.] In addition, it was found that the magnitude of STP was influenced by the frequency of afferent stimulation, such that higher frequencies favored larger STP. This finding may explain why the extent of STP observed in different experiments is highly variable. In particular, a brief high-frequency tetanus followed by a low rate of test stimulation (as typically used in field potential recordings) would favor the generation of a large-magnitude STP with slow decay, whereas an intermediate frequency of stimulation for both the induction and expression periods (as typically used during pairing experiments) militates against STP. This may explain why pairing induced potentiation generally lacks the STP component.

### 10.4.3 Early LTP Involves Multiple Protein Kinase-dependent Mechanisms

Many studies have presented evidence that protein kinases are involved in LTP (Fig. 10–8). Most of this work relates to the study of E-LTP. With few exceptions, STP is resistant to kinase inhibitors. The role of protein kinases in L-LTP is discussed later in this section.

#### Protein Kinase C

The first kinase to be implicated in LTP was protein kinase C (PKC) (Lovering et al., 1987) (Fig. 10–9A). However, the inhibitors used in these initial studies were relatively nonspecific, so the effects observed may have been via actions on other kinases. Indeed, several reports have observed no effect of potent, more specific PKC inhibitors on LTP (see Muller et al., 1992; Bortolotto and Collingridge, 2000). On the other hand, a role for PKC has been proposed based on the use of peptide inhibitors applied intracellularly (Malinow et al., 1989). In addition, effects of more selective (though not totally specific) PKC inhibitors have been described under certain circumstances, for example during de-depression (the tetanus-induced restoration of the response in a pathway in which LTD has previously been induced) (Daw et al., 2000). The most likely explanation is that PKC is involved in some, but not all, aspects of E-LTP. Understanding the role of PKC in LTP is complicated by the existence of multiple isoforms; the  $\text{Ca}^{2+}$  and diacylglycerol-activated, conventional PKCs (cPKCs:  $\alpha$ ,  $\beta I$ ,  $\beta II$ ,  $\gamma$ );  $\text{Ca}^{2+}$ -independent, diacylglycerol-activated, novel PKCs (nPKCs:  $\delta$ ,  $\epsilon$ ,  $\eta$ ,  $\theta$ ); and the  $\text{Ca}^{2+}$ -independent, diacylglycerol-independent atypical PKCs (aPKCs:  $\zeta$ ,  $\iota$ ). The spectrum of subtype selectivity of the various inhibitors is incomplete, and there is limited information available from knockout experiments. Elimination of the neuron-specific isoform PKC $\gamma$  leads to inhibition of LTP, although not if the LTP is preceded by low-frequency stimulation (Abeliovich et al., 1993). This suggests that PKC $\gamma$  may play a regulatory role

**Figure 10-8.** Signal transduction mechanisms in early LTP. The trigger for the induction of LTP is  $\text{Ca}^{2+}$  permeating through the NMDA receptor. This is amplified by  $\text{Ca}^{2+}$  release from  $\text{Ca}^{2+}/\text{IP}_3$ -sensitive stores. The amplified  $\text{Ca}^{2+}$  signal together with other activators of protein kinases (zigzag arrows) then leads to the phosphorylation of substrate proteins, including AMPA and NMDA receptors, and the insertion of AMPA receptors into the

postsynaptic membrane (not shown). These post-translational processes contribute to E-LTP. Protein synthesis-dependent mechanisms at the synapse and by signals passing to the nucleus are responsible for L-LTP. Putative retrograde messengers, Nitric oxide (NO) and arachidonic acid (AA), that may stimulate presynaptic changes are also indicated. (Source: After Bliss and Collingridge, 1993.)

in the induction of LTP. Of great interest is the finding by Sacktor and colleagues that a peptide substrate inhibitor of  $\text{PKM}\zeta$ , the autonomously active catalytic domain of  $\text{PKC}\zeta$ , blocks the expression of pre-established L-LTP (Ling et al., 2002; Serrano et al., 2005; see Section 10.4.9). Bath application of the inhibitor at the time of the tetanus has no effect on E-LTP but blocks the development of L-LTP.

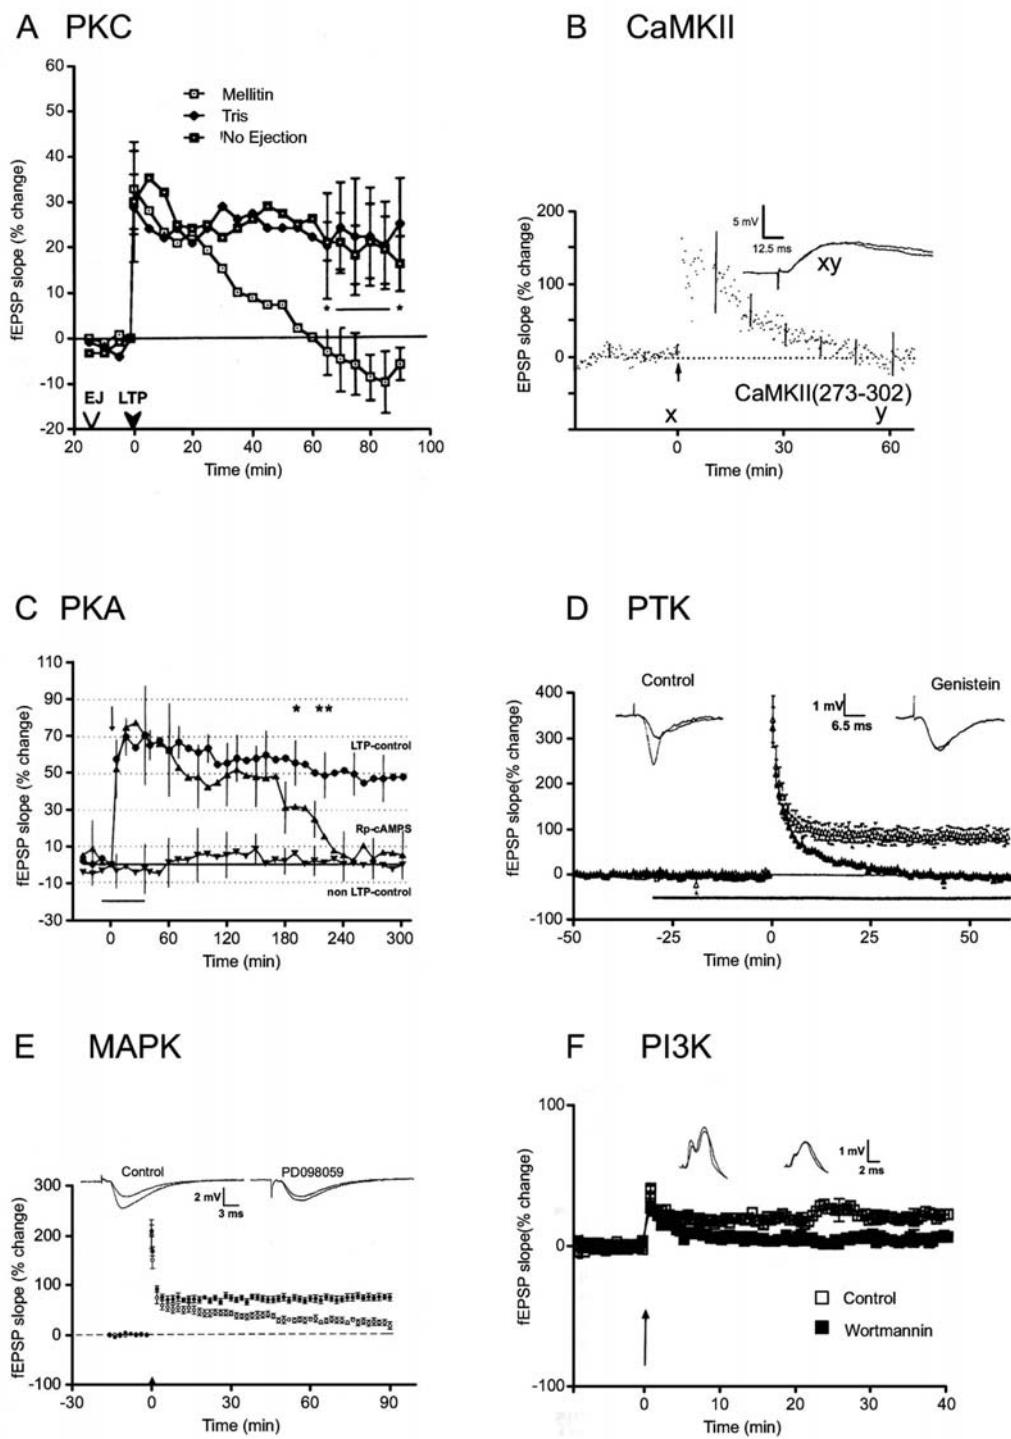

In other experiments phorbol esters have been used to activate PKC. This treatment leads to a potentiation of synaptic transmission which superficially resembles LTP (Malenka et al., 1986; Hu et al., 1987). However, the potentiation is reversible following washout of the phorbol ester and does not occlude with tetanus-induced LTP. Moreover, phorbol esters directly interact with other proteins, such as munc-13, a protein involved in neurotransmitter release, and so any effects of phorbol esters may be unrelated to activation of PKC (Kazanietz et al., 2000).

The trigger for the induction of PKC-dependent potentiation may be  $\text{Ca}^{2+}$  entering via NMDA receptors. An alternative route is via glutamate binding to group I mGluRs (mGluR1 and mGluR5), the activation of which leads to production of diacylglycerol and release of  $\text{Ca}^{2+}$  from intracellular stores—the two triggers for activation of cPKCs. In this context, potent PKC inhibitors prevent mGluR-mediated metaplasticity (Bortolotto and Collingridge, 2000).

### CaMKII

Calcium/calmodulin-dependent protein kinase II (CaMKII) is a major component of the postsynaptic density, comprising 2% of its protein content (Lisman et al., 2002). The holoenzyme

consists of dodecamers of  $\alpha$  and  $\beta$  subunits. In its inactive state, the ATP binding site of the catalytic region of the enzyme is bound to an autoinhibitory domain in the regulatory region. When calcium-loaded calmodulin binds to a calmodulin-binding region in the 3' region of the molecule, a conformational change occurs that separates the autoinhibitory domain from the ATP binding site and renders the enzyme active. Following a transient surge in calcium concentration, intramolecular autophosphorylation at threonine 286 can occur, producing a conformation that allows the enzyme to remain autonomously active when calcium levels fall, thereby endowing the enzyme with the properties of a molecular switch (Miller and Kennedy, 1986). Two isoforms of the calcium/calmodulin-dependent protein kinase II are present in the adult hippocampus,  $\alpha\text{CaMKII}$  and  $\beta\text{CaMKII}$ , of which the dominant form in area CA1 is  $\alpha\text{CaMKII}$ . There is a wealth of evidence to indicate that  $\alpha\text{CaMKII}$  is required for and, when activated, capable of producing LTP in area CA1 of the adult animal (reviewed by Lisman et al., 2002). First, specific peptide inhibitors of  $\alpha\text{CaMKII}$ , based on the autoinhibitory domain of the enzyme, which suppress both calcium-dependent and calcium-independent activity, block induction of LTP (Malinow et al., 1989) (Fig. 10-9B). Second, the membrane-permeable CaMKII inhibitors KN-62 and KN-93 block induction of LTP in a reversible manner (Ito et al., 1991). Third, LTP is impaired in  $\alpha\text{CaMKII}^{-/-}$  mice (Silva et al., 1992b), although there may be a background effect contributing to this deficit (Hinds et al., 1998). Fourth, mice with a threonine to alanine point mutation at residue 286 that prevents autophosphorylation do not display LTP in area CA1 (Giese et al., 1998). In addition, LTP is associated with the dendritic accumulation of

**Figure 10-9.** Role of protein kinases in the induction and expression of LTP. *A*. The PKC inhibitor mellitin, injected into the dentate gyrus *in vivo* 15 minutes prior to a tetanus, blocks E-LTP but spares STP. Similar findings were obtained with polymyxin B and H-7, implicating PKC as the kinase responsible. (*Source*: Lovinger et al., 1987.) In this and subsequent panels the slope of the fEPSP (or intracellular EPSP in *B*) is plotted versus time. Control experiments are also shown, except in *B*. In each case, a tetanus was delivered at  $t = 0$ . *B*. A peptide inhibitor of CaMKII [CaMKII(273-302)] loaded into CA1 neurons *in vitro* blocks E-LTP but not STP. Similar results were obtained using a peptide inhibitor of PKC. (*Source*: Malinow et al., 1989.) *C*. The PKA inhibitor Rp-cAMPS blocks L-LTP in the CA1 region of the hippocampus *in vitro*. STP and E-LTP are unaffected. (*Source*: Matthies and Reyman, 1993.) *D*. The tyrosine kinase inhibitor genistein blocks E-LTP but not STP at CA1 synapses *in vitro*. Similar results were obtained using lavendustin A. (*Source*: O'Dell et al., 1991a.) *E*. The MAPK inhibitor PD098059 blocks induction of E-LTP but not STP at CA1 synapses *in vitro*. activated CaMKII and an associated phosphorylation of AMPARs (Fukunaga et al., 1995). Finally, CaMKII mimics and occludes the induction of LTP (Pettit et al., 1994). However, as compelling as the evidence is for involvement of CaMKII in LTP under some circumstances, the situation is not as straightforward as it may seem. Although there is general agreement that the induction of LTP is associated with a persistent ( $> 1$  hour) phosphorylation of  $\alpha$ CaMKII, there is disagreement about whether the increase in enzyme activity is transient (Lengyel et al., 2004) or persistent (Fukunaga et al., 1995). Also there is currently no direct evidence that a constitutively active form of CaMKII is involved in the maintenance of LTP. Inhibitors of CaMKII applied following the induction of LTP have no effect (Ito et al., 1991; Chen et al., 2001b). However, these inhibitors compete with the calmodulin binding site, and hence the  $\text{Ca}^{2+}$ /calmodulin-dependent activation of the enzyme, but do not affect the constitutively active form. Thus whilst persistent re-activation of the enzyme can be discounted as a mechanism it is possible that a constitutively active form of CaMKII maintains LTP. Specific membrane permeable inhibitors of the constitutively active form are required to test this possibility. What is clear however is that CaMKII is not ubiquitous in its involvement in NMDAR-dependent LTP. For example, in area CA1 at an early stage in development (P9) CaMKII inhibitors have no effect on the induction of LTP (Yasuda et al., 2003), and at an intermediate stage of development (P14) CaMKII forms one arm of a parallel kinase cascade (Wikström et al., 2003). Thus, the importance of CaMKII in LTP increases during development. Even in the adult animal, however, autophosphorylation of  $\alpha$ CaMKII is not a general requirement for NMDAR-dependent LTP, since potentiation in the medial perforant path of the dentate gyrus is minimally affected in T286A mutant mice; in these mice autophosphorylation at residue 286 cannot occur (Cooke et al., 2006). However, as in juvenile CA1, there is evidence for involvement of CaMKII as part of a parallel pathway also involving PKA and MAPK (Cooke et al., 2006; see below). Finally, it should be noted that CaMKII is involved in metaplasticity in area CA1 (Bortolotto & Collingridge, 1998) and so biochemical changes that accompany LTP may relate to metaplasticity rather than the plasticity *per se* (see Abraham and Tate, 1997).

### Protein Kinase A

Protein kinase A (PKA) is another kinase involved in LTP, and again its role is complex and not fully understood. In general, PKA inhibitors appear to block L-LTP but spare E-LTP (Matthies and Reymann, 1993; Huang and Kandel, 1994) (Fig. 10–9C) via an action in the postsynaptic neuron (Duffy and Nguyen, 2003). A similar conclusion has, in general, been reached on the basis of various genetic experiments in mice (Nguyen and Woo, 2003). However, LTP lasting many hours can be induced in the presence of PKA inhibitors (Bortolotto and Collingridge, 2000). Conversely, E-LTP is affected by PKA inhibitors in some cases (Huang and Kandel, 1994; Blitzer et

al., 1995; Otmakhova et al., 2000). It seems that the role of PKA is determined by a variety of factors, such as the strength and patterns of the high-frequency trains used to induce LTP. Typically, PKA inhibitors are more effective when strong induction protocols are used (Nguyen and Woo, 2003). They are also more effective early in development, before the CaMKII-dependent form of LTP is expressed (Yasuda et al., 2003). Interestingly, the sensitivity of E-LTP to PKA inhibitors is also dependent on the prior level of experience of the animal, such that environmental enrichment results in a larger LTP with the additional component being selectively sensitive to PKA inhibition (Duffy et al., 2001).

Transient bath application of the constitutively active cAMP analogue Sp-cAMPS can produce a persistent, slow-onset enhancement of synaptic transmission in area CA1 that occludes with tetanus-induced LTP (Frey et al., 1993). However, like the PKA-dependent component of tetanus-induced LTP, this is not invariably observed. For example, in one study cAMP analogues did not affect basal transmission but reversed LTD, implicating PKA in de-depression (Kameyama et al., 1998). Intriguingly, there is a strong strain difference in the ability of mice to express cAMP-induced facilitation (Nguyen et al., 2000).

These various observations suggest that the role of PKA is probably to modulate, rather than directly mediate, NMDAR-dependent LTP. One idea is that PKA gates the activity of the pathway leading from activation of CaMKII to the expression of early LTP (Blitzer et al., 1995) via inhibition of the protein phosphatase 1 (PP1), which dephosphorylates CaMKII at ser831 and ser845 (Blitzer et al., 1998). Whether LTP-inducing stimuli induce an increase in the level of cAMP is disputed (Chetkovich and Sweatt, 1993; Blitzer et al., 1995; Pokorska et al., 2003). If there is no increase, constitutive levels of cAMP must be adequate to maintain the gate in its open state.

### Tyrosine Kinases

Initial pharmacological evidence, using relatively nonspecific PTK inhibitors, suggested that protein tyrosine kinases (PTKs) are necessary for E-LTP (O'Dell et al., 1991a Fig. 10–9D). Various nonreceptor tyrosine kinases are expressed in the central nervous system, including src and the src family members fyn and lyn. Genetic elimination of fyn resulted in a deficit in LTP (O'Dell et al., 1991a). Although this knockout was associated with gross structural changes in the dentate gyrus, a successful rescue experiment suggested that the LTP deficit reflected the loss of fyn in the adult, rather than impaired neuronal development (Kojima et al., 1997). The role of fyn appears to be developmentally regulated, as no LTP deficits are seen in animals at less than 14 weeks. Fyn probably acts as a regulatory molecule, as LTP can be induced in the fyn knockout when a strong induction protocol is used. One potential mechanism for how fyn regulates LTP is via phosphorylation of NMDARs (Rosenblum et al., 1996; Rostas et al., 1996) to increase their function. There is also evidence that src is

involved in the induction of LTP via upregulation of the function of NMDARs (Lu et al., 1998). This pathway involves the focal adhesion kinase CAK $\beta$ /PyK2 upstream of src (Huang Y et al., 2001).

### MAP Kinase

Of the several mitogen-associated protein (MAP) kinase cascades that carry extracellular signals to the nucleus, the two that have been extensively studied in the context of LTP are initiated by the small G proteins Ras and Rap-1. They activate the MAP kinase kinase kinases Raf-1 and B-Raf, respectively, the first of the kinases in the three-kinase cascade. The two pathways converge on the second kinase, MEK (MAP kinase kinase), which in turn phosphorylates a pair of MAP kinases known as extracellular regulated kinases 1 and 2 (ERK1, or p44MAPK, and ERK2, or p42MAPK). The ERK/MAP kinase pathway can be positively regulated by PKA via the Rap-1, B-raf pathway and by PKC via the Ras, Raf-1 pathway. PKA can also inhibit the latter pathway. The convergence of initial pathways onto MEK during the second stage of the cascade, and the fact that MAPKs are the only known substrates for MEK has provided a target for pharmacological intervention. Three specific inhibitors are available—PD098059, U0126, SL327—the last of which can cross the blood-brain barrier.

English and Sweatt were the first to explore the role of the MAPK pathway in LTP. They found that LTP-inducing stimuli resulted in increased phosphorylation of ERK1, 2 (English and Sweatt, 1996) and that MEK inhibitors blocked both E-LTP and L-LTP in area CA1 of hippocampal slices (English and Sweatt, 1997) (Fig. 10–9E). However, MAPK seems to be involved in only some forms of LTP. For example, in one study MEK inhibitors blocked induction of a form of theta-induced LTP but did not affect pairing-induced or tetanus-induced LTP (Opazo et al., 2003). The reduction in E-LTP has also been questioned by Kelleher et al. (2004b), who found that LTP in a transgenic mouse expressing a dominant negative MEK was indistinguishable from E-LTP generated in normal mice in the presence of protein synthesis inhibitors; they concluded that the main substrates of the MAP kinase pathway were kinases regulating the protein translational machinery in dendrites.

Nevertheless, local targets that might underlie a contribution of the MAP kinase cascade to E-LTP have begun to be identified. Ras, the small G protein that activates the first kinases (Raf and B-Raf) in the MAP kinase cascade, is implicated in AMPA receptor trafficking in LTP, and another G protein, Rap, which activates a member of the ERK family, p38, is involved in the removal of AMPA receptors from synapses during LTD (Zhu et al., 2002). There is also evidence that MAP kinases interact with scaffolding proteins and with cytoskeletal proteins. A further suggestive finding is that activation of MAP kinase through PKA and PKC can downregulate a dendritic A-type K<sup>+</sup> channel in CA1 pyramidal neurons, leading to a reduction in the threshold for back-propagation

and potential enhancement of LTP (Yuan et al., 2002; reviewed by Sweatt, 2004).

### PI3 Kinase

Phosphoinositide 3-kinase (PI3K) phosphorylates phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P<sub>2</sub>, or PIP<sub>2</sub>] to produce phosphatidylinositol 3,4,5-trisphosphate [PtdIns(3,4,5)P<sub>3</sub>, or PIP<sub>3</sub>], which in turn can activate Ca<sup>2+</sup>-independent isoforms of PKC (such as PKC $\gamma$ ), Akt/PKB, and phospholipase C $\gamma$ . PI3K was first implicated in NMDAR-dependent LTP in the dentate gyrus, where it was shown that the inhibitor wortmannin inhibited E-LTP but not STP at perforant path synapses (Kelly and Lynch, 2000) (Fig. 10–9F). Similarly, inhibition of E-LTP but not STP was observed at CA1 synapses using a different PI3K inhibitor, LY294002 (Raymond et al., 2002). In the dentate gyrus *in vivo*, this inhibitor blocked E-LTP induced by single but not multiple trains, suggesting that PI3K is not an obligatory enzyme in LTP induction (Horwood et al., 2006). Interestingly, PI3K may be required specifically for the expression of LTP, as inhibition of the enzyme led to depression of preestablished LTP and, following washout of the inhibitor, recovery of LTP to its initial level (Sanna et al., 2002; but see Opazo et al., 2003). The downstream processes modulated by PI3K are not known but may involve both MAPK-dependent and MAPK-independent pathways (Opazo et al., 2003) that affect the surface expression of AMPARs (Man et al., 2003).

### LTP Involves Multiple and Parallel Kinase Cascades

The principal message to emerge from studies investigating the role of kinases in NMDA receptor-dependent LTP is that several kinases are involved but none is obligatory. The situation is complicated by the fact that the kinase cascades underlying LTP change during development. In area CA1 of the adult animal, as we have seen,  $\alpha$ CaMKII is required for the induction of LTP, and LTP can be induced in the presence of PKA inhibitors. Earlier, at postnatal day 9, the lead role is taken by PKA, as inhibitors of PKA, but not of  $\alpha$ CaMKII, block induction of LTP (Yasuda et al., 2003; see Fig. 10–21C). The situation is made even more complex by the existence of parallel kinase cascades, as first identified at CA1 synapses in juvenile rats. Thus at 2 weeks of age, a combination of inhibitors is required to block the induction of LTP. Inhibitors of CaMKII, PKA, and PKC have no effect on induction when applied alone. Similarly, a PKA inhibitor plus a PKC inhibitor is ineffective. However, a CaMKII inhibitor applied together with either a PKA or a PKC inhibitor fully blocks the induction of LTP (Wikström et al., 2003). This suggests that two parallel kinase pathways, one involving CaMKII and the other involving both PKA and PKC, can each mediate LTP. As the animal matures,  $\alpha$ CaMKII assumes the dominant role, and PKA and PKC become more modulatory in nature. The involvement of parallel kinase cascades is, however, not simply a developmental issue, since a similar parallel pathway has

been observed in the medial perforant path in the dentate gyrus of adult mice (Cooke et al., 2006) and rats (Wu et al., 2006). Here we have a pathway that requires activation of CaMKII for one limb and PKA/MAPK for the other. Since both PKA and PKC can lead to activation of MAPK it is possible that in both juvenile CA1 and adult dentate gyrus the same two parallel pathways co-exist, one arm using CaMKII and the other PKA/PKC/MAPK.

#### **10.4.4 Site of Expression of Early LTP: Experimental Approaches**

LTP research during the 1990s was enlivened by intense debate as to whether NMDAR-dependent LTP is expressed presynaptically or postsynaptically. Many experiments relied on classical electrophysiological approaches, such as paired-pulse facilitation, failures analysis, or quantal analysis (see Box 10–1). Unfortunately, no clear consensus has emerged owing to the difficulty of obtaining accurate measurements coupled with an incomplete understanding of the quantal basis of synaptic transmission at central synapses (see Box 10–1).

Over the years considerable evidence has accumulated in favor of both presynaptic (Fig. 10–11) and postsynaptic (Fig. 10–12) mechanisms, and we examine the evidence for each in turn. First, though, we consider three experimental approaches that were designed to detect changes in transmitter release following the induction of LTP and that, by and large, failed to do so.

#### **Differential Potentiation of AMPA and NMDA Receptor-Mediated Responses**

An electrophysiological approach that has been used to address the locus of expression of LTP is based on a comparison of the relative potentiation of the AMPA and NMDA receptor-mediated components of synaptic transmission—the logic being that an increase in the probability of transmitter release ( $Pr$ ) should affect both components equally, while a postsynaptic modification of the AMPA receptor should result in selective potentiation of the AMPA receptor-mediated component. This makes the assumption that an increase in L-glutamate would increase both synaptic components equally. This would not be the case if, for example, NMDA receptors were saturated, or nearer to being saturated, than AMPA receptors—an issue that still has not been fully resolved at hippocampal synapses (see Section 6.6.1). Conversely, a similar increase in both synaptic components could occur by a postsynaptic mechanism that affects both AMPA and NMDA receptor-mediated components of synaptic transmission. In addition to these theoretical caveats, there has been no experimental consensus with respect to whether LTP involves a specific increase in the AMPAR-mediated component. While one early study reported a selective increase in the AMPAR-mediated component (Kauer et al., 1988), others have reported an increase in both components, ranging from

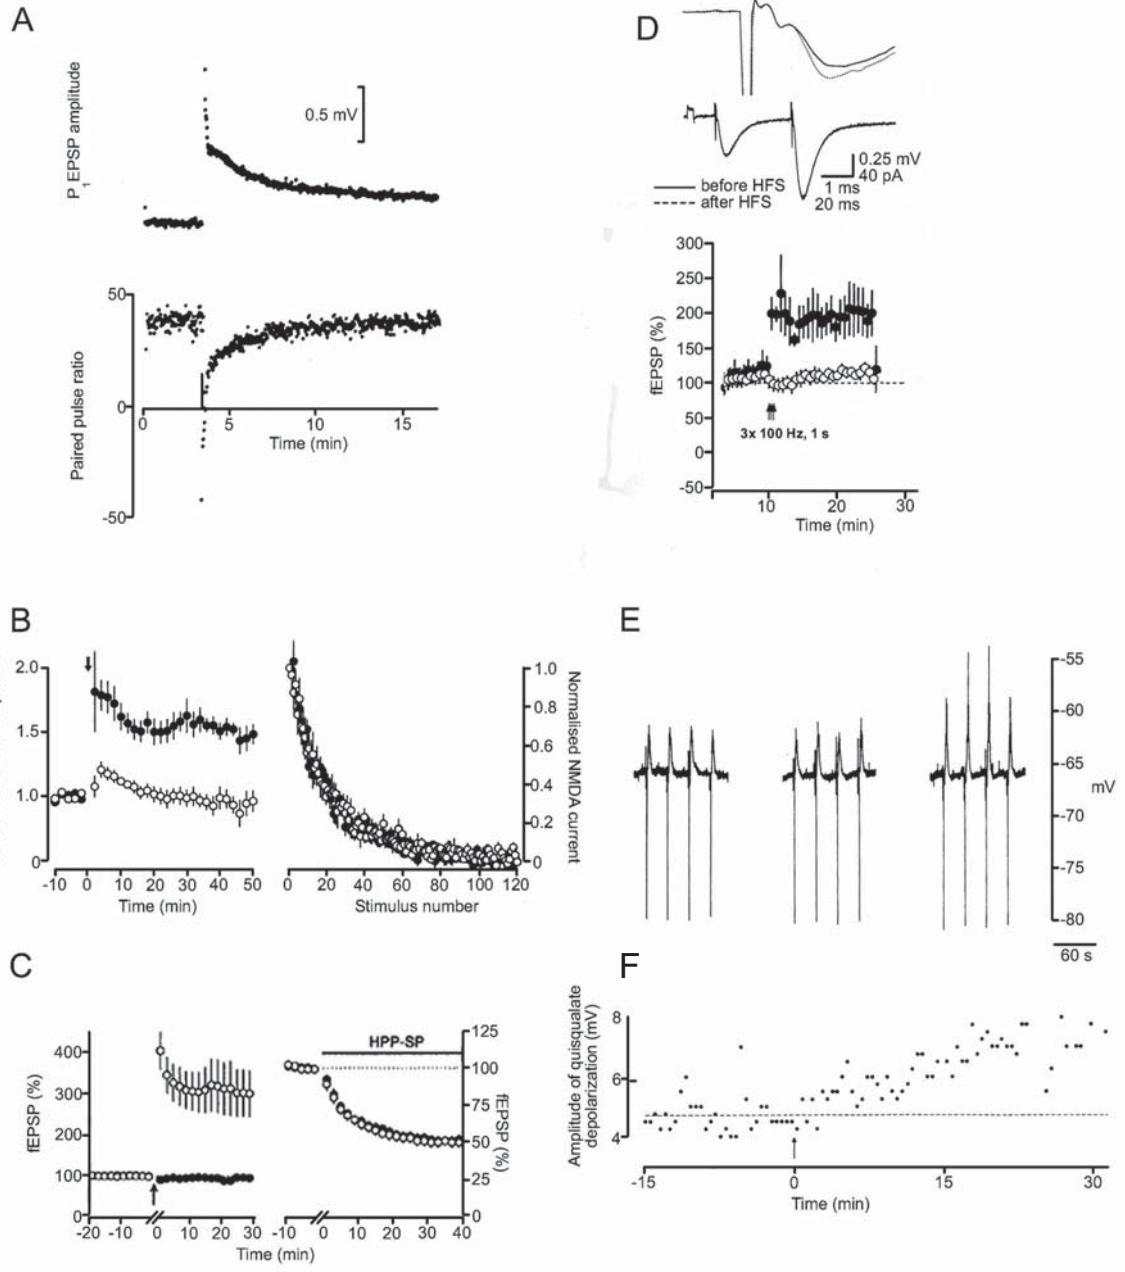

a larger increase in the AMPAR-mediated component (Muller et al., 1988; Kullmann et al., 1996; Dozmorov et al., 2006) to a similar increase in both synaptic components (Clark and Collingridge, 1995; O'Connor et al., 1995). The lack of consensus plus the issues of interpretation mean that little can be concluded from these experiments regarding the locus of expression of LTP. Another conclusion to have emerged from these studies is that the NMDAR-mediated component of synaptic transmission is plastic. Interpretation of alterations in the NMDAR-mediated component of dual-component synaptic transmission is complicated by the voltage escape associated with the AMPAR-mediated component coupled with the voltage dependence of the NMDAR-mediated conductance. However, LTP has been observed by several groups following blockade of AMPAR-mediated synaptic transmission (Bashir et al., 1991; Beretta et al., 1991; O'Connor et al., 1994; Grosshans et al., 2002). Plasticity of the NMDAR-mediated response has obvious functional implications for metaplasticity (see Section 10.3.13).

#### **Kinetics of Open Channel Blockers Do Not Indicate an Increase in Transmitter Release in LTP**

Another approach has been to use open-channel blockers to estimate the probability of release,  $Pr$ . The potent noncompetitive NMDAR antagonist MK-801 blocks NMDA receptors once they have been activated by synaptically released L-glutamate, and once in the channel the receptor remains blocked during the lifetime of the experiment (Hessler et al., 1993; Rosenmund et al., 1993). During repetitive stimulation high- $Pr$  synapses are therefore blocked more quickly than low- $Pr$  synapses. It was found that LTP of AMPA receptor-mediated synaptic transmission was not associated with any change in the MK-801 blocking rate of NMDAR-mediated synaptic transmission (Manabe and Nicoll, 1994) (Fig. 10–10B). This was taken as evidence that LTP does not involve an increase in  $Pr$ . A more direct approach was to use an open-channel blocker of the AMPAR-mediated component. Philanthotoxin (PhTx) blocks GluR2-lacking,  $\text{Ca}^{2+}$ -permeable AMPA receptors in a use-dependent manner and so can be used to monitor  $Pr$ . LTP was not associated with any change in the PhTx blocking rate in the GluR2 knockout mouse (Mainen et al., 1998) (Fig. 10–10C), again indicating no change in  $Pr$ . Similar experiments could not be performed in wild-type animals owing to the presence of GluR2 subunits in the great majority of the AMPA receptors on principal neurons.

#### **Electrogenic Uptake of Glutamate by Glia Reports an Increase in Extracellular Glutamate During PTP but Not During LTP**

Yet another approach has been to use glial currents as a monitor of neurotransmitter release. Glial cells accumulate synaptically released L-glutamate by an electrogenic uptake carrier: An increase in neurotransmitter release should therefore generate a larger glial current. An increase in electrogenic current was

**Figure 10–10.** Evidence that LTP involves postsynaptic changes. **A.** LTP is not associated with a corresponding alteration in paired-pulse facilitation in the dentate gyrus *in vivo*. The upper plot shows the amplitude of the EPSP evoked by the first stimulus of the pair. The lower plot shows the amplitude of the second EPSP divided by that of the first EPSP for each pair to generate the paired-pulse ratio. Note that there was a decrease in the paired-pulse ratio only during the initial phase of PTP, lasting approximately 10 minutes. (*Source:* McNaughton, 1982.) **B.** LTP is not associated with changes in Pr at CA1 synapses *in vitro*, as assessed by measuring the rate of blockade of NMDA receptor-mediated currents by MK-801. LTP of AMPA receptor-mediated EPSCs was induced (at  $t = 0$ ) in one input (filled symbols) but not in a control input (open symbols). AMPA receptors were then blocked and the neurons depolarized to reveal the NMDA receptor-mediated EPSC. MK-801 was applied and allowed to equilibrate before stimulation was commenced. Both inputs were blocked at the same rate, indicating that the average Pr at control and potentiated inputs was similar. (*Source:* Manabe and Nicoll, 1994.) **C.** LTP is not associated with changes in Pr at CA1 synapses *in vitro*, as assessed by measuring the rate of blockade of

AMPA receptor-mediated currents by spermine in the GluR2 knockout mouse. This experiment was conducted in a manner similar to that illustrated in **B** except AMPA receptor-mediated synaptic transmission was monitored throughout, and a spermine derivative (HPP-SP) was used to block the activated receptors. (*Source:* Mainen et al., 1998.) **D.** LTP is not associated with an alteration in L-glutamate release, as detected using glial transporter currents. LTP of fEPSPs is illustrated in the upper traces and in the time-course plot. The lower traces are glia-transporter currents in response to paired-pulse stimulation before and following the induction of LTP. Note that the records are superimposable, indicating no change in the glial current. (*Source:* Diamond et al., 1998.) **E.** LTP is associated with an increase in postsynaptic sensitivity to exogenous AMPA receptor activation. The upper records are depolarizations of a CA1 neuron in response to ionophoretic application of an AMPA receptor ligand (quisqualate) obtained before, immediately following, and 30 minutes following the induction of LTP (at  $t = 0$ ). The graph plots the amplitude of these depolarizations with time. Note the gradual increase in postsynaptic sensitivity, with a time course that correlates with E-LTP. (*Source:* Davies et al., 1989.)

observed during PTP but not during LTP in area CA1, providing evidence against increased release as an expression mechanism for LTP (Diamond et al., 1998; Luscher et al., 1998) (Fig. 10–10D). An analogous result was obtained in area CA3. LTP at mossy fiber synapses, but not at associational-commissural synapses, was associated with a sustained increase in glial uptake current (Kamamura et al., 2004). This observation is consistent with other evidence that LTP at mossy fibers is maintained by presynaptic mechanisms (see Section 10.5) and suggests that LTP at associational-commissural synapses lacks a strong presynaptic component.

#### **Evidence for Presynaptic and Postsynaptic Mechanisms in LTP**

Disagreements among laboratories notwithstanding, these three approaches have generally been seen as providing evidence against presynaptic changes and hence as strengthening the case for a purely postsynaptic change. There is, nevertheless, as we discuss below, a corpus of data that provides evidence for both presynaptic and postsynaptic changes. Although there is a sufficient body of data to make a convincing case for presynaptic changes, relatively little insight has yet been gained into molecular mechanisms that support an increase in transmitter release. For the postsynaptic side, there are also direct experiments demonstrating changes in response to applied transmitter following induction of LTP. In addition, there is now a large and compelling set of data that gives detailed insights into how postsynaptic changes are brought about by posttranslational modifications of existing receptors and trafficking of receptors between the cytoplasm and extrasynaptic and synaptic membranes. A cautionary note should be entered here; almost all the work that has characterized the molecular substrate of postsynaptically mediated LTP and LTD has been carried out in *in vitro* preparations during the first hour or so of early LTP or LTD. The mechanisms that support the enduring changes seen in late LTP or LTD are more likely to be structural in nature, and such changes almost certainly involve both sides of the synapse.

#### **10.4.5 E-LTP: Presynaptic Mechanisms of Expression**

The induction of LTP in the dentate gyrus *in vivo* is associated with a persistent increase in the efflux of L-glutamate (Dolphin et al., 1982) (Fig. 10–11A). The increase is activity- and NMDA receptor-dependent and has been detected using both a push-pull perfusion technique (Errington et al., 1987, but see Anksztejn et al., 1989) and a glutamate-sensitive electrode (Errington et al., 2003). There are several ways, not mutually exclusive, in which LTP could be expressed presynaptically. There could be an increase in the number of release sites, either within a presynaptic terminal or as a result of the formation of new terminals. Alternatively, there could be an increase in the number of vesicles released per impulse. Another possibility is an alteration in the amount of L-

glutamate stored in or released from each vesicle. Finally, there could be an increase in the probability that an action potential in an afferent fiber leads to transmitter release, either because of a more efficient conduction of the impulse to the terminal or because of a higher probability of release ( $Pr$ ) in response to the invading action potential. The studies that have measured the gross amount of L-glutamate released cannot distinguish between these possibilities or other alterations that affect the extracellular concentration of L-glutamate. In this context, however, there is little evidence that the uptake or diffusion of L-glutamate is affected during LTP.

Several lines of evidence are consistent with an increase in the probability of transmitter release. Using minimal stimulation to activate a putative single release site, Stevens and Wang (1994) showed that LTP in area CA1 was associated with a decrease in failure rate without change in potency (the mean amplitude of responses excluding failures) (Fig. 10–11B). Bolshakov and Siegelbaum (1995) also reported an increase in  $Pr$  in the same region in neonatal rats. These findings are subject to the usual caveats regarding interpretation of quantal observations (see Box 10–1), although it should be emphasized that these were not silent synapses.

Consistent with the idea of an increase in  $Pr$ , a few studies have detected a decrease in paired-pulse facilitation (PPF) during LTP (Schulz et al., 1994; Kleschevnikov et al., 1997). For example, in slices from P6 rats there is a large decrease in PPF that fully accounts for the LTP in most, but not all, neurons (Palmer et al., 2004) (see Fig. 10–21D). This alteration is not due to changes in fiber failures, suggesting that an increase in  $Pr$  is the most likely explanation. However, the effect was tightly regulated developmentally and was absent by P12. Moreover, many studies have not observed changes in PPF.

Direct evidence for a presynaptic mechanism in cultured hippocampal neurons was obtained by measuring exocytotic-endocytotic cycling with antibodies against the synaptic vesicle protein synaptotagmin (Malgaroli et al., 1995) (Fig. 10–11C). A novel mechanism proposed by Tsien and colleagues involves an LTP-dependent modification of the fusion pore such that more L-glutamate is released from a fused vesicle (Choi et al., 2000). Under basal conditions the amount of L-glutamate released may be so small as not to elicit a detectable AMPAR-mediated postsynaptic response. Glutamate concentration may, however, be high enough to activate NMDARs, thus providing a potential presynaptic explanation for silent synapses. LTP then modifies the release machinery to enable a greater amount of L-glutamate discharge from each fused vesicle. Another direct way of estimating the probability of glutamate release is to measure the rate of destaining of synaptic vesicles loaded with the steryl dye FM1-43. Activity-dependent destaining was more rapid following induction of LTP, an effect that was blocked by NMDA receptor antagonists (Fig. 10–11D). An intriguing example of presynaptic unsilencing has been provided by Ma et al. (1999), who showed that in hippocampal cultures treated with a cAMP analogue (a treatment that induces a late, protein synthesis-dependent

form of LTP), there was a dramatic increase in the number of active boutons taking up the dye FM1-43 (Fig. 10–11E).

Long-term potentiation is associated with an increase in phosphorylation of the presynaptic protein GAP-43 (Routtenberg and Lovinger, 1985; Gianotti et al., 1992). Other studies examined glutamate-induced LTP in cultured hippocampal neurons and found an increase in presynaptic boutons associated with clusters of the presynaptic proteins synaptophysin (Antonova et al., 2001) and  $\alpha$ -synuclein (Liu et al., 2004b).

Changes in Pr at single synapses following induction of LTP in pyramidal cells of areas CA1 and CA3 has been assessed using  $\text{Ca}^{2+}$  indicators to monitor synaptic events at single visualised spines in organotypic hippocampal cultures (Emptage et al., 2003; Fig. 10.11F). Emptage et al. argued that the probability of evoking a  $\text{Ca}^{2+}$  transient in the visualised spine, PCa, provides an accurate measure of the probability of transmitter release, Pr, at that synapse, since manipulations that reflect an increase in Pr, such as paired pulse facilitation, also result in an increase in PCa, whereas manipulations that decrease Pr, such as bath application of adenosine, lead to a decrease in PCa. In the majority of spines examined, induction of LTP by high-frequency stimulation was accompanied by an increase in PCa at the imaged spine, whereas in experiments in which LTP was blocked by D-AP5, or in which the threshold for LTP was not reached, no change in PCa was seen. The  $\text{Ca}^{2+}$  signal is NMDA receptor-dependent, but the extent to which the evoked  $\text{Ca}^{2+}$  transient in spines reflects  $\text{Ca}^{2+}$  entering through the NMDA receptor varies with cell type and preparation (Yuste and Denk, 1995; Kovalchuk et al., 2000; Sabatini et al., 2002).  $\text{Ca}^{2+}$  entering via the NMDA receptor following a single stimulus could not be resolved by Emptage et al. (2003), but the trigger signal was greatly amplified, and the event thus made visible, by calcium-induced calcium release from internal stores (Emptage et al., 1999). The indirect nature of the  $\text{Ca}^{2+}$  transient raises the possibility that the observed increase in PCa following LTP may reflect an increase in the coupling between the initial trigger  $\text{Ca}^{2+}$  and store release, rather than an increase in Pr. Failures, according to this account, would include not only failures of release but also failures of postsynaptic coupling, so that pCa gives an underestimate of Pr. In this view, the reason that pCa is increased in LTP is that enhanced AMPAR function leads to an increase in the EPSP at the spine, a consequent increase in trigger  $\text{Ca}^{2+}$  entering through the NMDA receptor, and hence to a reduction in the number of failures due to failed coupling. This interpretation is rendered unlikely by the observation that bath application of a low dose of the AMPAR antagonist CNQX, which greatly reduces the amplitude of the AMPAR-mediated EPSP recorded at the soma, has little if any effect on PCa (Emptage et al., 2003). Nevertheless, a more direct method of measuring Pr would be desirable. One promising approach is to transfect neurons with a glutamate-binding protein tagged with a pair of fluorophores that yield a fluorescence resonance energy transfer (FRET) signal when L-glutamate is released from the presynaptic terminal (Okumoto et al., 2005).

#### 10.4.6 E-LTP: Postsynaptic Mechanisms of Expression

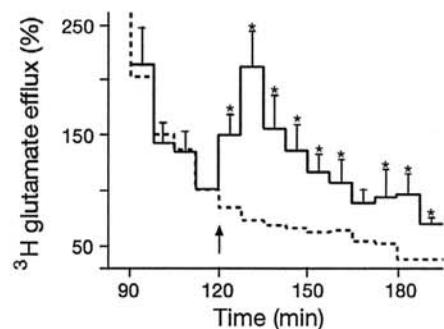

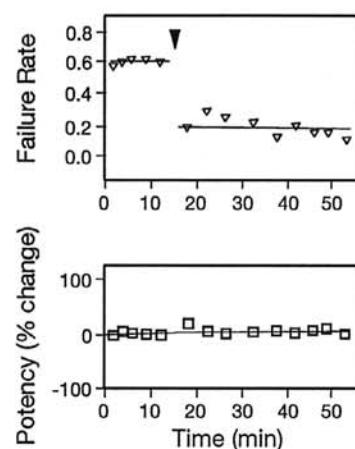

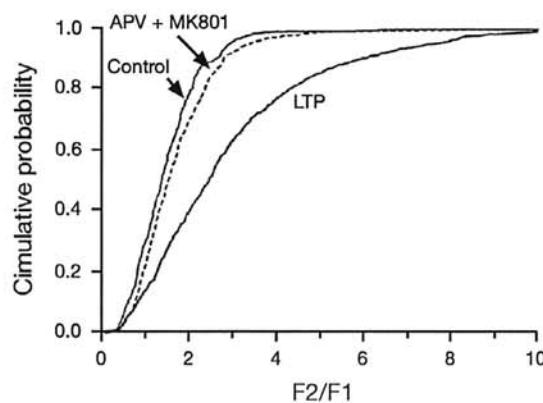

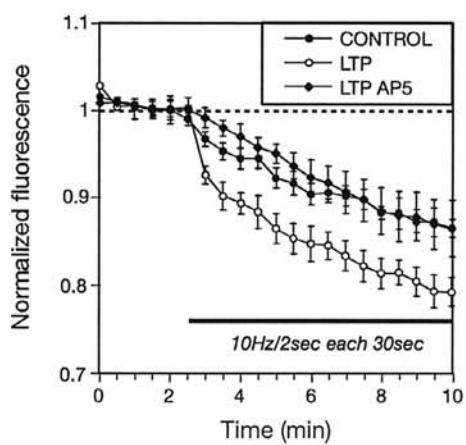

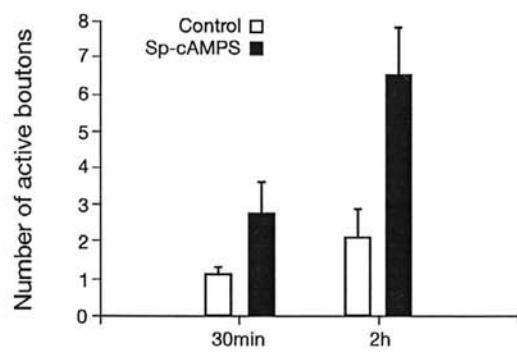

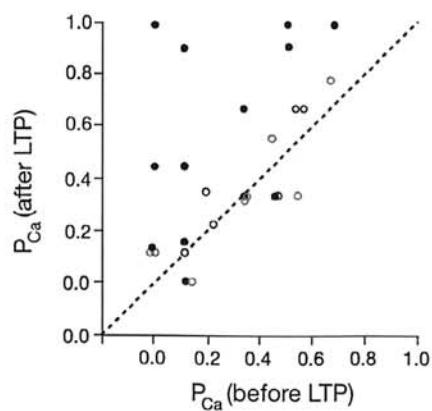

There is also direct evidence for postsynaptic alterations. Initial experiments compared the sensitivity of neurons, before and after the induction of LTP, to ligands that act on AMPA receptors. LTP was invariably associated with an NMDA receptor-dependent increase in AMPA receptor sensitivity (Davies et al., 1989) (Fig. 10–10E). The effect was not immediate but occurred after a short delay (a few minutes or tens of minutes depending on the precise experimental protocol used). Subsequent work has also detected an increase in sensitivity to exogenously applied AMPA receptor ligands (Montgomery et al., 2001). A more refined approach is to deliver L-glutamate locally by photolytic release of glutamate from a caged precursor. Under these conditions, a rapid NMDAR-dependent increase in sensitivity has been observed (Matsuzaki et al., 2004; Bagal et al., 2005).

Broadly speaking, there are three categories of postsynaptic mechanisms by which LTP can be expressed. The first is modification of the properties of the receptors already present at the synapse. The second is an increase in the number of receptors available at the synapse to respond to the synaptic release of L-glutamate. The third involves changes downstream of glutamate receptors, such as alterations in voltage-gated or leak channels to affect the spread of depolarization (e.g., Fan et al., 2005). Although there is evidence for alterations in voltage-gated ion channels, most emphasis has been on the glutamate receptors themselves. As discussed above, NMDA receptor-dependent LTP is expressed as changes in both AMPA receptor- and NMDA receptor-mediated synaptic transmission. Because synaptic responses evoked at resting membrane potentials by low-frequency stimulation are mediated predominantly by the activation of AMPA receptors (Herron et al. 1986), it is these receptors that have been at the center of attention.

#### Modification of Existing Receptors Contributes to LTP

The amount of current that passes through an AMPA receptor is determined by the probability of opening ( $P_o$ ) on binding L-glutamate, the mean open time, and the single-channel conductance ( $\gamma$ ). Alterations in mean open time of AMPARs would be reflected as a change in the kinetics of EPSCs. Despite claims to the contrary (Kolta et al., 1998), it is usually accepted that the decay of AMPAR-mediated EPSCs is not changed by LTP. This is most clearly seen when dendritic recording is used to maximize the signal-to-noise of minimal EPSCs and to reduce the dendritic filtering that is unavoidable with somatic recording (Benke et al., 1998). Also, treatment with cyclothiazide, which inhibits both deactivation and desensitization to cause pronounced slowing of the EPSC, does not affect the expression of LTP (Rammes et al., 1999).

Electrophysiological experiments cannot easily distinguish between insertion of AMPA receptors, and changes in  $P_o$  or  $\gamma$ . However, in a few cases  $\gamma$  has been estimated by nonstation-

**A****B****C****D****E****F**

ary fluctuation analysis. At CA1 synapses of 2-week-old rats it was found that in most neurons  $\gamma$  increased sufficiently to account for LTP (Benke et al. 1998) (Fig. 10–12A). In other neurons  $\gamma$  did not change, suggesting that any postsynaptic change was due to an increase in N, the number of receptors, or Po. The simplest explanation for the increase in  $\gamma$  is a modification of receptors already present at the synapse, but it could theoretically be due to the exchange of lower for higher  $\gamma$  receptors at the synapse. The estimate of  $\gamma$  derived from nonstationary fluctuation analysis is the weighted mean of all subconductance states (Cull-Candy and Usowicz 1987; Jahr and Stevens, 1987). Because AMPA receptors can adopt multiple conductance states, it was suggested that LTP was due to an alteration in the relative time spent in these various states (Benke et al., 1998). Consistent with this idea, CaMKII-mediated phosphorylation of ser831 on GluR1 not only occurs during LTP (Barria et al., 1997a,b) but leads to an increase in precisely this parameter in HEK293 cells expressing GluR1 (Derkach et al., 1999). Furthermore, synaptic potentiation induced by postsynaptic application of a constitutive form of CaMKII is associated with an increase in  $\gamma$  (Poncer et al., 2002). Thus a simple scheme for the induction and expression of LTP is that  $\text{Ca}^{2+}$  entering via NMDA receptors triggers

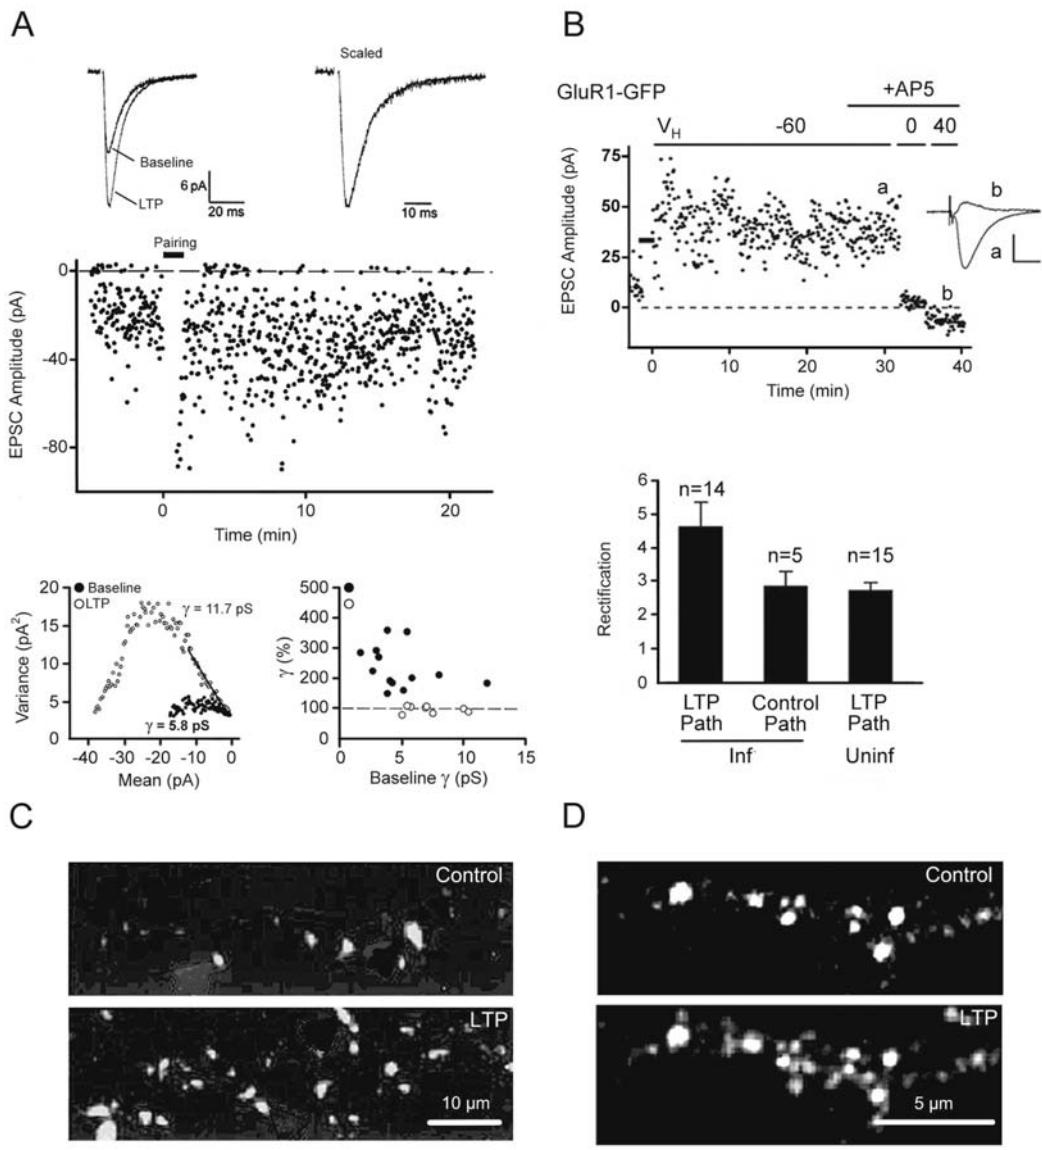

CaMKII-dependent phosphorylation of GluR1 to increase the single-channel conductance of existing AMPA receptors. However, although this mechanism may occur, it cannot be the whole story, as CaMKII inhibitors applied alone fail to inhibit LTP at this stage of development (Wikström et al., 2003; Yasuda et al., 2003).

### Insertion of AMPA Receptors Contributes to LTP

A popular hypothesis for the expression of LTP is an increase in the number of AMPA receptors available to respond to synaptically released L-glutamate. These receptors could be inserted from an intracellular compartment and/or diffuse laterally from extrasynaptic regions. In the simplest scenario, the new synaptic receptors would have conductance properties identical to those of the existing ones. Alternatively, the new receptors could have a different subunit composition, thereby conferring different conductance properties (i.e., single-channel conductance, rectification,  $\text{Ca}^{2+}$  permeability) to the potentiated synapses. Indeed, early in development (around the first week of life) LTP was observed in some neurons that was associated with a decrease in  $\gamma$  (Palmer et al., 2004), the simplest explanation of which is the insertion of

**Figure 10–11.** Evidence that LTP involves presynaptic changes. A. LTP in the dentate gyrus of the anesthetized rat is associated with an increase in the efflux of  $^3\text{H}$  glutamate. At the beginning of the experiment a bolus of  $^3\text{H}$ -glutamine was injected into the dentate gyrus. The dentate gyrus was perfused using a push-pull cannula; and perfusates were collected for the measurement of  $^3\text{H}$ -glutamate, newly synthesized from  $^3\text{H}$ -glutamine. In control animals, the concentration of  $^3\text{H}$ -glutamate declined exponentially (dotted line). Field responses were recorded at the same time (not shown). In animals in which LTP was induced by high-frequency stimulation (arrow), the concentration of  $^3\text{H}$ -glutamate was increased relative to control values for the following hour (solid line). Abscissa, time since injection of  $^3\text{H}$ -glutamine; ordinate,  $^3\text{H}$ -glutamate concentration normalized to its value in the collection interval immediately preceding the tetanus. (Source: Dolphin et al., 1982.) B. LTP at presumptive single synapses in area CA1 is associated with a decrease in failure rate (upper panel), with no change in the potency of the response (i.e., the amplitude of the evoked synaptic current for trials where a release event occurred) (lower panel). Responses were evoked by minimal stimulation to Schaffer-commissural axons in the acute hippocampal slice. (Source: Stevens and Wang, 1994.) C. Increase in synaptic activity visualized at single synapses in cultured hippocampal neurons following glutamate-induced LTP. Goat or rabbit antibodies recognizing the intraluminal domain of the vesicular protein synaptotagmin were used to measure vesicular cycling. Cultures were incubated with one of the antibodies for an hour. LTP was then induced by brief application of glutamate, and the second antibody then applied for a second hour. The degree of internalization of each antibody was measured using fluorescence-labeled anti-goat and anti-rabbit antibodies. The ratio of fluorescence during the second hour relative to the first ( $F_2/F_1$ ) was measured in several hundred individual synapses. The shift to the right in the cumula-

tive distribution curve in potentiated cultures compared to control cultures or cultures in which LTP was blocked by NMDA receptor antagonists indicates a significant increase in vesicular cycling after induction of LTP. (Source: Malgaroli et al., 1995.) D. Visualization of increased transmitter release after LTP using the dye FM1-43. The rapidly recycling pool of vesicles in Schaffer-commisural terminals was loaded in vitro by exposing slices to FM1-43 in hypertonic ACSF to stimulate transmitter release. Activity-induced destaining was measured 30 minutes after reperfusion with ACSF by stimulating with 10 Hz, 2-second trains at 30-second intervals. The rate of destaining was accelerated in potentiated tissue (open circles), relative to tissue treated with AP5 to block LTP (filled diamonds) or to control tissue (filled circles). (Source: Stanton et al., 2005 with addition of control data courtesy of the authors.) E. A membrane-permeable analogue of cAMP induces an increase in the number of boutons taking up FM1-43 in CA3-CA1 neuronal cultures. The bars show the ratio of the number of stained boutons before and 30 minutes or 2 hours after exposure to the control solution (open bars) or solution containing Sp-cAMP. Exposure to cAMP itself can induce slow-onset late LTP (see Section 10.4.3). Both cAMP-induced LTP and the increase in the number of active boutons is protein synthesis-dependent. (Source: Ma et al., 1999.) F. Tetanus-induced LTP in organotypic hippocampal cultures is associated with an increase in the probability of obtaining a synaptically generated  $\text{Ca}^{2+}$  transient ( $p_{\text{Ca}}$ ) in single visualized spines on pyramidal neurons. The graph plots  $p_{\text{Ca}}$  before and 30 minutes after the induction of LTP for a group of individual spines (filled circles). In other experiments (open circles), LTP was not induced either because no tetanus was given or induction was blocked by AP5. There was a significant increase in  $p_{\text{Ca}}$  in the group of tetanized spines from cells in which LTP was induced relative to control spines. (Source: Emptage et al., 2003.)

**Figure 10-12.** Postsynaptic mechanisms involved in the expression of LTP. **A.** LTP is associated with an increase in single-channel conductance ( $\gamma$ ) of synaptic AMPA receptors at CA1 synapses in vitro. The traces are the mean amplitudes before and following induction of LTP superimposed (left) and expanded and peak-scaled (right). Note the lack of change in the shape of the potentiated EPSC. The graph plots the amplitude of EPSCs versus time before and following pairing induced LTP. The graph below (left) plots the variance of the decay phase of the EPSC versus the amplitude of each point on the EPSC decay. The initial slope of the plot provides an estimate of  $\gamma$ , which is this neuron approximately doubled following LTP. The graph (right) plots the change in  $\gamma$  associated with LTP against the baseline value of  $\gamma$ . Note that in most neurons  $\gamma$  increased (and this was sufficient to account for LTP), but in some neurons there was no change in  $\gamma$ . The latter neurons tended to have a higher baseline  $\gamma$ . (Source: Benke et al., 1998.) **B.** LTP involves the insertion of AMPA receptors at CA1 synapses in vitro, as determined using recombinant receptors with distinct electrophysiological properties. The graph plots EPSC amplitude versus time, and LTP was induced at  $t = 0$ . The rectification of the AMPA receptor-mediated EPSC was estimated by comparing its amplitude at positive and negative membrane potentials following blockade of NMDA receptors. LTP caused an increase in rectification in GluR1-transfected cells (Inf), indicating insertion of new GluR1 homomeric receptors. (Source: Hayashi

et al., 2000.) **C.** LTP in cultured neurons is associated with the insertion of native AMPA receptors, as assessed using a GluR1-specific antibody. AMPA receptors in cultured hippocampal neurons were labeled with a GluR1-specific antibody, and a nonfluorescent secondary antibody was then bound to them. LTP was induced by perfusion with glycine. The cultures were then challenged with GluR1 antibody, which bound to the newly inserted GluR1 receptors and were detected using a fluorescent secondary antibody. The panels show a representative portion of a dendrite from a control neuron (upper) and a neuron following glycine-induced LTP (lower). (Source: Lu et al., 2001.) **D.** LTP in cultured neurons is associated with the insertion of native AMPA receptors, as assessed using a pan-AMPA antibody. AMPA receptors in cultured hippocampal neurons were labeled with a GluR1-4-specific antibody, and their distribution visualized using a fluorescent secondary antibody. LTP was then induced by transient depolarization ( $3 \times 1$ -second pulses of 50 mM K<sup>+</sup>). The cultures were then challenged with pan-AMPA antibody raised in a different species. This bound to newly inserted AMPA receptors, which were detected using a fluorescent secondary antibody directed against the second species. The panels show a representative portion of dendrite from a neuron before (upper) and following (lower) induction of LTP. Note the appearance of new clusters of AMPA receptors at sites that had previously lacked any detectable AMPA receptors. (Source: Pickard et al., 2001.)

new receptors with a lower  $\gamma$  than the existing population of receptors.

To address AMPA receptor movement in relation to LTP more directly, two complementary approaches have been used, each with its own relative advantages and disadvantages. In one approach, recombinant AMPA receptor subunits are constructed containing a reporter, such as green fluorescent protein (GFP). LTP in organotypic slice cultures was found to be associated with delivery of GFP-GluR1 to dendritic spines (Shi et al., 1999). However, because imaging could not determine whether these constructs were inserted into the plasma membrane, mutated receptors were used that had a distinct electrophysiological signature (Hayashi et al., 2000). The synaptic delivery of these receptors was then determined by alterations in the rectification properties of the synaptic currents (Fig. 10–12B). Based on these studies it is clear that recombinant AMPA receptors can be rapidly inserted into synapses during LTP in organotypic slices. Whether the recombinant receptors are inserted selectively into potentiated synapses and, if so, whether they fully account for the potentiated response remains to be established.

In the second method, antibodies that recognize extracellular epitopes of AMPA receptor subunits are used, in conjunction with protocols that induce NMDAR-dependent LTP in dissociated cultured hippocampal neurons. The alteration in native AMPA receptor distribution is determined using fluorescently conjugated secondary antibodies. Using this approach, insertion of native AMPA receptors during NMDAR-dependent LTP has been described (Lu et al., 2001; Pickard et al., 2001). These studies identified the insertion of GluR1-containing AMPA receptors into synapses that previously lacked GluR1 (Lu et al., 2001; Fig. 10–12C) via a PI3K-dependent process (Man et al., 2003). They also demonstrated insertion of AMPA receptors into anatomically “silent” synapses (synapses where AMPA receptors could not be detected on the cell surface) (Pickard et al., 2001; Fig. 10–12D). The use of AMPA receptor antibodies has also enabled the lateral mobility of AMPA receptors to be studied in the plasma membrane. Single-molecule fluorescence microscopy has revealed that there are both mobile and immobile receptors contained within spines and extrasynaptically (Tardin et al., 2003). Stimulation with L-glutamate increases synaptic AMPA receptor diffusion rates, raising the possibility that LTP involves the mobilization of extrasynaptic AMPA receptors and their targeting to the postsynaptic density. Consistent with this idea, there is evidence that following exocytosis AMPA receptors are diffusively distributed along dendrites before accumulating at synaptic sites (Passafaro et al., 2001).

**Molecules that bind to AMPARs give clues to the molecular mechanisms involved in LTP.** Understanding the molecular mechanisms of AMPA receptor synaptic trafficking during LTP has been greatly aided by the identification of proteins that bind directly to, and regulate the synaptic function of, AMPA receptors. Different proteins interact with the GluR1 and GluR2 subunits, and seem to play distinct roles in LTP

and LTD (see sections 10.3.7 and 10.7.3). From this has arisen the concept of the subunit-dependence of synaptic plasticity. In broad terms, the GluR1 subunit seems to play a major role in LTP whilst the GluR2 subunit is the more important in LTD. However, as we shall see, this is to simplify a complex situation.

**GluR2 interactors: Evidence for rapid recycling and regulation of subunit composition of AMPARs at synapses.** An initially surprising observation was that *N*-ethylmaleimide-sensitive fusion protein (NSF), an ATPase involved in membrane fusion events, binds directly to the GluR2 subunit (Nishimune et al., 1998; Osten et al., 1998; Song et al., 1998). Blockade of the GluR2-NSF interaction resulted in a rapid decrease in electrically evoked AMPAR-mediated synaptic transmission, suggesting that AMPA receptors can rapidly recycle at the synapse (Nishimune et al., 1998). Blockade of this interaction also led to internalisation of AMPARs, suggesting that NSF regulates the membrane insertion or stabilisation of synaptic AMPARs (Noel et al., 1999; Lüscher et al., 1999). These observations raised the possibility that modification of recycling rates could underlie LTP. Indeed, there is some evidence for a role of NSF and soluble NSF attachment proteins (SNAPs) in AMPA receptor insertion during LTP (Lledo et al., 1998).

A second region of the C-terminal tail of GluR2 is the site of interaction of the PDZ-containing proteins GRIP (glutamate receptor interacting protein), ABP (AMPA receptor binding protein), and PICK1 (protein interacting with C-kinase 1). ABP and GRIP contain multiple PDZ domains and probably serve to anchor AMPA receptors at both synaptic (Osten et al., 2000) and intracellular (Daw et al., 2000) locations. Some isoforms of ABP/GRIP are palmitoylated, which targets them to the synaptic membrane (Yamazaki et al., 2001; DeSouza et al., 2002). These molecules presumably also localize other proteins involved in the LTP process, close to AMPA receptors. For example, GRIP binds to an associated protein, GRASP-1, which is a neuronal RasGEF and so may link AMPA receptors to Ras signaling (Ye et al., 2000).

PICK1 can also bind PKC $\alpha$ , suggesting that one of its functions is to target PKC to phosphorylate AMPA receptors. Indeed, there is evidence that PICK1 may phosphorylate GluR2 on ser880 to inhibit the binding of AMPA receptors to ABP/GRIP (Matsuda et al., 1999), and this mechanism may be involved in the mobilization of AMPA receptors from their ABP/GRIP tethers. In the context of LTP, it has been proposed that PICK1-PKC phosphorylation of ser880 on GluR2 mobilizes AMPA receptors from intracellular sites during depression (i.e., reversal of LTD by an LTP induction protocol) (Daw et al., 2002). PICK1 is a particularly interesting molecule since it also regulates the GluR2 content of AMPA receptors at synapses (Terashima et al., 2004), raising the possibility that it may play a role in LTP by altering the conductance properties of synaptic AMPA receptors. Indeed, it has been found that LTP at CA1 synapses in two-week-old animals involves the rapid insertion of GluR2-lacking AMPARs followed by their replacement with GluR2-containing AMPARs, over a period

of 20 minutes or so (Plant et al., 2006). The transient insertion of calcium permeable AMPARs may provide a signal, or tag, to mark recently potentiated synapses. Given that PICK1 is able to regulate the GluR2-content of AMPARs, and is the only molecule known to do this, it is a prime candidate for mediating this effect.

**GluR1 interactors: A key role in LTP?** There is evidence that GluR1 receptors are particularly important for synaptic delivery during LTP (Hayashi et al., 2000). Malinow and his colleagues have proposed that GluR1/GluR2 heteromers are inserted into the membrane during LTP, whilst GluR2/GluR3 heteromers are important for constitutive recycling of AMPA receptors at synapses (Shi et al., 2001). However, the mechanisms involved are unclear. Both spine delivery of GluR1 and LTP in organotypic slices requires activation of CaMKII, but deletion of ser831, the CaMKII phosphorylation site on the C-terminal tail of GluR1, did not prevent either of these effects (Hayashi et al., 2000). However, a point mutation on the PDZ domain at the extreme C-terminus of GluR1 (T887A) did prevent spine delivery and LTP suggesting that CaMKII may phosphorylate a protein that binds to this site. One such candidate is the membrane associated guanylate kinase (MAGUK) SAP97, which binds to GluR1 via its PDZ domain and has been implicated in trafficking to the synapse (Leonard et al., 1998). SAP97 enhances AMPAR-mediated synaptic transmission in cultured neurons, an effect mediated by a SAP97 splice variant containing a binding site for a GluR1 binding protein, 4.1, that has been implicated in linking AMPA receptors to the cytoskeleton (Rumbaugh et al., 2003). Overexpression of SAP97 leads to an enhancement of AMPAR-mediated transmission in hippocampal organotypic cultures that partially occludes with LTP (Nakagawa et al., 2004); the effect depends on the L27 domain of SAP97, which is involved in forming multimeric assemblies of SAP97, either with itself or other proteins containing a similar domain. Another pertinent finding is that CaMKII is able to phosphorylate SAP97 and this targets SAP97 to synapses (Mauceri et al., 2004), an effect that may explain the actions of CaMKII in driving AMPARs into synapses and into the PSD. Such a process may involve the motor protein myosin VI, since this forms a complex with both GluR1 and SAP97 (Wu et al., 2002). However, deletion of the entire PDZ domain of GluR1 does not prevent the induction of LTP in transgenic mice (Kim et al., 2005a). Further work is therefore required to establish the role of the PDZ domain of GluR1 in LTP.

There is also evidence for a role of PKA in driving GluR1-containing AMPARs into synapses (Esteban et al., 2003). Mutagenesis of ser845 has shown that this PKA site is required though its phosphorylation is not sufficient for LTP, suggesting that this is one stage in a multi-step process. One possibility is that PKA-dependent phosphorylation of ser845 is involved in the membrane targeting of AMPARs to extrasynaptic sites (Oh et al., 2006). PKC is also implicated in the trafficking of GluR1 and LTP, via phosphorylation of ser818 (Boehm et al., 2006).

**Tarps add a new dimension.** AMPA receptors also bind to stargazin, which in turn binds to PSD95 (Chen et al., 2000). Stargazin is one of a class of TARPs (transmembrane AMPAR regulatory proteins) that are involved in the recruitment of AMPA receptors from extrasynaptic to synaptic sites during LTP (Bredt and Nicoll, 2003). Consistent with this role of TARPs and PSD95, overexpression of PSD95 selectively enhances AMPAR-mediated synaptic transmission and occludes LTP (Stein et al., 2003; Ehrlich and Malinow, 2004). Indeed, the level of PSD95 at the synapse, which may be regulated by ubiquitination (Colledge et al., 2003) and palmitoylation (El Husseini et al., 2002), could directly determine the number of AMPA receptors at synapses. In addition, the interaction of AMPA receptors with TARPs is dynamically regulated both allosterically via ligand binding and through phosphorylation of TARPs (Chetkovich et al., 2002; Tomita et al., 2004).

In addition to regulating the number of AMPARs on the membrane surface, TARPs also increase the apparent affinity of AMPARs for glutamate. They slow the rate of both deactivation and desensitization and enhance  $\gamma$ , by increasing the prevalence of high conductance substates (Tomita et al., 2005). It has been estimated that TARPs increase the charge transfer of synaptic currents by approximately 30%.

The  $\gamma$ -8 TARP isoform is highly enriched in the hippocampus and the knockout of this protein leads to a profound loss of AMPAR subunits and a reduction in AMPAR-mediated EPSCs. LTP in knockout animals was greatly reduced, suggesting that TARPs are involved in synaptic plasticity (Rouach et al., 2005). TARPs can be phosphorylated by both CaMKII and PKC and dephosphorylated by PP1 and PP2B. Mutation of the target serines to alanine resulted in block of LTP, whilst conversely mutation of these residues to aspartic acid, to mimic phosphorylation, drove AMPARs to synapses and blocked LTD (Tomita et al., 2005). Thus, regulation of TARPs seems play a critical role in hippocampal synaptic plasticity.

In summary, a scheme is emerging whereby alterations in AMPA receptor number are controlled by protein–protein interactions and phosphorylation. The types of binding partners and kinases involved seem to vary depending on the AMPA receptor subunit and the stage of development. During LTP, AMPA receptors probably diffuse laterally in the synaptic membrane from extrasynaptic sites to the PSD to increase the number of receptors available to bind to synaptically released L-glutamate. This process may also be associated with insertion of AMPA receptors from an intracellular reservoir via exocytosis.

#### Locus of Expression of NMDAR-dependent LTP: a Site Inspection

What emerges from this summary of a large literature is that there is no clear consensus on the question of the locus of hippocampal LTP. Most camps were, and some remain today, highly entrenched in their view that LTP can be expressed only via their own favored mechanism. Objective analysis of all of

the evidence, however, points to a multitude of expression mechanisms that may vary according to the component of LTP under investigation (i.e., STP, E-LTP, L-LTP), the developmental stage of the animal (see Fig. 10–21), and even the experimental approach used to tackle the problem. More recently, attention has focused on trying to understand the molecular mechanisms responsible for pre- and postsynaptic changes.

There are several indisputable facts. First, there is strong evidence in favor of both pre- and postsynaptic mechanisms, so NMDAR-dependent LTP can involve changes at both sides of the synapse. Second, there are pronounced differences in the signalling and expression mechanisms of LTP at different stages of development (see Section 10.9). Third, there is evidence that the various phases of LTP may involve different expression mechanisms. For example, the increase in sensitivity to AMPA receptor ligands correlates with E-LTP but not STP. Fourth, the type of LTP and its expression mechanism may depend on how it is induced; a tetanus causes repetitive activation of the presynaptic cell whereas pairing does not. We conclude therefore that LTP is expressed by alterations in either L-glutamate release and/or AMPA receptor function, the extent of each component depending on several factors, of which the list above is unlikely to be exhaustive.

#### **10.4.7 Retrograde Signaling Is Required for Communication Between the Postsynaptic Site of Induction and the Presynaptic Terminal**

We have seen that the trigger for the induction of LTP in the Schaffer-commissural and perforant pathways is the entry of calcium through activated NMDA channels located on the postsynaptic cell. Evidence from a variety of techniques and preparations points to a presynaptic component to the expression of LTP (Section 10.4.5). Early evidence for increased transmitter release in LTP led Bliss and Dolphin (1984) to postulate that a diffusible retrograde signal is released from the postsynaptic site of induction to interact with the presynaptic terminal and in some manner stimulate transmitter release. To date, there has been no unequivocal identification of a retrograde signaling molecule mediating LTP or LTD at hippocampal excitatory synapses. Most attention has focused on two candidates, the unsaturated membrane fatty acid arachidonic acid (AA) and the gas nitric oxide (NO) synthesized from L-arginine by nitric oxide synthase. Other potential retrograde messengers not considered further here that at one time had their champions include platelet-activating factor (Miller et al., 1992) and carbon monoxide (Stevens and Wang, 1993). Other potential diffusible messengers are brain-derived trophic factor (BDNF) (see Section 10.6.1) and an endogenous endocannabinoid, 2-AG, discussed above in the context of E-S potentiation (Section 10.3.12), which appears to act as a retrograde mediator of heterosynaptic LTD at inhibitory synapses in area CA1 (Chevaleyre and Castillo, 2003). Intersynaptic communication via membrane-spanning adhesion molecules is another way in which signals could be com-

municated in a retrograde direction (Murai and Pasquale, 2004). In this section we review the evidence for these various candidates. Before starting, we consider a set of criteria that a diffusible candidate messenger should satisfy. Note that a retrograde messenger is required only to generate the presynaptic component of LTP; this is designated  $LTP_{pre}$  in the following list.

- The cellular machinery for synthesis of the messenger exists in the postsynaptic cell.
- The synthesis of the messenger is upregulated by LTP-inducing stimuli.
- Postsynaptic injection of drugs that block synthesis inhibits LTP induction.
- The messenger is released into the extracellular compartment following induction of  $LTP_{pre}$ .
- Perfusion with extracellular scavengers small enough to access the synaptic cleft inhibit  $LTP_{pre}$ .
- A target molecule in the presynaptic terminal, positively linked to transmitter release, is activated by the messenger.
- Drugs that inhibit the link between messenger and exocytosis suppress  $LTP_{pre}$ .
- Exogenous application of the messenger induces  $LTP_{pre}$  or lowers the threshold for its induction.

No candidate retrograde messenger has yet been shown to satisfy all the criteria on this admittedly demanding list.

#### **Arachidonic Acid**

Arachidonic acid (AA) is produced by the action of a calcium-dependent enzyme, phospholipase A2, on membrane phospholipids. In 1987, Piomelli et al. (1987) suggested that AA, or one of its lipoxygenase metabolites, might serve as a synaptic retrograde messenger in LTP on the basis of experiments in *Aplysia* that identified lipoxygenase metabolites of arachidonic acid as a novel class of second messenger. A year later, Bockaert and his colleagues made the significant observation that activation of NMDA receptors in cultured striatal neurons led to the release of AA into the culture medium (Dumuis et al., 1988). The first evidence that the AA cascade played a role in LTP followed in the same year in a report that an inhibitor of AA production blocked chemically induced LTP in area CA1 and the dentate gyrus (Williams and Bliss, 1988). Subsequent studies, reviewed in Bliss et al. (1990), demonstrated that AA satisfies several of the criteria for a retrograde messenger: (1) LTP is accompanied by an increase in the concentration of AA in a postsynaptic membrane fraction and an increase in the extracellular concentration of AA; (2) inhibitors of phospholipase A<sub>2</sub> block induction of LTP; (3) the application of arachidonic acid to active hippocampal synapses causes delayed but persistent potentiation of evoked responses. Nevertheless, these results, although pointing to a role for arachidonic acid in LTP, do not compel the conclusion that it is a retrograde messenger; there are missing gaps in the evidence (Do extracellular scavengers of AA block induction? What is the

presynaptic mode of action of AA that leads to an increase in transmitter release?). Moreover, some of the evidence can be explained by other known properties of AA, including inhibition of glutamate uptake into glia (Barbour et al., 1989) and its facilitatory action on NMDA currents (Miller et al., 1992). For these reasons, AA has fallen out of fashion as a candidate messenger for LTP. However, evidence that a 12-lipoxygenase metabolite of AA, 12(S)-HPETE, mediates the induction of mGluR-dependent LTD in area CA1 of young rats has been presented by Bolshakov and colleagues (Feinmark et al., 2003). It remains to be seen whether 12(S)-HPETE satisfies all the criteria for a retrograde messenger, including activity-dependent upregulation in the postsynaptic cell.

### Nitric Oxide

Nitric oxide has had a more durable career as a candidate retrograde messenger than AA, though again the evidence remains incomplete. NO is a small membrane-permeable molecule with a short half-life—two desirable properties for a potential retrograde messenger. In neurons, NO is derived from L-arginine in a reaction catalyzed by nitric oxide synthase, of which two isoforms, nNOS and eNOS, are expressed in dendrites of hippocampal neurons. Like AA, NO is released from cultured neurons exposed to NMDA (Garthwaite et al., 1988). The target of NO is soluble guanylyl cyclase, which activates cyclic guanosine monophosphate (cGMP), one substrate for which is protein kinase G (PKG). Little is known of the effector molecules linked to this second messenger system in hippocampal synaptic terminals (see review by Hawkins et al., 1998).

Attempts to block induction of LTP with inhibitors of nitric oxide synthase have met with variable success. In vitro (Cummings et al., 1994) and in vivo (Bannerman et al., 1994) experiments failed to confirm initial reports that inhibition of NO synthase blocked the induction of LTP (Bohme et al., 1991; Schuman and Madison, 1991; Haley et al., 1992). In experiments in hippocampal slices, inhibition of LTP by NO synthesis inhibitors was seen at room temperatures but not at higher, more physiological temperatures (Williams et al., 1989). There is also disagreement about whether the application of NO, in combination with weak synaptic activation, produces LTP; two groups reported that it did (O'Dell et al., 1991b; Bon and Garthwaite, 2003), whereas a third found that it did not (Murphy et al., 1994). However, the latter finding, based on the release of NO by flash photolysis from an inactive caged precursor, has been shown to reflect an interaction between NO and ultraviolet light, leading to artifactual inhibition of NMDA receptor currents (Hopper et al., 2004). Knockout by homologous recombination of either of the two genes encoding the two isoforms of NO in hippocampal neurons fails to block LTP. However, LTP is compromised, though not abolished, in a double knockout of both genes (Son et al., 1996).

Evidence linking postsynaptically generated NO to enhanced transmitter release has emerged from a study on cultured hippocampal neurons, in which NO released by synaptic

stimulation led to accelerated vesicle endocytosis via a cGMP-dependent pathway (Micheva et al., 2003). An interesting insight from this work is that NO acts only on stimulated terminals, consistent with the possibility that it could selectively affect neighboring active terminals, in addition to the terminal(s) whose activity was responsible for evoking its release from postsynaptic cell(s). The observed changes were blocked by NMDA receptor antagonists, establishing the likelihood that NO was produced postsynaptically and was thus acting as a genuine diffusible retrograde messenger. There is also evidence that NO affects vesicle recycling in LTD (see Section 10.7.4), suggesting that the direction of change is determined by the interaction of NO with presynaptic factors (see Section 10.4.9 for discussion of a potentially similar role played by somatically generated plasticity factors in their interaction with synaptic tags that are set either for LTD or LTP).

In a provocative study, Madison and Schuman (1994) made the intriguing observation that intracellular injection of NO synthase inhibitors blocked LTP when it was induced by pairing of single stimuli with depolarization of the impaled cell but not when it was induced by high-frequency trains. Their explanation of this dissociation is as follows. When pairing is used to induce LTP, the paired cell itself is the sole source of the putative retrograde messenger. If it is NO (or a messenger downstream of NO synthesis), intracellular application of an NO synthase inhibitor would be expected to block LTP, as observed. However, when LTP is induced by a tetanus, the surrounding cells are subject to LTP and themselves make and release the putative retrograde messenger. This could act on the single cell in which NO synthesis has been shut down. Thus, aided and abetted by its neighbors, terminals afferent to this cell can share in the potentiation induced by the high-frequency train. However, this ingenious interpretation is at odds with earlier, well established reports that maneuvers that block LTP at the level of the single cell, such as intracellular injections of calcium chelators (Lynch et al., 1983) or hyperpolarization (Kelso et al., 1986; Malinow and Miller, 1986), block both pairing-induced and tetanus-induced LTP in pyramidal cells. Little further work has been done on this aspect of hippocampal NO signaling, and there for the moment the story rests.

### 10.4.8 Membrane Spanning Molecules Contribute to Signaling Between Presynaptic and Postsynaptic Sides of the Synapse

The retrograde messengers we have considered so far are diffusible substances released from the postsynaptic spine to act in ways that are still somewhat mysterious to affect transmitter release. Another way in which communication can be effected between the two sides of the synapse is via the various classes of membrane-spanning molecules that have partners on the opposite side. In this section we summarize the little that is known about the way in which these interneuronal interactions are regulated by activity and the consequent effects on synaptic function.

## Ephrins and Eph Receptors

Members of the large Eph family of receptor tyrosine kinases and their ephrin ligands play important roles in axon guidance, migration, and boundary determination in neural development (Wilkinson, 2001). Evidence is emerging that Eph receptors and ephrins are involved in the synaptic processes leading to LTP and LTD (reviewed by Murai and Pasquale, 2004) (see Section 10.5.3 for a discussion of their role in mossy fiber LTP). Eph receptors bind to ephrins via their extracellular domains and in doing so trigger reciprocal signaling pathways initiated via the carboxy cytoplasmic regions of both Eph receptors and ephrins, a capability that for Eph receptors is referred to as forward signaling and for ephrins as reverse signaling. EphB2, a member of one of the two major subfamilies of Eph receptors, interacts with NMDA receptors and also, via a PDZ binding domain, with the AMPA receptor scaffolding protein GRIP. These interactions are presumably the route by which Eph receptors become responsive to synaptic activity, and they also provide a route for modulating synaptic function (Henderson et al., 2001). This possibility is reinforced by the demonstration by Grunwald et al. (2004) that ephrinB ligands are required for full expression of LTP and LTD at CA3-CA1 synapses. In both sets of studies, the functionality of the Eph receptor/ephrin partnership was unimpaired by removing the cytoplasmic tail of the Eph receptor, suggesting that reverse signaling by ephrins is the active route to LTP and LTD (Grunwald et al., 2004).

Another potentially important role for Eph receptors and their ephrin partners is in the regulation of spine morphology. EphA4 receptors are expressed on spines of cultured hippocampal pyramidal cells and can be targeted by ephrinA3, which is strongly expressed on the astroglia that envelop spines. This interaction leads to the retraction of spines (Murai et al., 2003). In this way Eph receptors and ephrin interactions could provide a mechanism for structural changes underlying synaptic plasticity.

## Cell Adhesion Molecules

Cell adhesion molecules (CAMs) comprise a large class of diverse membrane-spanning molecules with extracellular ligand-binding domains that are important for cell-cell recognition during neural development and are potential candidates for both anterograde and retrograde transsynaptic signaling. CAMs expressed by neurons fall into four broad types: integrins, cadherins, immunoglobulin superfamily CAMs, and neuroligins and their ligands neurexins (reviewed by Benson et al., 2000 and Yamagata et al., 2003). CAMs, via their extracellular domains, can bind to the same members of the family (homophilic binding) or to other members (heterophilic binding). The C terminal region of many CAMs is associated directly or via accessory proteins to the actin cytoskeleton and can potentially initiate changes in the morphology of the spine or bouton in which they are embedded. In this section

we briefly review the evidence for the involvement of immunoglobulin superfamily members, cadherins, integrins, and neuroligins in LTP.

**Immunoglobulin Superfamily Members.** Mice treated with antibodies to the immunoglobulin superfamily member NCAM and mice with a targeted deletion of NCAM show reduced LTP in area CA1 and in the mossy fiber projection to area CA3 (Benson et al., 2000). PSA-NCAM, a form of NCAM carrying multiple copies of polysialic acid linked to the fifth immunoglobulin domain on the extracellular part of the molecule, has also been implicated in LTP. Enzymatic removal of PSA from NCAM inhibits LTP in area CA1 (Muller et al., 1996). Similarly, LTP is impaired in area CA1 in a knockout mouse lacking one of the two polysialyltransferases that link PSA to NCAM. However, in this mouse, LTP is normal in area CA3, suggesting that whereas PSA-NCAM is required for LTP in area CA1, NCAM itself is needed to support LTP in the mossy fiber projection (Cremer et al., 1998). The roles of two other members of the NCAM family, L1 and Thy-1, in hippocampal synaptic plasticity have also been examined. LTP in a Thy-1 knockout mouse was normal in area CA1 but impaired in the dentate gyrus *in vivo*; performance on the Morris watermaze was unaffected (Nosten-Bertrand et al., 1996; Errington et al., 1997). There is disagreement about whether L1 plays a role in LTP. In an *in vitro* study using functional antibodies against L1, Lüthi et al. (1994) saw reduced LTP in area CA1, but Bliss et al. (2000) found no effect on LTP in area CA1 *in vitro* or in the dentate gyrus *in vivo* in an L1 knockout mouse.

**Cadherins.** Cadherins are an extensive family of cell adhesion molecules with cytoplasmic signaling domains that are linked to the actin cytoskeleton through two accessory proteins:  $\beta$ -catenin, which binds to cadherin, and  $\alpha$ -catenin, which binds to both  $\beta$ -catenin and actin. Cadherin dimers form strongly adhesive homophilic partnerships with similar cadherin dimers on the other side of the synapse. Interestingly, although both E- and N-cadherins are strongly expressed in the hippocampus, N-cadherins are found only at excitatory synapses (Huntley, 2002). The importance of cadherins in the induction of LTP is beginning to emerge from studies using inhibitors, targeted mutations, and confocal microscopy. Tetanus-induced LTP in area CA1 is reduced by peptide blockers of N-cadherin (Tang et al., 1998). Late, delayed-onset LTP, induced in hippocampal slices by bath application of a membrane-permeable cAMP analogue, is accompanied by a rise in synaptic puncta containing both N-cadherins and the presynaptic marker synaptophysin (Bozdagi et al., 2000). Conversely, cAMP-induced LTP is abolished by bath application of blocking antibodies against the dimerization and homophilic interaction domains of N-cadherins (Bozdagi et al., 2000).

The effect on spine morphology of blocking N-cadherin in cultured hippocampal neurons was investigated by Togashi et al. (2002), who found that over a period of 2 days or more spines became longer and more filopodia-like. The same effect

was observed in mutant mice lacking  $\alpha$ -catenin, suggesting that cadherin signaling through actin is required for spine shortening. There is some information on how synaptic activity modulates N-cadherin function. Strong synaptic activation can change the conformation of N-cadherin (Tanaka et al., 2000), and Murase et al. (2002) have made the significant observation that  $\beta$ -catenin is rapidly (within 30 minutes) translocated from dendrite to spine in an NMDAR-dependent manner following synaptic activity. Finally, tyrosine dephosphorylation of  $\beta$ -catenin promotes its movement into the spine, providing a potential point for regulation by synaptic activity via a calcium-dependent tyrosine phosphatase (Murase et al., 2002).

**Integrins.** Integrins are heterodimeric glycoproteins formed from  $\alpha$ , and  $\beta$ , subunits; each comprises a single membrane-spanning domain linking the ligand-binding extracellular domain to a cytoplasmic tail that is connected to actin via the accessory proteins  $\alpha$ -actinin, talin, and vinculin (Benson et al., 2000). There are multiple forms of each subunit, a number of which have been identified in hippocampal pyramidal neurons, including  $\alpha 3$ ,  $\alpha 5$ ,  $\alpha 8$ , and  $\beta 8$  (Chan et al., 2003). The primary extracellular ligands of integrins are matrix proteins, but integrins also participate in cell-cell adhesion through binding to cadherins and members of the immunoglobulin superfamily of cell adhesion molecules. Their role in the stabilization of LTP has been explored by Lynch, Gall, and colleagues (reviewed in Gall and Lynch, 2004). Broad-spectrum peptide inhibitors of integrins attenuate the magnitude and duration of LTP and can reverse LTP if given within a few minutes after induction (Staubli et al., 1998). In a survey of mice with heterozygous deletions of  $\alpha 3$ ,  $\alpha 5$ , or  $\alpha 8$  integrin (homozygous deletions are lethal), Chan et al. found that LTP was attenuated only in the  $\alpha 3$  mutants. Complete suppression of LTP and a deficit in watermaze performance was only seen in mice heterozygous for all three integrins (Chan et al., 2003).

**Neuroligins and Neurexins.** Neuroligins and their ligands neurexins are brain-specific cell adhesion molecules, with multiple forms arising from differential splicing. Neurexins are localized presynaptically, and members of the  $\beta$  subgroup make heterophilic connections with postsynaptic neuroligins. The intracellular C-termini of neuroligins bind to the PDZ region of the postsynaptic protein PSD-95, and the C-termini of neurexins are linked to another PDZ-containing protein, CASK. As Benson et al. (2000) pointed out, these interactions make neuroligins and neurexins potentially well suited for intercellular signaling. Their involvement in LTP has yet to be explored.

## Summary

It is evident from this brief survey of the large, diverse families of neural cell adhesion molecules that there is still much to learn about their role in synaptic plasticity. Disruption of

intercellular interactions has little effect on baseline transmission but, as we have seen, can impair the magnitude and duration of LTP. A major gap in our knowledge is how synaptic activity is signaled to and detected by CAMs. It seems likely that the major contribution of CAMs is as mediators of structural changes, where they can ensure that pre- and postsynaptic changes can be kept in register. However, the potential for two-way signaling, from cytoplasm to cell adhesion molecule and vice versa, remains a highly attractive mechanism for conveying information across the synapse that is only now beginning to be explored.

### 10.4.9 Late LTP: Persistent Potentiation Requires Gene Transcription and Protein Synthesis

Late LTP (L-LTP) is defined as the temporal component of LTP that is abolished by protein synthesis inhibitors or by transcriptional blockers. Because no stimulus protocol has been found that produces L-LTP without the preceding early LTP, the time course of L-LTP must be estimated by a subtraction process. This reveals slow-onset potentiation rising from baseline to reach a plateau after 1 to 2 hours. The slowly growing L-LTP induced by BDNF (Fig. 10–2D) or cAMP analogues has a similar time course.

In principle, persistent changes in synaptic efficacy could occur through self-perpetuating renewal of posttranslational changes (Crick, 1984; reviewed by Routtenberg and Rekart, 2005). Indeed, Kandel and colleagues found evidence for such a mechanism in the translational regulator CPEB (cytoplasmic polyadenylation element-binding protein), a protein with prion-like self-perpetuating properties that is involved in long-lasting facilitation in *Aplysia* (Si et al., 2003). However, the same year that Crick's proposal was published, the first evidence appeared that protein synthesis was indeed essential if LTP in the hippocampus was to persist for more than a few hours. Krug et al. (1984) infused the protein synthesis inhibitor anisomycin into the lateral ventricles of freely moving rats and found that the potentiated fEPSP in the dentate gyrus slowly declined to baseline over 3 to 5 hours. The baseline response was not affected in control experiments. This result appeared to establish an upper limit for the duration of post-translational changes. A similar result was obtained in the anesthetized rat (Otani and Abraham, 1989) and in area CA1 in the hippocampal slice (Frey et al., 1988) (Fig. 10–2C). Transcriptional inhibitors such as actinomycin also block L-LTP in area CA1 in vitro (Nguyen et al., 1994) and in the dentate gyrus in vivo (Frey et al., 1996; but see Otani et al., 1989). Mossy fiber L-LTP, too, as discussed in Section 10.5, is dependent on protein synthesis and gene transcription (Huang et al., 1994). In addition, the slowly growing L-LTP elicited by cAMP analogues (Nguyen et al., 1994) or by BDNF (Kang and Schuman, 1996; Messaoudi et al., 2002) (see Section 10.6.1) is susceptible to translational and transcriptional inhibitors. Thus, all forms of L-LTP that have been identified in the hippocampus require protein synthesis. Persistent LTD induced by mGluR agonists or by paired-pulse low-frequency stimula-

tion is also rapidly blocked by protein synthesis inhibitors (see Section 10.7.4).

The rapid effect of translational inhibitors suggests that the initial phase of L-LTP is dependent on protein synthesis from preexisting mRNA in the dendrites of potentiated synapses (see below). In fact, despite an earlier negative report (Frey et al., 1989), there is persuasive evidence that isolated dendrites can support L-LTP (Vickers et al., 2005). Moreover, local dendritic application of a protein synthesis inhibitor reduces L-LTP in intact slices (Bradshaw et al., 2003). Nevertheless, dendritic protein synthesis cannot be the whole story, given the impairment of L-LTP by transcriptional inhibitors. The effect of transcriptional inhibitors is delayed, beginning 1 to 2 hours after induction. The delay is consistent with a model in which a signal from stimulated synapses is transported to the nucleus, where it triggers transcription of new mRNA species. The products of transcription, whether mRNA transcripts themselves or the proteins they encode, are delivered to dendrites to stabilize LTP at potentiated synapses.

We consider in more detail below the evidence that the initial phase of L-LTP is supported by dendritic protein synthesis. We then discuss the role of transcription in generating the persistent late phase, which leads to a description of the two (somatopetal and somatofugal) signaling trade routes and the largely unidentified molecular cargoes that are exchanged between soma and dendrite. Finally, we consider the concept of synaptic tagging and the surprising answers this gives to the perplexing question of how a dendritic flow of “plasticity molecules” generated by transcription is restricted to potentiated synapses to preserve the input specificity of LTP. Comprehensive reviews of the ways in which translation and transcription may be regulated to achieve persistent L-LTP can be found in Kelleher et al. (2004a) and West et al. (2002).

### Time Window for Blocking Induction of Late LTP by Protein Synthesis Inhibitors

An important and somewhat puzzling feature of the block of L-LTP by protein synthesis or transcriptional inhibitors, both *in vitro* and *in vivo*, is that the drugs are effective when given during or immediately after induction of LTP (Otani et al., 1989; Nguyen et al., 1994) but are ineffective once LTP has become established. The existence of this time window implies that the synthesis of the proteins necessary to support L-LTP occurs at the time of or soon after the tetanus and that thereafter new protein synthesis is not required, even though expression of L-LTP can take some hours to reach its maximum and is then maintained at that level. A similar profile is seen in behavioral experiments when protein synthesis inhibitors are given around the time of one-trial learning; short-term memory is unaffected by the inhibitors, and long-term memory is blocked (Squire and Barondes, 1972). As we shall see later when considering the synaptic tag experiments of Frey and Morris (1997), there are circumstances in which L-LTP can be induced in the presence of protein synthesis inhibitors. We also note here that the reconsolidation of

memories after retrieval may open up another window of protein synthesis dependence in the hippocampus (Alberini, 2005).

It is not known if there are proteins that are expressed only in the context of synaptic plasticity and in no other circumstance, but it is important to distinguish between synthesis of proteins that are related to the changes in synaptic strength and synthesis of general housekeeping proteins that reflect and service overall changes in neural activity (see discussion in Sanes and Lichtman, 1999). These two possibilities cannot be distinguished on the basis of a general blockade of protein synthesis. However, the fact that translational and transcriptional inhibitors are effective only during a narrow temporal window around the time of induction, well before L-LTP is established, implies that proteins synthesized during that time are not predominantly housekeeping genes.

Does protein synthesis in presynaptic neurons contribute to L-LTP? In the transverse hippocampal slice, axons projecting to granule cells are severed from their cell bodies in the entorhinal cortex. The fact that L-LTP can be induced in the dentate gyrus *in vitro* (Balschun et al., 1999) therefore demonstrates that presynaptic gene transcription is not a requirement for L-LTP in the perforant path. Presynaptic protein synthesis, however, cannot be excluded on this evidence alone, and an LTP-associated increase in a number of presynaptic proteins has been reported following the induction of LTP in perforant path-granule cell synapses (Kelly et al., 2000). Whether these changes are necessary for the full expression of L-LTP is not known.

### Dendritic Protein Synthesis Plays a Role in the Initial Phase of Late LTP

Proteins required for L-LTP could be all be generated in the soma and transported to where they are required. However, there is increasing evidence that this is not what happens and that dendritic protein synthesis plays an important role in generating the initial phase of late LTP. Local protein synthesis has the conceptual merit of providing an immediate solution to the problem of input specificity at the metabolic cost of transporting a population of mRNAs to the far reaches of the dendritic tree. It would, on the face of it, make the cell's life a good deal easier if the machinery for late as well as early LTP were located at the synapse, and there are good reasons for supposing that protein synthesis does in fact occur in dendrites. It has long been known that ribosomes and other elements of the protein synthetic machinery are positioned subsynaptically at many hippocampal synapses (Steward, 1983; reviewed by Steward and Schuman, 2001), and ultrastructural studies have shown that polyribosomes redistribute from dendrites to the base of dendritic spines with enlarged postsynaptic densities following the induction of LTP (Ostroff et al., 2002). An estimated 400 mRNA species are found in hippocampal dendrites (Eberwine et al., 2001), including components of the translation machinery as well as mRNAs for several proteins known to play a role in the induction or

expression of LTP, among them  $\alpha$ CaMKII, PKM $\zeta$ , arc/arg3.1, BDNF and its receptor trkB, and AMPA receptor subunits GluR1 and GluR2 (Martin and Kosik, 2002; Martin, 2004). The demonstration that isolated dendrites of CA1 pyramidal cells can support BDNF-induced LTP and mGluR-dependent LTD provides direct evidence that dendritic protein synthesis is sufficient to support persistent synaptic plasticity (Kang and Schuman, 1996; Hüber et al., 2000); in both cases the effects are blocked by protein synthesis inhibitors. Tetanus-induced LTP lasting a number of hours also occurs in isolated dendrites, and its decay is hastened by protein synthesis inhibitors (Frey et al., 1989). These experiments demonstrate that translation of existing dendritic mRNA can support a component of L-LTP that extends well beyond the duration of E-LTP. Evidence that local protein synthesis is necessary for the full expression of L-LTP in intact cells has come from experiments in which local perfusion of the protein synthesis inhibitor emetine selectively depressed L-LTP in the perfused region without affecting its time course at distant synapses (Bradshaw et al., 2003). Overall, these observations strongly suggest that local protein synthesis plays an important part in the early stabilization of LTP or, to put it another way, in the passage from early to late LTP.

#### **Transcription and Translation of New mRNAs: Dialogue Between Synapse and Nucleus**

What is the evidence that the conversion from early to late LTP requires gene transcription and/or somatic protein synthesis? First, as we have seen, transcriptional blockers such as actinomycin block L-LTP in area CA1 *in vitro* (Nguyen et al., 1994; Frey et al., 1996; Kelleher et al., 2004b) and in the dentate gyrus *in vivo* (Frey et al., 1996; but see Otani et al., 1989). Second, upregulation of immediate early genes such as *c-fos*, *zif268*, and *arc/arg3.1* reveal a correlation between transcription and LTP induction (reviewed by Kuhl and Skehel (1998). The absence of L-LTP in the dentate gyrus of a mutant mouse with targeted inactivation of the immediate early gene and transcription factor *zif268* confirms a causal role for gene transcription in the induction of L-LTP (Jones et al., 2001), as does the impairment of L-LTP when the same region is infused with antisense mRNA to *arc/arg3.1* (Guzowski et al., 2000). Finally, experiments on synaptic tagging, described below, make it clear that a global signal, presumed to originate from the soma, is made available to the whole cell following the induction of L-LTP. As we shall see, this signal can be intercepted and utilized for the purposes of stabilizing LTP at other synapses that may have been activated up to 1 to 2 hours earlier or later than the pathway whose strong activation led to the initiation of transcription. Local protein synthesis alone cannot account for the observation that plasticity can be modulated in this associative manner by a geographically distant pathway; there has to be a transcriptional or translational signal from the soma that either supplies the required stabilizing proteins or transcripts or stimulates local protein synthesis to do so. Thus, it is difficult to avoid the conclusion that protein

synthesis at both the local and global levels is involved in the conversion of early to late LTP.

#### **Signaling to Nucleus**

A major route for activity-dependent protein synthesis proceeds via long-range activation of nuclear transcription factors, including members of the CREB family of proteins which bind to cAMP response elements (CREs) in the regulatory regions of target genes to initiate transcription. What is the signal, and how is it conveyed to the nucleus? We have seen that calcium influx through the NMDA receptor is the trigger for NMDAR-mediated LTP; and it is therefore no surprise that calcium, particularly when bound to calmodulin, is a key player in signaling to the nucleus (reviewed by Lonze and Ginty, 2002). There is disagreement, however, about how this is achieved. One possibility is that calcium is released from the endoplasmic reticulum as a traveling wave proceeding from dendrite to soma, where it binds to nuclear calmodulin to activate target kinases (Hardingham et al., 2001). A second possibility is that calcium/calmodulin translocates from synapse to nucleus (Deisseroth et al., 1998); and a third, discussed below, is that  $\text{Ca}^{2+}$  enters the nucleus via voltage-gated calcium channels in the somatic plasma membrane.

A principal target for nuclear calcium/calmodulin is CaMKIV, a member of the calcium/calmodulin-dependent kinase family whose location is predominantly nuclear (Lonze and Ginty, 2002). Activation of CaMKIV by phosphorylation at ser133 allows it to bind an accessory CRE-binding protein (CBP) and initiate transcription. Other  $\text{Ca}^{2+}$ -activated signaling pathways are also recruited, including the Ras/MAP kinase and PKA pathways (for reviews see Roberson et al., 1999; Lonze and Ginty, 2002; Sweatt, 2004).

The MAP kinase signaling cascade can be triggered by a wide variety of stimuli, including extracellular ligands binding to receptor tyrosine kinases and G protein-coupled receptors, and by synaptic activity leading to calcium entry through ionotropic glutamate receptors or voltage-gated calcium channels. We have seen in Section 10.4.3 that the MAP kinase cascade regulates both early LTP and late LTP via substrate proteins that control translation, probably at dendritic sites (reviewed by Sweatt, 2001b; Thomas and Huganir, 2004). Here, we are concerned with its role in establishing L-LTP by stimulating gene expression in the nucleus. Synaptic activity leads to the phosphorylation of ERK1, 2 in both dendrites and soma. As with the calmodulin signal, the mechanism by which the activated ERK signal is translocated to the nucleus is not known. Although phospho-ERK does not phosphorylate CREB, inhibition of MEK, the kinase that phosphorylates ERK, prevents phosphorylation of CREB on ser133. There must therefore be intermediate kinase(s) that are substrates for phospho-ERK and allow it control over CREB phosphorylation; these intermediates are thought to be members of the RSK or MSK families of nuclear kinases (Lonze and Ginty, 2002; Thomas and Huganir, 2004) (see below).

Another route from synapse to soma is via the activation of G protein-coupled receptors, such as D1/D5 dopamine receptors. Late LTP in area CA1 is blocked by dopamine antagonists (Frey et al., 1990) and facilitated by D1/D5 agonists, although the report by Huang and Kandel (1995) that stimulation of dopamine receptors can induce late potentiation in an activity-independent manner has been disputed by Mockett et al. (2004). Dopamine receptor activation leads to upregulation of cAMP and presumptive translocation of activated PKA to the soma, where it can directly phosphorylate CREB on ser133 (Lonze and Ginty, 2002).

### Action Potential Signaling as a Form of Synapse-to-Nucleus Signaling

As Adams and Dudek (2005) have pointed out, there are two problems with the concept of synapse-to-soma signaling that are often overlooked. First, how does the signal generated by one or a few potentiated synapses (in the limit, a single synapse) located at any position on the dendritic tree reach a concentration in the nucleus that allows activation of transcription factors? Second, transcription of immediate early genes such as *c-fos* and *zif268* begins within a few minutes of LTP induction. How does the signal reach the soma so quickly? Adams and Dudek (2005) suggested that both problems can be circumvented if the signal is generated not at the synapse but by somatic action potentials. Because action potential(s) generally (though not always, see Section 10.3.6) occur during the induction of LTP, the nuclear signal could in principle be generated by  $\text{Ca}^{2+}$  entering through somatic voltage-gated channels. Such a mechanism would provide an economical solution to both the problems noted above. A number of observations are consistent with the hypothesis. Antidromically driven action potentials can induce expression of immediate early genes, and antidromic stimulation of CA1 axons converts E-LTP to L-LTP, suggesting that action potentials can induce expression of soma-to-synapse plasticity factors (Dudek and Fields, 2002). Moreover, it is well established that the synaptic activation of NMDA receptors during high-frequency stimulation can drive somatic action potentials and so provide a rapid NMDAR-dependent signal from synapse to soma (Herron et al., 1986). Furthermore, synaptic activation of NMDA receptors can lead to somatic  $\text{Ca}^{2+}$  entry via L-type voltage-gated  $\text{Ca}^{2+}$  channels (Alford et al., 1993). In addition, strong induction protocols that induce NMDAR-independent L-LTP in area CA1 also lead to a large somatic  $\text{Ca}^{2+}$  signal that is blocked by L-type  $\text{Ca}^{2+}$  channel inhibitors (Raymond and Redman, 2006). Note that the somatic  $\text{Ca}^{2+}$  hypothesis predicts an absolute requirement for postsynaptic action potentials to secure L-LTP by this route.

### The Nuclear Transcription Factor CREB Is a Target for Several Kinases

CREB is activated by phosphorylation on ser133. Not all active kinases can directly phosphorylate CREB on this residue: PKA

can, MAPK cannot. Unexpectedly, however, it was found that MEK inhibitors completely block the increase in CREB phosphorylation caused by bath application of the cAMP activator forskolin, thus establishing that ERK1, 2 acts downstream of the PKA cascade (Roberson et al., 1999). The activation of PKA by cAMP leads to activation of the GTPases Rap-1 and Braf and thence to phosphorylation of MEK. The kinase intermediaries linking MAPK to CREB in the L-LTP pathway *in vivo* are probably members of the RSK and/or MSK kinase families. A second arm of the MAP kinase cascade is activated by ligand binding to metabotropic glutamate receptors, activating PLC and leading to the release of diacyl glycerol and activation of PKC. PKC activates Ras/Raf-1, the first links in the three-kinase MAP cascade, leading to phosphorylation of MEK. BDNF, acting on its receptor TrkB, also uses the Ras/Raf-1 pathway, again converging on MEK, as does acetylcholine (ACh) acting on muscarinic receptors (Sweatt 2004). Thus, many of the extracellular stimuli (ACh, BDNF, glutamate) that are known to cause CREB phosphorylation on ser133 and thence gene expression, are funneled through the Ras/Raf-1 arm of the MAPK pathway (Sweatt, 2001a, b).

Our discussion of signaling pathways in L-LTP has so far avoided the question of how specific genes are targeted by different stimuli if the same signal cascades are engaged in each case. It is likely that different combinations of kinases are activated by different stimuli and that expression of specific target genes is achieved by combinatorial selection from the cell's portfolio of transcription factors. For example, transcription of the immediate early gene *c-fos* can be triggered by any one of several stimuli (growth factors, neuromodulators, neurotransmitters), all of which lead to phosphorylation of CREB on serine 133. Neurotransmitters, but not growth factors or neuromodulators, increase calcium levels, either directly through opening calcium permeable receptor channels (e.g., the NMDA receptor) or indirectly through depolarization-gated opening of L-type voltage-sensitive calcium channels. High  $\text{Ca}^{2+}$  levels can lead to phosphorylation of another transcription factor, calcium response factor (CRF), and to phosphorylation of CREB at ser141 and ser143; phosphorylation at the latter two serine residues reduces the ability of ser133 phospho-CREB to bind to CBP. The combination of these two transcription factors (CRF and CREB phosphorylated at ser141 and ser143 but unassociated with CBP) directs the stimulus-dependent transcription of BDNF (West et al., 2002). Similarly, activation of at least two transcription factors, CREB and Elk1, is required to drive expression of the immediate early gene *zif268* (Davis et al., 2000).

The LTP connection was taken a step further when CREB phosphorylation induced by tetanic stimulation was also shown to be blocked by MEK inhibitors, both in CA1 *in vitro* and in the dentate gyrus *in vivo* (Impey et al., 1998; Davis et al., 2000). In the latter case, upregulation of *zif268*, one of the target genes of CREB, was also suppressed. While CREB is rapidly phosphorylated in a  $\text{Ca}^{2+}$  dependent manner by stimuli that induce LTP, it is also the case that CREB is activated by patterns of synaptic activity that do not elicit potentiation

(Deisseroth et al., 1966). Thus, CREB phosphorylation may be required for the transcription of genes encoding effector proteins whose role is to sustain synaptic activity in general, rather than specifically to promote synaptic plasticity. Initial studies of genetically hypomorphic CREB mice supported the idea that CREB was important for LTP as well as for hippocampus-dependent memory (Bourtchuladze et al., 1994). Later work on CREB knockout mice failed to detect a robust effect on LTP, though there remained the possibility that this result could be explained by the upregulation of other members of the CREB family. However, Balschun et al. (2003) generated a mouse in which expression of all CREB isoforms was either absent or limited, and found no effect on L-LTP. The role of CREB in generating L-LTP cannot therefore be regarded as securely established.

What are the target genes for CREB? Some of them at least are transcription factors—the immediate early genes such as *c-fos* and *zif268* and others of unknown function such as *arc/arg3.1*. An upper limit on the number of genes that might be activated by CREB can be estimated from genes containing CRE sequences in their promoter regions (Lonze and Ginty, 2002). More than 80 have been identified, coding for: neurotransmitters and peptides ( $n = 35$ ), growth factors and their receptors ( $n = 7$ ), structure-related proteins ( $n = 4$ ), proteins involved in cellular metabolism ( $n = 16$ ), transcription factors ( $n = 13$ ), signal transduction proteins ( $n = 8$ ). The presence of transcription factors opens up the potential for a second wave of target genes.

#### **Markers of LTP: Immediate Early Genes**

##### ***zif268, c-fos, and arc/arg3.1***

Long-term potentiation is associated with the rapid, transient expression of several transcription factors, including *c-fos*, *cJun*, *krox 20*, and *zif268*, of which *c-fos* and *zif268* have been the most intensively studied (Dragunow, 1996; Lanahan and Worley, 1998). These and other genes, such as *arc/arg 3.1* and *homer1a*, which encode for proteins that contribute to synaptic scaffolding complexes, are members of a group of genes known as immediate early genes (IEGs) whose transcription is upregulated by activity without the need for prior protein synthesis. Enhanced mRNA expression for both *c-fos* and *zif268* (a member of the *krox* family of transcription factors; synonyms are *krox24*, *egr1*, and *NGF1*) occurs within minutes of induction and peaks around 30 minutes after induction, returning to baseline levels (which in the dentate gyrus is very low for *zif268*, *c-fos*, and *arg/arc3.1*) within 2 to 4 hours. Expression of the corresponding proteins lags by 1 to 2 hours. Transient upregulation of IEGs is a marker for LTP in the dentate gyrus in the sense that whenever a stimulus is sufficiently strong to induce L-LTP immediate early gene expression is triggered. Moreover, maneuvers that block induction of LTP also block the enhanced expression of immediate early genes (Wisden et al., 1990; Dragunow, 1996). As we have seen, L-LTP is not expressed in the dentate gyrus of mice with a targeted

inactivation of *zif268*, indicating that *zif268* is required for L-LTP, though it is not necessary for E-LTP (Jones et al., 2001). However, enhanced expression of transcription factors such as *zif268* and *c-fos* can be induced by procedures that do not induce LTP, such as nonsynaptic excitation of neurons by antidromic stimulation. The mechanical disturbance involved in cutting a hippocampal slice can also induce long-lasting upregulation of IEG expression in the dentate gyrus (French et al., 2001). In these cases, upregulation of IEGs is not sufficient to induce LTP, possibly because synaptic tags have not been set. Note too that although *zif268* and other immediate early genes can be activated by seizure activity in all areas of the hippocampus they are not readily switched on by LTP-inducing stimulation in area CA1, in contrast to their robust upregulation in the dentate gyrus (French et al., 2001). On the other hand, there is an increase in the number of pyramidal neurons in area CA1 expressing *arc/arg3.1* mRNA following exposure to a novel environment (Guzowski et al., 1999). Until the reasons for these puzzling and intriguing discrepancies between the pyramidal and granule cell fields are resolved, the use of IEG expression as a marker for the induction of L-LTP is probably justified only in the dentate gyrus.

#### **Beyond Immediate Early Genes: Effector Genes that Promote Late LTP**

The identities of effector genes that are activated either in the first round of gene expression by constitutively active transcription factors such as CREB, or in the subsequent round by IEG transcription factors such *c-fos* and *zif268* are still largely unknown. Some clues can be gathered from the fact that not all IEGs encode for transcription factors, and several of those that are not transcription factors are targeted to dendrites, either as mRNA (*arc/arg3.1*, *homer*,  $\alpha$ CaMKII) or as protein (BDNF). Transcription of *Arc/arg3.1* is itself regulated by *zif268*, and by another member of the egr family of transcription factors, *egr3* (Li et al., 2005). Differential screens for genes up- or downregulated by the induction of late LTP in the dentate gyrus of the freely moving animal have yielded lists of a dozen or so transcripts that are upregulated 75 minutes after LTP induction in the freely moving rat (Matsuo et al., 2000) or 1.5 to 7.0 hours after induction in the anesthetized rat (Hevroni et al., 1998). These plasticity-related genes are in each case a subset of a considerably larger group of genes whose expression is stimulated by seizure activity. Another differential display study followed the time course of the regulation of a transcript for A kinase anchoring protein (AKAP-150). Unusually for an activity-regulated transcript, AKAP mRNA was not altered by seizures but was markedly affected by LTP-inducing stimulation, exhibiting an initial decrease at 1 hour and climbing to a peak increase at around 6 hours before falling back to baseline by 24 hours after induction (Génin et al., 2003). Using probes for specific transcripts at different times after induction Thomas et al. (1994) were able to follow the time course of tetanus-induced changes in
